54. Hitherto nothing has been said of the situation of the range of hot-houses. In many gardens, these occupy a very considerable part of the south wall, that is, the wall on the north side of the garden. In the area behind them, are sheds for tanners bark, rich mould, and other requisites; while there is a cart access to the doors of the furnaces, and these, with all the rubbish necessarily attending the operations of forcing, are completely hid from view. In some places all the forcing-houses form a continuous range; but generally the pine stove and succession pit, being of different dimensions, are placed separately In some elegant gardens, as at Raith-House and Wemyss-Castle in Fife, the hot-houses have a flower-garden in front of them, while every thing offensive is excluded from view, as in the former case. In other places the hot-houses are disposed in a different manner: the several kinds of houses stand detached from one another, each being set down as it were in a separate grass lawn; the back part, where the furnaces are situated, is concealed by shrubs, so that the houses seem to stand in little thickets, and thus form an agreeable variety with clumps and patches of trees in the park. Donibristle, the seat of the Earl of Moray in Fife, may be mentioned as an example of this sort of arrangement.

55. In many instances, the flower garden is separated from the fruit and kitchen garden merely by a wall, perhaps by a quick hedge. But in modern *places*, (as gardeners speak) this garden is removed from the other by a considerable distance. To it belongs the green-house and the orangery; there is often connected with it a conservatory; and sometimes, where the owner has a taste for the culture of rare plants, a stove merely for the keeping of tender exotics.

Where the interior of the walled garden does not afford space enough for raising a sufficient supply of culinary vegetables for the family, a piece of ground is fenced off on the outside of the walls, on one or more sides, and is called the *slip*. If the melon and cucumber ground be not situated at the back of the principal suite of hot-houses, it may very conveniently be placed in the slip.

*Hedges.*

56. For tall hedges, to afford additional shelter to particular quarters, or to screen objects from view, various evergreen plants are employed. Holly answers admirably, for height, strength, and thickness; but it is of very slow growth, and flourishes only in clayey ground. Yew is also excellent, and much used. Several deciduous trees are likewise employed, such as lime, beech, and horn-beam. English elm is occasionally used; and in wet places alder is justly preferred. In very large gardens a hedge of holly or beach, running from north to south, is of incalculable advantage, especially if the garden be in the form of a parallelogram, and much exposed to high winds. Small ornamental divisions in gardens are formed of many different kinds of plants, according to the taste of the owner, and the size of the hedge wished for. Laurel, laurustinus, phillyrea, and evergreen oak, are suited to this purpose; as well as pyracantha, sea-purslane, rosemary, and French tamarisk; the last two, however, will not form hedges unless in our southern counties, where the myrtle can withstand the cold of ordinary winters. But of all shrubs used for such division hedges, evergreen privet seems the best; and it is the plant now most frequently employed for that purpose. Some persons are fond of flowering hedges: they are composed of different kinds of rose-bushes, sweet-briars, and honeysuckles; the lately introduced Rosa Indica, making here a conspicuous appearance, being equally covered with flowers early and late in the year. Garden hedges of any kind are now much less frequently planted than they used to be. In our climate the fruit-garden must be surrounded with brick or stone walls: these serve not merely for protecting the trees fixed against them, but supersede the necessity of tall hedges for the purpose of shelter. The flower-garden, however, is still chiefly sheltered by evergreen hedges, with rows of tall deciduous shrubs, or low-growing trees, behind. In some places these are situated on the declivity or talus of a bank, forming a highly ornamented screen, analogous to the *brise-vent* of the French. From the interior of this garden, however, hedges have been nearly banished, by the change of taste, and dislike of every thing formal.

In this country, as formerly remarked, the Fruit-garden and the Kitchen-garden are locally blended together, both being inclosed by the same walls: the objects of each, however, are quite distinct, and may conveniently be treated of separately. The general disposition of the departments of the garden has been already spoken of, and likewise the forming of fruit-tree borders. Other matters particularly connected with the *fruit-garden* shall now be considered.

## FRUIT-GARDEN.

57. The kinds of fruits usually cultivated within the walled garden, but in the open air, are eighteen in number; and of these ten are considered as indigenous to the country, and eight are exotics. The native fruits are, the apple and pear (*Pyrus*); plum and cherry (*Prunus*); the medlar (*Mespilus*); the red and the black currant, and the gooseberry (*Ribes*); the raspberry (*Rubus*); and the strawberry (*Fragaria*). The exotic fruits are, the peach, nectarine, and almond (*Amygdalus*); the apricot (*Prunus*); the grape (*Vitis*); the fig (*Ficus*); the quince (*Pyrus*); and the mulberry (*Morus*). The apples and pears, plums and cherries, found native in our woods, however, differ so completely in appearance and taste from those of our gardens, that none but a botanist could easily be persuaded to consider them as of the same original species. The chestnut (*Fagus*); hazel-nut (*Corylus*); sorb (*Sorbus*); elderberry (*Sambucus*); and berberry (*Berberis*), are likewise natives: these are also cultivated, but generally in the pleasure-grounds exterior to the walled garden. The walnut (*Juglans*) is a foreign tree, planted chiefly in lawns, or on the outside of the orchard. The pine-apple (*Bromelia*), and the melon (*Cucumis*), constantly require artificial heat. Oranges, lemons, and shaddocks (*Citrus*) must at least spend the winter under glass. The pomegranate (*Punica*) is sufficiently hardy to live in the open air in our climate; but it does not generally produce its fruit. This, with some other fruits occasionally cultivated, shall be noticed, after speaking of the more common.

Before treating of each of the fruits in detail, it will be proper to explain the operations of grafting and budding, training and transplanting, all of which must afterwards be frequently referred to.

### *Stocks for Grafting.*

58. When a cion, or part of a cion, is taken from a fruit-tree, and inserted either on a young stem, or on the bough of a full grown tree, it is called *grafting*. But in the former case a new or additional tree is procured; and in this way, chiefly, apples and pears are propagated; and sometimes plums and cherries. A good cion may generally be cut into two or three pieces, which are called *grafts*; the stems on which they are placed being named *stocks*. The raising of stocks, and the propagation of fruit-trees, will properly fall under the article Nurseries: a few explanatory observations in this place may therefore suffice. The subject is not without interest; for every one, who wishes to keep his garden and orchard well supplied with fruit-trees, should establish a small private nursery, in which, upon stocks of different kinds, according to the end in view, he may graft or bud the kinds of fruit which experience shews to be best suited to the soil and climate of the place, and which best meet his own views.

59. It is necessary that the stock should be a member of the same genus or natural family with the graft or bud to be inserted on it. The principal kinds of stocks employed are the following:

For *apples*,
- Common apple, from the kernels, for full standards.
- Crab apple, from the kernels, for half standards.
- Codlin, from layers or cuttings,
- Paradise, from layers,
- Creeper, from layers, all for dwarf trees.

For *pears*,
- Common pear, or wilding, from the kernels, for full standards.
- Quince, from the kernels, or by layers, for dwarf and espalier trees.

For *plums*, *apricots*, *peaches*, *nectarines*, and *almonds*,
- Red-wheat plum, either from stones, or layers, or suckers.
- Black muscle plum, the same.
- Greengage plum, the same.
- Bullace-plum, a common native species, which has received its trival name, *P. insititia*, from being used for stocks.

For *cherries*,
- Small black cherry of the woods *Prunus cerasus*; and,
- Wild red cherry of the woods, *P. avium*.

60. It may here be remarked, that seedling stocks, which have a natural tendency to attain the full height of the species to be grafted on them, are by horticulturists universally denominated *free-stocks*. If the seeds of different varieties of apples and pears be sown, free-stocks, suited for the grafting of apples and pears, are, generally speaking, produced. When very great numbers of such stocks are wanted, the seeds are procured from the manufactures of cider and perry; but where a private gentleman wishes only to have a few hundreds of stocks, it seems much better to employ only select seeds, that is, the kernels from good specimens of hardy and healthy kinds of choice fruits, when in a ripe state. Crab stocks are very much used: the seeds are to be procured in quantity only where verjuice is made from the fruit. The paradise apple is of no estimation as a fruit; but the tree being naturally dwarf, grafting on it tends to dwarf the engrafted tree. The creeper apple has got its name, from its tendency to throw up suckers, which are easily detached with roots: it is sometimes called the Dutch paradise. Pear-trees, as already said, are grafted either on free-stocks from the seeds, or on quince stocks from layers or suckers. The latter are employed chiefly for dwarfing the trees, and throwing them more early into bearing; but with the view also (whether well or ill-founded is not the question) of imparting some degree of hardness and sharpness to the melting sugary pears; the hard and breaking pears, on the other hand, being placed on free-stocks. For all practical gardeners, it may be observed, concur in stating, that the nature of the fruit is, to a certain extent, affected by the nature of the stock. Miller says, decidedly, that crab stocks cause apples to be firmer, to keep longer, and to have a sharper flavour; and he is equally confident that, if the breaking pears be grafted on quince stocks, the fruit is rendered gritty or stony, while the melting pears are much improved by such stocks. This is scarcely to be considered as inconsistent with Lord Bacon's doctrine, that "the cion overruleth the graft quite, the stock being passive only;" which, as a general proposition, remains true; it being evident, that the graft or the bud is endowed with the power of drawing from the stock that peculiar kind of nourishment which is adapted to its nature, and that the specific characters of the engrafted plant remain unchanged, although its qualities may be partially affected. Quince stocks, it may be added, are also proper, where the soil of the garden is naturally moist, the quince agreeing with such a soil. Peaches and nectarines are, in this country (as noticed in the tabular view) generally budded on plum stocks, particularly the black muscle: but the more tender sorts are placed on seedling stocks of their own kind, raised from peach-stones, or perhaps on apricot stocks. In France, almond stocks are much used; and

for this reason the French peach-trees seldom last good more than twenty years, while the English endure twice that period. Apricots also are chiefly budded on plum stocks, the red wheat plum being preferred for them.

61. In the second volume of the London Horticultural Transactions, Mr Knight has given a few remarks on the effects of different kinds of stocks in grafting,—well deserving of attention, as being the result of more than thirty years experience. He is of opinion, that a stock of a species or genus different from that of the fruit to be grafted upon it can rarely be used with advantage, unless where the object of the planter is to restrain or debilitate. If, therefore, extensive growth and durability be required, the peach, nectarine, or apricot, should not be grafted on the plum; but if it is intended to diminish the vigour and growth of the tree, and if durability be not thought an important quality, the plum stock is proper. The same remark is applicable to the grafting of pears on quince stocks. The finer sorts of peaches and nectarines are often budded on apricot stocks. Of this Mr Knight approves; but he adds, that, if lasting and vigorous trees be wished for, the bud cannot be placed too near the ground.

62. The seeds for stocks are commonly sown in March, in four-feet beds. The germination of some kinds is promoted by placing them in moist sand, in a greenhouse or cellar, for some time previously. Next season, the seedlings are transplanted into nursery rows. Here they remain till they reach the size wished for, in order to the forming of wall or espalier dwarfs, or dwarf standards, half standards, or full standards,—the characters of which will be immediately explained. For the first three kinds, they are generally ready after two seasons: for the last, not sooner than after three or four. The finer kinds of plums are budded or grafted on plum stocks, raised from the stones. The common kinds of plums, and the almond, are propagated chiefly by suckers; figs, mulberries, and quinces, principally by layers; gooseberries and currants, by cuttings. Several varieties of apple, as the original or burknot, the brown apple of Burntisland, and some others, grow by cuttings; and many kinds, indeed all those sorts of fruit trees that have small buds, may be propagated by laying down branches, having a ligature of leather or wire passed firmly around them, either above or below a bud, in the part buried in the earth. At the place of binding, the circulation of the sap being interrupted, a swelling ensues, and roots break forth. The layer is separated the following year, and planted where it is intended to remain. This mode of propagating fruit trees is well known and often practised on the continent, though little attended to in this country; by it, in the course of three years, bearing trees are produced, without the trouble of grafting. Stocks for cherry trees, raised either from the native black cherry or guigne, or the wild red cherry, are considered as less apt to prove gummy or diseased than those raised from the stones of garden cherries, and they are at the same time accounted more durable.

### *Nursery Training.*

63. Fruit trees are trained as *standards*, of different kinds; as *wall trees*, or as *espalier trees*. For these, stocks of different ages or sizes are requisite. Standards are subdivided into three kinds, full standards, half standards, and dwarf standards.

*Full standards* are less used in Scotland than in England, where stems six or seven feet in height, before the branches are set out, are indispensable in orchards to which cattle are frequently admitted. Apples and pears are very commonly trained as full standards, and also cherries and plums.

*Half standards* have shorter stems, perhaps from three to five feet. These are particularly well calculated for standards in small gardens.

*Dwarf standards* have low stems, from one foot to two feet high; they are grafted on the most dwarfing stocks of their respective kinds, (apples on paradise stocks, and pears on quinces,) to make them produce low heads, suited to small compartments or borders; they come soon into bearing, produce large fruit, and in considerable abundance; while so humble is the tree, that the fruit may often be reached by the hand. Apples, pears, plums, cherries, and filberds, are very often trained as dwarf standards; and sometimes apricots, peaches, and figs. The French frequently train them to a cylindrical or somewhat pyramidal shape (*en quenouille*): in this way their appearance is improved, and the ground is less shaded; but, in general, the giving this shape must prove detrimental to the fruitfulness of the tree. In this country, they are usually trained like bushes (*en buisson*); from which, it is presumed, Mr Nicol denominates them *buzelars*.

For dwarf *wall trees*, stems five or six inches in length are sufficient; these, it will be observed, are the trees which are ultimately destined to cover the garden wall, being named *dwarfs* only from the humble stocks on which they grow.

*Riders* are wall trees grafted or budded on tall stocks, and are generally meant for the temporary purpose of filling the wall till the dwarfs get forward. The term *riders* is of Scottish origin, English gardeners having no appropriate name for wall trees trained in this manner, but merely calling them standards.

*Espalier trees* are intended for being trained against low treillages or latticed work, or rails which consist of simple upright posts; stems or stocks, six or eight inches in height, are therefore sufficient. To those who may look into French horticultural books, it may be useful to observe, that *en espalier* is their term for what we call wall training, and that our espalier training is by them denominated *en contre-espalier*.

The management of these different kinds of trees, from the time of their being grafted till they be fit for transplanting, belongs, equally as the raising of stocks, to the nursery department. The operations of grafting and budding, however, being of general importance, and among the nicest operations in horticulture, must here be described.

### *Grafting.*

64. *Grafting* may be performed in several different ways. The most important points are, to apply the inner bark of the stock and of the graft precisely to each other, and to bind them firmly in that situation. M. Thouin of Paris, in his laboured but excellent papers in the *Memoires du Museum d'Histoire Naturelle*, has made many minute distinctions, enumerating and describing no fewer than forty modes of grafting, independent altogether of several modes of grafting by approach, and of budding. We shall content ourselves, however, with explaining only the principal kinds practised by our own gardeners. These, as well as several other sorts of grafting, are very distinctly described, and illustrated by figures, by the late Mr Curtis, in his "Lectures," vol. iii.

65. The mode of grafting most commonly adopted in forming young fruit trees is called *tongue grafting*. Here it is desirable that the top of the stock, and the extremity of the graft, should be nearly of equal diameter. Both

are cut off obliquely, at corresponding angles, as nearly as the eye can guess; and the tip of the stock is cut off horizontally. A slip (or very narrow angular opening made by cutting out a thin piece) is then made in the centre of the stock downwards, and a similar slip in the graft upwards. (Plate CCCIX. Fig. 1.) A very sharp and narrow-bladed knife is necessary. The thin point of the upper half of the sloping end of the graft is then inserted into the slip in the stock; this is sometimes called *lipping*. The barks of stock and graft are brought closely to unite, at least on the right hand side, so as not to be displaced in tying, which is always done from left to right, or in the course of the sun. Strands of fresh bass-matting, steeped for a little time in water to render them more pliant, and to prevent the knot from slipping, are generally used for ties. A quantity of clay is worked fine, and mixed with some hay chopped small, or horse droppings, and sometimes with a little salt. It is found better to have it prepared a day or two beforehand, and to beat it up with a little water as needed. The tying is then covered with this clay, in the form of a collar, or ball tapering at both ends, the upper end being applied closely to the graft, and the under to the stock. These balls are not removed till after midsummer. A neat substitute for clay is mentioned by Abercrombie: a composition of turpentine, bees wax, and rosin, at first melted together, and afterwards heated as wanted; care being taken not to apply it too hot. A coatling, laid on with a brush, to the depth of a quarter of an inch, is said to be less liable to crack than clay; and, it is added, that when the full heat of summer arrives, the composition melts away of its own accord. It may be remarked, that the *whip grafting* mentioned in old horticultural books, is merely the kind now described, wanting the important improvement of the tongues or lips.

66. When the stocks to be grafted upon are strong, or perhaps branches of large trees, *cleft grafting* is often resorted to. The head of the stock or branch, (which we may suppose to be two or three inches in diameter,) is first cut off obliquely, and then the sloped part is cut over horizontally near the middle of the slope; a cleft, nearly two inches long, is made with a stout knife or thin chisel in the crown downwards, at right angles to the sloped part, taking care not to divide the pith. This cleft is kept open with the knife. (Plate CCCIX. Fig. 2. *a.*) The graft has its extremity for about an inch and a half cut into the form of a wedge, (Fig. 2. *b.*); it is left about the eighth of an inch thick on the outer or bark side, and is brought to a fine edge on the inside. It is then inserted into the opening prepared for it; and the knife being withdrawn, the stock closes firmly upon it. A circular incision is now made in the bark of the stock at the base of the wedge, to the extent of three parts of the circumference of the stock; by this means a shoulder can be formed on each side of the cleft.

67. Old stocks are sometimes grafted in another way, called *grafting in the bark* or *rind*, or *crown grafting*. The head of the stock or thick branch is cut off horizontally; a perpendicular slit is made as in budding, (to be presently described); a narrow ivory folder, or a silver fruit-knife, is thrust down between the wood and the bark, at the places where the grafts are to be inserted. The graft is cut, at the distance of an inch and a half from its extremity, circularly through the bark, not deeper than the bark on one side, but fully half way through, or beyond the pith, on the other. The cut portion is then sliced away; the end of the graft is pointed, being sloped a little to the point on the outside, but left straight on the inside. A shoulder is likewise left, to rest on the bark of the stock. The grafts are then inserted into the openings made by the ivory folder; and either three or four grafts are inserted on a crown, according to its size. This mode cannot be practised till the sap be in full motion, perhaps in the end of March, as till then the bark cannot easily be raised from the wood. When the grafts are placed on old trunks, they are apt to be drawn from their places by violent winds; it is proper, therefore, to bind them to stakes for the space of perhaps two years, when they will have acquired a sufficient hold of the stock.

68. *Saddle grafting* consists in cutting the top of the stock into a wedge-like form, and in making a corresponding angular notch in the bottom of the graft, to fit the wedge like a saddle. It is a mode sometimes adopted in the grafting of orange trees.

69. *Side grafting* is merely tongue grafting, performed in the side of a branch, or in the body of a stock, without heading down. The bark, and a little of the wood, are sloped off for the space of an inch and a half, or two inches; a slit is then made downwards, and the graft is cut to fit the part, with a tongue for the slit, (Plate CCCIX. Fig. 3.); the parts, being properly joined, are tied close, and clayed over. This mode is sometimes employed for supplying vacancies on the lower parts of full grown fruit trees. It cannot properly be performed till the sap is in action, or till about the middle of March.

70. *Grafting by approach*, *inarching*, or *ablactation*, as the older horticulturists termed it, is practised on some kinds of fruit trees, chiefly tender, such as oranges, lemons, pomegranates, and mulberries, and on several ornamental trees which do not readily succeed by the ordinary means, such as myrtles, jasmines, andrachnes, and some rare species of oaks, firs, and pines. Walnut trees are sometimes also increased in this way. The principle is, that the graft shall continue to have a degree of attachment to the parent plant sufficient to keep it alive, until such time as its bark shall have become united to the bark of the stock which is approached to it. The stock is often planted in a pot (Plate CCCIX. Fig. 4. *a.*) at least a year before, and is brought close to the tree or shrub to be grafted on it, (Fig. 4. *b.*); if too low, it is raised on a slight stage to the required height. Where the tree is strong, the pot is sometimes fixed upon one of the branches of the tree. The operation of inarching is seldom performed before the middle of April, or the beginning of May. When it can be accomplished, tongue grafting is even in this way advisable. In four or five months the inarched graft is generally found to be fairly united to the stock; the head of the stock is then cut off; but the graft is not separated from the parent plant till nearly a year has elapsed. Sometimes, for sake of curiosity, branches of contiguous trees are joined by approach-grafting. To make this experiment succeed, it is necessary to fix the branches to poles, to prevent wind-waving; and indeed this caution is in general necessary in all kinds of inarching practised in the open air.

71. Recourse is sometimes had to *root-grafting*, either for curiosity, or on account of seedling stocks being scarce. A piece of the root of a tree of the same genus, well furnished with fibres, is selected, and a graft placed on it, tied and clayed in the ordinary way. Thus united, they are set with care in a trench in the ground, the joining being covered, but the top of the graft being left two inches above ground. Some gardeners have thought that in this way the plant must preserve a nearer resemblance to the parent tree; but Abercrombie remarks, that though it is an expeditious way of obtaining a new plant, such a graft cannot be materially different from a cutting or layer.

72. What is called *shoulder* or *cheek grafting*, was formerly much more frequently employed than it is now. The head of the stock being first cut off horizontally, one side

of it is then sloped. The graft is sloped in the same manner, and a shoulder left at the point where the sloping begins. This shoulder is applied to the horizontal head of the stock, and the bark is brought to join at each edge, if possible. Another old method of grafting was called *terebration*, or *peg-grafting*: the head of the stock was cut off horizontally, and a hole was bored in the centre of it; the graft was selected of equal bole with the stock; within an inch and a half of the lower end of the graft, a circular incision was made, and the bark and a great part of the wood were removed, leaving only a peg to fit the hole bored in the stock.

*Cions for Grafts.*

73. The *cions* are gathered a good many weeks before the season for grafting arrives: the reason is, that experience has shewn, that grafting may most successfully be performed, by allowing the stock to have some advantage over the graft in forwardness of vegetation. It is desirable that the sap of the stock should be in brisk motion at the time of grafting; but by this time, the buds of the cion, if left on the parent tree, would be equally advanced; whereas the cions, being gathered early, the buds are kept back, and ready only to swell out when the graft is placed on the stock. Cions of pears, plums, and cherries, are collected in the end of January or beginning of February. They are kept at full length, sunk in dry earth, and out of the reach of frost, till wanted, which is some time from the middle of February to the middle of March. Cions of apples are collected any time in February, and put on from the middle to the end of March. The selecting of proper cions is a matter of the greatest importance, if we wish to enjoy the full advantage which may be derived from grafting. They should be taken from a healthy tree in full bearing, and from the outer side of the horizontal branches of such a tree, where the wood has freely enjoyed the benefit of sun and air. It is however the observation of a judicious practical gardener, Mr James Smith, at Hopetoun House, that particular notice should be taken, whether the tree to be grafted from be in a luxuriant or in a debilitated state. If the former be its condition, the grafts are very properly taken from the extremities of bearing branches; but if it be in the latter predicament, the most healthy shoots in the centre of the tree should be resorted to; and if no proper shoots exist, the amputation of some central branches will quickly tend to produce them. The least reflection must convince every one, how extremely improper it must be to take cions from young trees in the nursery lines, as is too often done. It may be remarked, that the middle of the cion generally affords the best graft.

*Budding.*

74. Budding, or inoculating, as it is sometimes, though not very correctly, called, depends on the same principle as grafting, the only difference between a bud and a graft being, that a bud is a shoot in embryo. On this account, grafted trees usually produce fruit two seasons earlier than budded trees: but those kinds of trees that are apt to throw out gum are not grafted without difficulty, while they are readily propagated by budding; such are, the peach and nectarine, the apricot, the cherry, and the plum; the cherry, however, being occasionally grafted, and the plum not unfrequently. In the case of both these sorts of fruit trees, there is another reason for preferring budding, —that gum is apt to exude at the places necessarily cut in performing the process of grafting. Budding is performed any time from the beginning of July to the middle of August, at which period the buds for next year are completely formed in the axilla of the leaf of the present year, and they are known to be ready by their easily parting from the wood. The buds preferred are the shortest observed on the middle of a young shoot, on the outside of a healthy and fruitful tree; on no account should an immature tree, or a bad bearer, be resorted to for buds. For gathering the shoots containing the buds, a cloudy day, or an early or late hour, are chosen, it being thought that shoots gathered in full sunshine perspire so much as to drain the moisture from the buds. The buds should be used as soon after being gathered as possible, and the whole operation should be quickly performed.

In taking off the bud, the knife is inserted about half an inch above it, and a thin slice of the bark and wood along with it taken off, bringing out the knife about an inch and a half below the bud. (Plate CCCIX. Fig. 5. *a*.) This lower part is afterwards shortened and dressed; and the leaf is cut off, the stalk being left about half an inch long. (Fig. 5. *b*.) Perhaps it is better to insert the knife three quarters of an inch *below* the bud, and to cut upwards; at least this mode is practised in the Scottish nurseries. The portion of wood is then taken out, by raising it from the bark, and pulling it downwards or upwards, according as the cut has been made from above or below. If the extraction of the wood occasion a hole at the bud, that bud is spoilt, and another must be prepared in its stead; as gardeners speak, the *root* of the bud has gone with the wood, instead of remaining with the bark. It is to be noticed, that the bud, and the portion of bark above and below it, receive together from gardeners, simply the name of a *bud*.

On a smooth part of the bark of the stock, a transverse section is now made, through the bark down to the wood: from this is made a longitudinal cut downward, about an inch and a half long, so that the incision may somewhat resemble a Roman T; by means of the flat ivory haft of the budding-knife, the bark is raised a little on each side of the longitudinal incision, so as to receive the bud. (Plate CCCIX. Fig. 5. *c*.) The prepared bud is placed in the upper part of the incision so made, and drawn downwards: the upper part is then cut off transversely, and the bud pushed upwards, till the bark of the bud and of the stock join together. (Fig. 5. *d*.) It is retained in this situation by means of tying with strands of moistened bass-matting.

In about a month after the operation, the tying is slackened: buds that have *taken* appear swelled, and the footstalk of the old leaf falls off on being slightly touched. All shoots that spring below the budded part are carefully cut off. The head of the stalk is not removed till the following March; after this, the bud grows vigorously, and in the course of the summer makes a considerable shoot. Against the next spring, the shoot is headed down, in the manner of young grafted trees.

*Production of New Varieties of Fruits.*

75. From the well-known facts, that some of the favourite cider apples of the 17th century have become extinct, and that others are fast verging to decay, the conclusion has been drawn, that our varieties of fruit are but of limited duration. Each variety springs from an individual at first; and this individual has been extended by means of grafting and budding. Dr Darwin, indeed, in his *Phytologia*, has contended, that each bud is a separate plant, the viviparous offspring of a bud of the preceding year, and deriving nourishment from the soil by means of a set of lengthened radicles peculiar to itself. This opinion cannot be support-

ed. Mr Knight's view is more rational, and more consistent with observation. All the extensions, by means of grafts and buds, must naturally partake of the qualities of the original; where the original is old, there must be inherent in the derivatives, the tendency to decay incident to old age. Some popular writers, such as Southey, have represented this doctrine as on a par with that of the hamadryads, or as equivalent to saying that a graft could not survive the trunk from which it was taken: but these authors are more lively than accurate; for such an absurdity was never taught by any horticulturist. It may be assumed as a fact, that a *variety* or *kind* of fruit, such as the golden pippin or the ribston, is equivalent only to an *individual*. By careful management, the health and life of this individual may be prolonged; and grafts placed on vigorous stocks, and nursed in favourable situations, may long survive the parent plant, or original ungrafted tree. Still there is a progress to extinction; and the only renewal of an individual, the only true reproduction, is by seed. This doctrine seems to be true, at least, as to fruit trees, and more particularly as to varieties of these, produced by cultivation: whether it can safely be extended to plants in general may admit of some doubt.

76. As the production of new varieties of fruit from the seed is a subject which now very much occupies the attention of horticulturists, it may be proper here to state the precautions adopted by Mr Knight and others in conducting their trials. It is, in the first place, a rule to take the seeds of the finest kinds of fruit, and from the ripest, largest, and best flavoured specimens of that fruit. When Mr Knight wished to procure some of the old apples in a healthy and renovated state, he adopted the following method: he prepared stocks of the best kinds of apple that could be propagated by cuttings, and planted them against a south wall in very rich soil; these were next year grafted with the stire, golden pippin, or some other fine old kind. In the course of the following winter, the young trees were dug up, and the roots being retrenched, they were replanted in the same place. By this mode of treatment they were thrown into bearing at two years old. Only one or two apples were allowed to remain on each tree; these consequently attained a large size, and more perfect maturity. The seeds from these fruits Mr Knight then sowed, in the hopes of procuring seedlings possessed of good or of promising qualities; and these hopes have not been disappointed.

It may here be mentioned, that in order to produce a hybrid variety, possessing perhaps a union of the good properties of two known kinds, Mr Knight had recourse to the nice operation of dusting the pollen of one variety upon the pistils of another: He opened the unexpanded blossom, and cut away, with a pair of fine-pointed scissors, all the stamina, taking great care to leave the styles and stigmata uninjured. The fruits which resulted from this artificial impregnation were the most promising of any; and the seeds of these he did not fail to sow. Mr Knight has generally observed in the progeny a strong prevalence of the constitution and habits of the female parent: in preparing seed for raising new pears, therefore, he would employ the pollen only of such delicate pears as the chaumontel, crassane, and St Germain, upon the flowers (deprived of stamina) of the swan-egg, longueville, muirfowl-egg, auchan, or green yair, which are hardy.

Every seed, though taken from the same individual fruit, furnishes a distinct variety: these varieties, as might be anticipated, prove of very various merit; but to form a general opinion of their value, it is not necessary to wait till they produce fruit: an estimate may be formed even during the first summer, by the resemblance the leaves bear to those of the highly cultivated or approved trees, or to those of the wild kinds; the more they approach to the former, the better is the prospect: the leaves of good kinds improve in character, becoming thicker, rounder, and more downy, every season. The plants whose buds in the annual wood are full and prominent, are usually more productive than those whose buds are small, and shrunk into the bark. But their future character, as remarked by Mr Knight, must depend very much on the power the blossoms possess of bearing cold, and this power is observed to vary in the different varieties, and can only be ascertained by experience. Those which produce their leaves and blossoms early are preferable; because, although more exposed to injury from frosts, they are less liable to the attacks of caterpillars. It is also to be observed, that even after a seedling tree has begun to produce fruit, the quality of this has a tendency to improve, as the tree itself becomes stronger and approaches maturity; so that if a fruit possess any promising qualities at first, great improvement may be expected in succeeding years.

Mr Knight has of late brought into public notice several new varieties of apples, pears, and cherries. Some of these seem likely to maintain a high character of excellence: they will be noticed in their proper places. He has, at his seat at Downton in Herefordshire, many hundreds of promising seedlings coming on, some of them annually improving in character.

77. From this digression we return to the young grafted or budded fruit trees. When they have been trained one year, they are called *maiden plants;* and these, especially in the apple and pear, are considered as forming the best plants. But trees of two, three, or four years growth, or even more, succeed very well, provided due care be taken in transplanting.

### *Transplanting.*

78. Here it may be enough to observe, in general, that in raising young fruit trees from the nursery lines, or in transplanting them from one part of the garden to another, much more care should be bestowed than is often given, particularly in public nurseries. The surface earth should be removed, and the horizontal roots carefully traced, and raised at full length, if possible: should this be inconvenient, or thought unnecessary, the roots should be cut with a sharp knife, not hacked with a blunt spade. A tap root, or one which penetrates straight down, should not be left more than a foot long at most. If the trees are only to be carried a short way, the roots should be as little cut as possible. When they are to be carried to a distance, it is thought best to prune off the small and soft fibres, which are apt to rot and injure the whole root. If the tree be several years old, and have a large head, it is proper to dig a trench all round, and to scoop out the earth from under the root. In this way a ball of earth rises with the tree, and its success is ensured. A bass-matting is sometimes introduced as far as possible beneath the tree on one side; and when it comes to be turned over on the other side, the root and ball of earth are completely included in the matting; but this is seldom necessary. As it unavoidably happens that some roots are destroyed at the time of transplanting, and the means of drawing nourishment are thus lessened, many consider it proper to prune the tops of the trees to a certain extent, that the demand on the roots may be diminished. This however must be done cautiously, and by an experienced gardener; to lay down rules for it is impossible.

It may here be observed, that when the plants are of considerable size, they are prepared for transplanting, by cutting the roots a year beforehand, or in some sorts even two years before lifting. In this way the remaining short roots are induced to set out many radicles or fibres, and the entire roots of the tree are contained within a small compass. If the trees be young, this abridgment of the roots may be effected by a downright cut with a sharp spade all around, at a short distance from the stem; passing the spade entirely under the plant on one side, if it be wished to cut off the tap root.

It may scarcely be necessary to remark, that an essential preliminary to transplanting, is the preparing of the ground to receive the trees, by digging it over. The distances should likewise be fixed, and even the holes dug. Some gardeners make a point of digging the holes for the trees perhaps a fortnight before planting: in this way the soil into which the fibres are likely soon to penetrate, is softened and meliorated by the action of the air; but this practice is more applicable to orchard planting. In putting in wall trees, it is not uncommon, not only to have the border well prepared generally, but to have a quantity of very good friable mould for each tree in particular, into which it may strike young fibres freely: this mould however should not be screened or made fine, but should be of the ordinary degree of roughness natural to garden soil. When the trees have been brought from a very great distance, so as to have been several days on their journey, Miller recommends the placing the roots in water for eight or ten hours before planting.

It may be considered as a safe general rule, to plant shallow, more especially for dwarf standards and half standards, the soil for which is not particularly prepared. Whether the general soil be cold and moist, or thin and gravelly, it is found better to place the roots of the young trees almost on the surface, and rather to heap earth over them in the form of a hillock than to sink them into the soil. Suppose the subsoil be a mouldering rock, and a hole be dug in it, it is evident that the tree will be placed in a sort of well, which will at once retain water, and hinder the spread of the roots. If the tree be placed on the surface, it will insinuate its roots into and draw nourishment from many invisible crevices. Since shallow planting has been recommended, it follows as a necessary consequence, that stakes are indispensable for dwarf standard and half standard trees.

From about the end of October, or after the shedding of the leaf, till the end of November, is considered as the best time for the planting of fruit-trees in this country, particularly in light soils. The weather is then mild, and the earth has time to settle about the roots during winter, before the first approaches of genial spring. But trees may be transplanted, in open weather, any time from the end of October till the beginning of March; and for heavy or wet land, planting in this latter month is accounted preferable. Young wall trees are planted about six or eight inches from the wall, and the part that has been cut at the time of grafting is placed next to the wall. The tree is planted at the same depth at which it formerly stood; but the roots are not the better for being deeply covered; if they be saved from the frost, they can scarcely be too near the surface. At the time of planting, the mould should be moderately dry, so as readily to crumble down. If, however, very dry weather occur, the ground is *mulched* at some distance around the roots, so as to prevent the bad effects of drought. *Mulching*, it may here be explained, consists in rendering a portion of the ground thoroughly moist by adding water, and working it like mortar. To increase the retentiveness of moisture, some short stable dung, or other litter, is added. When the roots are covered, the tree is gently raised and shaken, so as to cause the earth to apply closely to the roots. The soil is at the same time slightly pressed down. Wall-trees are not nailed up till the following spring. In this way they settle or subside along with the loose earth of the border. Were they nailed to the wall, they would run the risk of being suspended.

*Garden Training.*

79. Towards the end of March, young trees that have been planted out since October of the former year are headed down, or have their shoots shortened back to three, five, or six buds, according to their strength, and the purpose for which they are intended. When the trees have stood two, three, or more years in the nursery, after grafting or budding, the heading down is of course confined to the last year's shoots, and its extent, as well as the thinning out of superfluous shoots, must be left to the judgment of the experienced gardener, it being impossible to lay down rules where the circumstances must be perpetually varying.

80. The two principal methods of training wall-trees which are followed in this country, are called the *fan* and the *horizontal* modes. In the former, the branches are arranged like the spokes of a fan, or like the hand opened and the fingers spread. In the other way, a principal stem is carried upright, and branches are led from it horizontally on either side. The Dutch style consists in taking a young tree with two branches, and leading these horizontally to the right and left, to the extent perhaps of twelve feet each way, and in then training the shoots from these perfectly upright to the top of the wall. This is now seldom practised here, excepting perhaps with fig-trees, or white currants. In some places a few of the wall-trees are trained in a stellate form, the stem being led upright for about six feet, and then some branches trained downwards, others laterally, and others upwards. When walls exceed seven feet in height, the best gardeners seem to concur in giving the preference to the fan training, variously modified: in this way they find that a tree can much sooner be brought to fill its allotted space, and the loss of a branch can much more easily be supplied at any time. For lower walls, the horizontal method is preferred; and the same plan is adopted almost universally on espalier rails. Mr Hitt strongly recommends this mode for most sorts of wall-trees; and for pears he adopts what is called the *screw* stem, or training the stem in a serpentine manner, the branches going off horizontally, as in the ordinary straight stem.

In the first volume of the transactions of the London Horticultural Society, Mr Knight has made some ingenious and excellent remarks on the training and pruning of fruit-trees. His year-old plants are headed down, as usual, early in the spring, and two shoots only are trained from each stem, in opposite directions, and in an elevation of about 5°. (Plate CCCIX. Fig. 6) To procure the shoots to be of equal lengths, the stronger is depressed, or the weaker elevated. All lateral shoots are destroyed. Thus far it may be remarked, Mr Knight's method agrees very much with Hitt's, described in his Treatise on Fruit-trees. This shape, Mr Knight observes, ought to be given to young trees in the nursery, and is perhaps the only one that can be given to them without the risk of subsequent injury. Next season, as many branches are suffered to spring from each plant as can be conveniently trained, without shading each other; and by selecting the strongest and earliest buds towards the points of the year-old branches, to be trained lowest, and the weakest and latest near their bases, to be trained inclining upwards, each annual shoot will be nearly equal in vigour. (Fig. 7.) In the following winter, the shoots are alternately shortened, and left at full length. In the course of the third year, (Fig. 8.) if the tree be a peach, the central part consists of bearing wood: And, upon the whole, the size and general health of the trees trained in this way, afford evidence of a more regular distribution of the sap than Mr Knight has witnessed in any other mode.

The distance at which the branches are laid in, in all the different modes, varies from eight to ten inches, according to the nature of the tree, or the size of its foliage or fruit. While fan-trained trees are still in progress, a few more shoots are preserved at the summer pruning, than are likely to be ultimately laid in: this is for fear of accidents. Trees that have filled the spaces allotted to them, are disbudded of most of the woodbuds that appear. Woodbuds on old spurs are always displaced. Trees which are in training for the horizontal method require different management. The leading stem is constantly to be attended to; all the buds that appear on it are carefully preserved, till enough be procured to lay right and left, and form the tree. All wood-buds on the horizontal branches, excepting the leading one, are displaced. The fan-training is considered as best for apricots, cherries, and plums, placed against walls, even though the walls be low. None of these kinds of fruit answer well for espaliers; cherries or plums succeed better as half standards or dwarf standards.

81. The wall-trees which have now been spoken of are called *dwarfs* by the gardeners. It is a very common practice to train high standards on the intermediate spaces between the dwarf trees; such trees are in Scotland termed *riders*, (§ 63.) Plants four or five years old are preferred, because they are but temporary, and the object is to get fruit as soon as possible. Some good judges have condemned this plan of temporary trees as hurtful; being calculated to deprive the permanent trees of a proportion of the nourishment which they would otherwise draw from the border: but if the border be tolerably rich, and be only slightly cropped with herbaceous plants, it does not seem likely that the temporary trees can do much injury.

82. In popular language, the term *Espalier* is somewhat equivocal: it means either rows of fruit-trees planted like hedges, or the individual trees composing the rows; or, lastly, it means the stakes or rails to which the branches of the trees are tied. By using the terms espalier-*tree* and espalier-*rail*, ambiguity may always be avoided. Of late years, some have proposed to banish espalier-trees altogether, alleging that they injure the kitchen-garden quarters, by depriving them of sun and air. But in point of fact, they exist in the greater number of kitchen-gardens, and are not likely soon to be laid aside. If they are sometimes injurious by depriving the plants of air, they are at other times very useful, acting as a hedge in protecting the young crops from the violence of strong winds. Espalier trees generally produce excellent fruit, the sun and air having access to both sides of the tree; they commonly afford abundant crops, and the fruit is not apt to be shaken by high winds. Further, they tend to hide the crops of culinary vegetables from the eye, and to render the walk of the kitchen garden as pleasant as an avenue in the shrubbery.

Apples and pears are the fruits best suited for espaliers. The apples are generally grafted on crab stocks, to keep them of moderate size; or, if the tree be wished still smaller, on Dutch paradise stocks. The distance allowed between the former is from 30 to 40 feet; between the latter, 25 is found sufficient. These may seem large spaces at first; and, to take away the naked appearance, a small cherry-tree, or white currant bush, is sometimes planted in each interval. It is to be studied that, in the same line of rail, trees of similar growth be planted, so that the whole may be nearly equally filled. The trees, when planted, should be of one year's growth, or at most of two years. If the rail be not previously erected, so that the branches can be tied to it, a stake is necessary, to prevent wind-waving. Very often, the permanent rails are not put up till the trees have been two or three years trained on temporary stakes. Simple ash-poles firmly stuck in the ground, and either charred or smeared with tar at the bottom, to retard rotting, form a very efficient substitute for a rail; for it is to be observed, that during summer, when the leaves are expanded, they equally hide the roughest poles, or the most finished rail. Mr Nicol, however, recommends sinking hewn stones in the earth, and fixing a wooden rail in them: and a writer, in the Scottish Horticultural Memoirs, vol. i. has described a kind of cast iron espalier-rail, which of course must be highly durable, and, what is remarkable, is cheaper at the first than a wooden one. Some gardeners shorten the head of the tree in the usual way; others preserve the original branches at full length, never cutting a branch unless where there is a real deficiency of wood for filling the rail. The pruning is chiefly done by disbudding in the summer season. The distance at which the branches are laid in depends on the size of the fruit and leaves; when these are large, seven or eight inches are required; when small, four or five may be sufficient.

83. Dwarf trees were formerly much in vogue; and, strange as it may appear, the prospect of fruit was generally sacrificed to a fine shape. It was thought necessary that the lower branches should spread horizontally near the ground, and should decrease in width upwards, so that the tree should have a conical form. Now, it is well known that the fruit-buds of pears and apples in general, and of many sorts of plums and cherries, are produced at the end of the former year's shoots, which therefore should remain at full length; yet these were necessarily shortened, in order to preserve the desired shape, and it may easily be conceived that trees so dressed could not prove fruitful. For these reasons, the training to espalier-rails has generally been preferred. A few dwarf trees, however, prove ornamental, and they sometimes afford a great deal of fruit. The kinds of dwarf fruit-trees now in request are chiefly pears and apples. The pears must be of the summer and autumn sorts, the later fruits requiring a wall in our climate. Dwarf pears are chiefly budded on quince stocks. The trees are planted out, at two or three years old, where they are to remain, and they are placed from 20 to 25 feet asunder. A few stakes are driven into the ground, and, by means of tying down, the lower branches may soon be made to acquire a horizontal direction. No branches must cross each other, and no central upright shoots are permitted. The only other particular to be attended to is, when the trees are to be trained in a concave form, that, in shortening the shoots, the uppermost eye or bud is to be left *outwards*, as in this way the hollowness in the middle of the tree is better preserved. Sometimes the branches are trained round a hoop, which is supported by three or four small poles. Dwarf-standard apple trees on paradise stocks may be planted very closely, as they occupy but little room: they do not require more than 10 or 15 feet; on crab stocks they need at least 25. Plums are now seldom planted as dwarf-standards; cherries more frequently; apricots scarcely ever.

*Preserving of Blossom.*

84. In this country, particularly on the east coast and in the northern division of the island, it is an important part of the gardener's duty, to preserve the blossoms of apricots, nectarines, peaches, and the finer sorts of plums, from being destroyed by spring frosts, and especially frosty winds. One of the means first employed is still occasionally resorted to; namely, shading the trees slightly with branches of spruce fir, yew, or beech; but the branches ought to be so firmly fixed as not easily to be displaced by the winds, or to shake much: if this precaution be neglected, they will be ready to beat off the blossom which they are intended to defend. Strong fronds of the common brake (*Pteris aquilina*) have been used with advantage in this way; being the remains of the former year's growth, they are light and dry, and much less apt to injure the blossom than branches of trees.

The most effectual protection, however, is afforded by canvas-screens, in moveable frames; the fabric of the canvas being made thin enough to admit light, and yet affording sufficient shelter. The stuff called *buntine*, of which ships' flags are sometimes formed, is recommended by Nicol; and he adds, that it may be rendered more transparent, and more durable, by being oiled. The stuff called *osnaburg*, manufactured in the towns of Dundee, Arbroath, and Montrose, answers equally well, especially if made on purpose, of a wider texture, so as to resemble gauze. These screens are kept clear of the tree, a foot at top, and 18 inches at bottom. If, when not in use, they may be stowed in a dry loft, they last for many years. Sometimes the canvas is used in the form of sheets to hoist up and down; and in some places (as at Dalmeny Park garden, one of the finest in Britain) the contrivance is such, that the covering can be drawn up or let down the entire stretch of the wall, by two men, in the course of a minute. These screens are employed only at night, or in bad weather; and chiefly from the end of March to the beginning of May. Blossom thus partially protected is perhaps more tender than if no protection whatever had been given. The screens must therefore be continued till all risk of danger be over; perhaps till the leaves of the tree be pretty fully expanded, the blossom of several of our fruit-trees preceding the unfolding of these.

Frames covered with oiled paper have been successfully employed at Grangemuir garden in Fifeshire. The frames are of wood, inch and half square, with cross bars mortised into the sides. To give support to the paper, strong packthread is passed over the interstices of the frames, forming meshes about nine inches square. Common printing paper is then pasted on; and when this is quite dry, a coating of boiled linseed oil is laid on both sides of the paper with a painter's brush. These frames are placed in front of the trees, and made moveable, by contrivances which must vary according to circumstances. If the slope from the wall be considerable, a few triangular side frames may be made to fit the spaces. At Grangemuir, the frames are not put up till the blossoms be pretty well expanded; till which time they are not very apt to suffer from spring frosts or hail showers. In this way, it may be remarked, there is much less danger of rendering the blossom delicate by the covering, than if it were applied at an earlier period. The paper frames, if carefully preserved when not in use, will endure for a good many years, with very slight repairs.

At Dalkeith garden, in order to break the force of the winds, screens made of reeds are projected, at right angles with the wall, perhaps to the distance of ten feet, and at intervals of thirty or forty feet from each other; and at the same time nets wrought with straw are placed in front of the trees. These straw nets are very well deserving the attention of gardeners who may find their walls too much exposed to the east winds during the spring months. Old fishing-nets, kept at the distance of fifteen or eighteen inches from the tree by means of hooked sticks, are sometimes employed; these may be doubled over, in order to render the interstices closer. But nets made of coarse woollen yarn or carpet-worsted, are preferable to these. At Haddington, in East Lothian, woollen nets for this purpose are manufactured in the loom, and can thus be afforded at much less expence. They are woven very thick, the meshes not being larger than to admit the point of the finger, even when stretched out. The advantage of woollen yarn over flax for this purpose is evident; every small mesh being in effect rendered still smaller, by the bristliness of the material, and its constant tendency to contract; and from its aptitude to attract and concentrate moisture, such as cold dews and hoar-frost, the blossom derives additional security. These nets, and indeed nets of any kind, remain on night and day, till the season be sufficiently advanced.

To guard against the effects of hoar-frosts falling perpendicularly, some make a temporary coping of boards, to project a foot or eighteen inches over the tree at the top of the wall. Hitt recommends, that, in what are called *black frosts*, the borders opposite to the trees should be watered every night, affirming that he perceived advantage from this. So it might be; but he is, no doubt, wide from the true *rationale*, when he ascribes the good effects to some thinning of the glutinous juices, &c. Perhaps the latent caloric evolved in the freezing of the newly moistened surface, may preserve a higher temperature immediately around the plant.

85. We now proceed to the consideration of the different species of fruits cultivated within the walled garden, and the principal varieties of each. The order in which these are treated of, seems to be of little moment: the following arrangement is adopted, partly on account of the importance of the fruits, and partly because of natural alliances:

| | |
|---|---|
| Peach, and<br>Nectarine;<br>Almond, | *Amygdalus.* |
| Apricot,<br>Plum,<br>Cherry, | *Prunus.* |
| Apple,<br>Pear,<br>Quince, | *Pyrus.* |
| Vine,—*Vitis.* | |
| Fig,—*Ficus.* | |
| Mulberry,—*Morus.* | |
| Medlar,—*Mespilus.* | |
| Red Currant,<br>Black Currant,<br>Gooseberry, | *Ribes.* |
| Raspberry,—*Rubus.* | |
| Strawberry, six species,—*Fragaria.* | |

Some other hardy fruits and nuts, which are planted exterior to the garden, will afterwards be noticed; as also the pine-apple and the melon, which require a constant high temperature, and the orange, lemon, and shaddock, which are rather inhabitants of the green-house.

All the common fruit trees and fruit-bearing plants are extremely well known, both here and on the continent; any botanical description of them seems therefore unnecessary. The generic and trivial names given by Linnæus shall merely be mentioned, and at the same time the class and order in his system, and the family in the Natural Method of Jussieu, to which the plant belongs. Occasionally, when it may appear useful, some of the foreign names of the trees or the fruits shall be given.

### Garden Fruits.

#### *Peach.*

86. The *Peach tree* is the *Amygdalus Persica* of Linnæus, belonging to the class and order Icosandria Monogynia; and natural order Rosaceæ of Jussieu. This species is by Linnæus divided into two varieties; 1. With downy fruit, the *peach*; 2. With smooth fruit, the *nectarine*. Peaches and nectarines have sometimes occurred on the same tree; in a few cases, on the same branch; and one instance is on record, of an individual fruit partaking of the nature of both. Yet they are generally considered as distinct kinds of fruit, and they shall here be spoken of separately.

A good peach possesses these qualities: the flesh is firm; the skin is thin, of a deep or bright red colour next the sun, and of a yellowish green next the wall; the pulp is of a yellowish colour, full of high flavoured juice; the fleshy part thick, and the stone small. Those varieties, the flesh of which separates readily both from the skin and the stone, are the proper *pêches* of the French, and are by our gardeners termed *free-stones*. Those with a firm flesh, to which both the skin and the stone adhere, are the *pavies* of the French, by our gardeners named *cling-stones*. The latter require more shelter and better seasons to bring them to perfection than the former. In countries possessing sufficient climate, as in France and the warmer states of North America, the pavies are preferred: in this country, the preference is generally given to the free-stones, pavies being chiefly planted in forcing-houses, where the climate can be made.

87. Parkinson, in his *Paradisus*, enumerates twenty-one kinds of peaches, several of which, particularly the Old Newington, are still cultivated. Miller gives a list of thirty-one, with their characters; but as these are taken only from the fruit, without any notice of the bud, blossom, or leaf, they sometimes prove unsatisfactory. The following are the names:

| | |
|---|---|
| 1. White Nutmeg, | Boudine, |
| Red Nutmeg, | Rossana, |
| Early or small Mignone, | Admirable, |
| Yellow Alberge, | 20. Old Newington, |
| 5. White Magdalen, | Rambouillet, |
| Early Purple, | Bellis (Belle de Vitry.) |
| Large Mignone, | Portugal, |
| Belle Chevreuse, | Teton de Venus, |
| Red Magdalen, | 25. Late Purple, |
| 10. Early Newington, | Nivette, |
| Montauban, | Royal George, |
| Malta, | Persique, |
| Noblesse, | Monstrous Pavie, |
| Chancellor, | 30. Catherine, |
| 15. Bellegarde or Galande, | Bloody Peach. |
| Lisle, | |

88. The characters of such of these as are chiefly cultivated, and chiefly deserving of attention in this country, may be mentioned.

The *White Magdalen*, or Early Magdalen, is a round fruit, of a middling size, with a deep furrow; of a pale colour, and the flesh white to the stone; melting, juicy, with considerable flavour; ripening in August; the tree sometimes succeeds on the open wall, even in North Britain.

The *Red Magdalen*, however, is altogether a superior fruit; it is large, round, and of a fine red next the sun; the juice very sugary, and of exquisite flavour; ripening in the end of August: the tree is a free grower and great bearer: the blossoms are small. Nicol recommends the red magdalen as the "best peach we have, either for the open air or the hot-house." In doing so he is justified by the experience of Scottish gardeners; for the peach commonly known in Scotland by the name of red magdalen ripens well, in ordinary years, even in the northern districts of the country. This we believe to be the same which goes by that name in the south; but we have reason to think that the same name is applied, in some parts of England, to another peach; for English horticulturists sometimes complain that the red magdalen does not succeed well.

The *Large Mignone* is somewhat oblong in shape, and generally swells out on one side; the juice is very sugary, and of high flavour: this, though a free-stone, being rather a tender sort, is generally budded on a peach or apricot stock.

The *Early Newington*, or Smith's Newington (supposed to be the *pavie blanc* of Duhamel) is a fruit of middling size, of a fine red next the sun; flesh firm, with a sugary well-flavoured juice; ripening the beginning of September: a cling-stone: the tree a good bearer.

The *Noblesse* is a large fruit, red or marbled next the sun; flesh greenish white and melting, very juicy, and, against a good wall and in a favourable season, the juice becomes rich and well-flavoured; ripens in the beginning of September; and should be eaten *sharp ripe*, as the gardeners term it, the fruit being apt to become mealy if not taken just when it ripens.

The *Boudine*, sometimes called the bourdine, is a large round fruit, of a fine red next the sun; the flesh white, melting, juice vinous and rich; ripens from the beginning to the middle of September: the tree a plentiful bearer, especially when old. In favourable situations in the south of England it has sometimes produced fruit on standards.

The *Old Newington*, already mentioned, is a large round fruit, of a beautiful red next the sun; the flesh white and melting; when ripe, the juice very rich and vinous; a clingstone, and not ready before the beginning of October.

The *Rambouillet*, often called rumbullion, is a fruit of middling size, deeply divided by a furrow; the flesh melting, of a bright yellow colour; juice rich, and of a vinous flavour: ripens about the middle of September: the tree a good bearer.

The *Téton de Venus* is a fruit of middling size and longish shape, of a pale red next the sun; flesh melting, white; juice sugary, and not without flavour; ripens the end of September: the tree is a free bearer, on a warm light soil; but the fruit comes to perfection only in fine seasons.

The *Royal George* is an excellent peach; and in a very good soil and aspect the fruit becomes large, dark red next the sun, juicy, and high-flavoured. If the soil and aspect be not favourable, the tree proves a shy bearer.

The *Catherine* is a large round fruit, of a dark red next the sun; the flesh white, melting, full of a rich juic ; a clingstone; ripens from the beginning to the middle of October, against a good wall, and in a favourable season;

the fruit, however, is improved by lying two or three days before being used: it is sometimes called the October Peach.

89. To the ample list of Miller, a few others might be added. The *Ann Peach*, sometimes called the Early Ann, is a small round fruit, of a yellowish white colour, faintly tinged with red on the sunny side; ripening about the middle of August. This is said to be of English origin. The *Royal Kensington* is described by Forsyth, and the tree is said to grow freely, and not to be liable to blight. The *Orange Peach* is mentioned by Nicol as the most elegant he was acquainted with, and the best-flavoured of the clingstones; rather large than otherwise, round, dark red or purple next the sun, and bright orange on the other side; the flesh of a deep orange colour, but purple at the stone; the tree a very great bearer. It is possible this may be the Yellow Alberge, the fourth in the tabular list above given. The *Double-flowering Peach* is sometimes cultivated for curiosity, on standards, being very ornamental while in bloom; the flowers being only semi-double, fruit is generally produced, and in fine seasons abundantly; in most cases, however, it is fit only for preserves.

90. That indefatigable and excellent horticulturist, Mr Knight, has produced several new peaches of the most promising qualities, at his seat of Downton in Herefordshire. After due precautions to bring his trees (small ones planted in large pots) to the highest state of health and vigour, he impregnated the pistil of one with the pollen of another: only three peaches were suffered to remain on each tree: from sowing the stones of these, he obtained his new varieties. The situation of Downton being rather high and late, it may reasonably be presumed that fruits produced there will succeed in all places not less favourably situated as to climate. Two of these new peaches deserve particular notice; 1. The *Acton Scott Peach*; the fruit ripens early, and uniformly attains perfection; it is juicy and sweet, with a rich flavour; where secluded from the sun's rays, the skin is very white: the tree is an abundant bearer, and not subject to mildew: and Mr Knight considers it as calculated to succeed in many cold and unfavourable situations, where the more delicate varieties would certainly fail. 2. The *Spring Grove Peach* has a firm flesh, but not hard; the exterior colours are bright yellow and dark red; it melts in the mouth, resembling a nectarine in consistence as well as taste, having a remarkably rich, brisk, and vinous flavour; the stone parts readily from the flesh, which is of a greenish cast: it never becomes over-ripe or mealy, but is apt to shrivel a little, and is then most perfect: the tree grows slowly, but the wood is healthy, and acquires maturity early in the season: It succeeds better on an apricot than a plum stock.*

By persevering in the track pointed out by Mr Knight, we may hope, in time, to obtain peach-trees sufficiently hardy to produce their fruit in almost every situation in Britain, perhaps even as standards. In Maryland and Virginia, peach-trees are propagated from the stones, without budding. Every peach orchard contains, of course, numerous varieties. Among these a few are always of superior quality; with the fruit of the rest, pigs are fed. One of these American seedlings, possessed of good properties, is now growing in the garden of Mr Braddick at Thames Ditton: it has produced fruit, which is figured in the second volume of the London Horticultural Transactions, under the title of Braddick's American Peach.

In arranging the different varieties of peach-trees in a new garden, the late kinds, especially the pavies, must have the full south aspect; the others may be a point or two to the east. The kinds which ripen nearly at the same time should, as far as possible, be placed together, as this afterwards saves much trouble in collecting for the dessert, especially in a large garden.

91. The fan mode of training is considered as best suited to peach-trees, and is the plan generally adopted. These trees may, to a certain extent, be considered as constantly in a state of training. In pruning them, the great object is, to keep every part of the tree equally furnished with bearing wood, that is, with a succession of new shoots, laid in to the wall every year. This is to be attended to in April, and especially in May: for the wood and young shoots laid in afterwards, seldom ripen sufficiently to stand the winter. Besides, at that early season, the superfluous shoots can be pinched or rubbed off, without the use of the knife. The blossom-buds, it may be remarked, rise immediately from the eyes of the shoots; they are round, short, and prominent; while the leaf and shoot buds are oblong, narrow and flattish. The winter pruning is performed any time from the end of October till the end of February; but the early part of winter is generally thought best. Where the trees are well managed, there is not a great deal of winter pruning required. In shortening branches, it is a rule to cut behind a wood-bud, which may become a leader, to attract nourishment towards the shoot; for a shoot possessing flower-buds, but having no wood-bud to act as a leader, may blossom, but will produce no perfect fruit. Branches which are considered as too weak to ripen fruit, are commonly cut, as they must tend to rob the other parts of the tree. When the trees have completely filled the spaces allotted to them, the principal shoots are not shortened, unless with the view of filling vacancies, or when the extremities of the shoots have remained unripe, and been checked by the frost.

Mr Knight has explained the nature of what are called *luxuriant shoots*, and also the right mode of managing them. Most gardeners have directed the shortening of these in summer, or the cutting of them out in the following spring: But Mr Knight has experienced great advantages from leaving them wholly unshortened, but trained with a considerable inclination to the horizon; for, in this way, they have uniformly produced the finest possible bearing wood for the succeeding year; and so far is this practice from tending to render naked the lower or internal parts of the tree, whence these branches spring, that the strongest shoots they afford invariably issue from the buds near their bases. The laterals from luxuriant shoots, if stopped at the first leaf, often afford very strong blossoms, and fine fruit in the succeeding season.

92. In the milder parts of England, the blossom of the peach-tree scarcely requires protection: in less favoured places, it is protected by some of the means already specified. Dr Noehden, in the second volume of the London Horticultural Transactions, has mentioned rather a singular mode of preventing the bad effects of frost on the blossom or young fruit of the peach-tree. It is this: after a frosty night, the first business of the morning is to sprinkle cold water over the trees by means of the garden engine, taking care that the blossom or young fruit receive their share, and that the operation be performed some time before the rays of the sun strike the trees. Whether the water is useful, merely by promoting a gradual thawing, has not been ascertained.

When the fruit has attained the size of large peas, or of

* These two varieties were sent by Mr Knight in the spring of 1816, to the garden of Sir George Mackenzie at Coul, in Ross-shire, where they are planted against a south wall. If they succeed well in that latitude, they will prove a great acquisition to Scotland.

small hazel-nuts, it is thinned, to the distance of five or six inches between each fruit. In this way it acquires a larger size, and the tree is not exhausted. The picking off of leaves which overshadow the fruit, as recommended by Nicol and others, is not a good practice; at least it must not be pushed to any considerable extent; for the flower-bud for the succeeding year, being lodged in the axilla of the leaf-stalk, must greatly depend on the leaf for its nourishment.

In dry seasons, and especially in soils naturally dry, a hollow basin, about six feet in diameter, is sometimes formed around the root of the tree; this is covered with *mulch* (small dung moistened, mixed with a little loam, and worked together like mortar,) and water is occasionally added, according to the state of the weather. This is practised only while the fruit is growing, and the intention is, to keep it always in a state of progress.

Mr Knight seems to think, that in the milder parts of England, plentiful crops of fruit might be procured from the hardier sorts of peach-trees, trained as espaliers: he suggests that they should be planted in rows in the direction of north and south; that they should not exceed five feet in height; and that while the blossom is exposed to danger from frost, mats should be thrown over them, so secured as to descend on each side nearly in the angle of an ordinary roof of a house.

On account of the usual mode of training and pruning peach-trees in this country, they do not occupy much space on the wall. Some of the old horticultural writers speak of twelve or fourteen feet as enough: but the trees are now permitted to spread wider, from fifteen to twenty feet being allotted to each tree. Near Paris, a single peach-tree may sometimes be seen covering sixty feet of wall. It is at Montreuil that peaches are cultivated in perfection, peach-gardens being here established for the supply of the capital. Making due allowance for the difference of climate, advantages might probably be derived from copying some of the practices of these French cultivators, whose whole attention is devoted to the management of peach-trees. In 1814, Mr John Mozard, who was bred under the famous gardener, Pepin, and is himself one of the principal proprietors of peach-gardens at Montreuil, published a little piece, entitled "*Principes pratiques sur l'éducation, la culture, la taille, et l'ébourgeonnement des arbres, fruitiers, et principalement du pêcher*," which is well deserving the attention of horticulturalists in this country.

*Nectarine.*

93. The *Nectarine*, as already observed, is merely a variety of the peach. The English name may be supposed to be derived from the nectareous flavour of the fruit. The skin is smooth, not downy as in the peach; and the flesh is rather more plump than in that fruit. Nectarines, like peaches, are either free-stones or cling-stones; the former are called by the French *Pêches lisses*, smooth peaches; the latter, *Brugnons*. Miller enumerates ten varieties:

| | |
|---|---|
| Fairchild's Early. | Red Roman. |
| Elruge. | Murrey. |
| Newington. | Golden. |
| Scarlet. | Temple's. |
| 5. Brugnon or Italian. | 10. Peterborough. |

Of these the following are in most esteem:

The *Elruge*, a middle-sized fruit; when ripe, of a dark red or purple next the sun, pale towards the wall; ready in the middle of August: the tree grows freely, and is a sure bearer; indeed it is perhaps the best nectarine for the open air, especially in the less favoured counties.

The *Newington* nectarine is rather a large fruit; of a beautiful red next the sun, and on the other side of a bright yellow; flesh melting; juice very rich, racy and high flavoured; a cling-stone, not ripening before September: the tree a good bearer, when in a favourable situation.

The *Red Roman* nectarine is a large fruit; deep red or purple next the sun, and yellowish on the other side; flesh firm and of excellent flavour; when quite ripe, it shrivels; a clingstone, not ready before the middle of September.

The *Murrey* (*i. e.* murrey-coloured) is a middle-sized fruit, of a dirty red colour next the sun; the pulp pretty well flavoured; ripens from the beginning to the middle of September.

*Temple's* nectarine is a middle-sized fruit, of a light red next the sun, and yellowish-green on the other side; pulp melting, with a fine poignant flavour; the skin shrivelling when the fruit is perfectly ripe, which seldom happens before the end of September: the tree grows freely, and is generally productive.

To these may be added the *Early Violet* nectarine, of middle size, violet purple next the sun, pale yellow on the other side; flesh sugary, juice with a vinous flavour; a clingstone, ripening in the beginning of September: the blossom is very small, but the tree very productive; it requires a good situation, and succeeds only in warm seasons.

The production of a new and early nectarine, suited to the climate of Britain, may be considered as one of the desiderata in our horticulture. It may here be mentioned, that a new variety of white nectarine is described by recent French writers as being remarkably early and of excellent flavour; the foliage of the tree is of a pale or whitish green; it was raised by Mr Noisette, a nurseryman at Brunoy.

The management of the nectarine-tree is in every respect the same as that of the peach. In this country nectarines require the best exposure in the garden; and to the northward of Yorkshire, they seldom acquire maturity without the aid of a fluid wall and artificial heat.

*Almond.*

94. The *Almond-tree*, (*Amygdalus communis*, L.) can scarcely be ranked as an effective fruit-tree in this country. In clumps of shrubs on the lawn, it makes a fine appearance in early spring, when covered with its beautiful blossoms. In good seasons, such standards produce some ripe fruit: but ornament is its principal recommendation; and if the fruit be no object, the double-flowered variety is preferable. Trained against a wall, the almond-tree perfects its fruit in our ordinary seasons, when the outer cover opens naturally to give out the stone containing the kernel. They are very sweet and fit for the table when green, and they are sometimes kept in sand till winter.

In France, the almond tree is much cultivated. Bastien enumerates nine varieties; among which is an *amandier pêcher*, or peach-almond tree, supposed to have been derived from an impregnation of the almond by the pollen of the peach. On the same tree, he tells us, two sorts of fruit occur; the one round, fleshy, and divided by a furrow like the peach; the other oblong, not fleshy, and resembling the common almond.

The kinds of almond chiefly cultivated for their fruit are,

The common sweet almond;
Tender shelled;
Hard shelled;

Sweet Jordan; and
Bitter almond.

These different varieties are propagated by budding on plum or peach stocks, or on almond stocks raised from the stones; plum stocks being preferred for strong and moist soils, and peach or almond stocks for such as are light and dry. In this country it often happens that the varieties are little attended to. Almond trees are raised from the stones, and of course are liable to *sport*, as gardeners speak. It may be remarked, that even when they are raised from the stones, budding or working of one new variety upon another, is extremely useful in hastening the production of fruit.

The general management in regard to pruning, &c. is similar to that of the peach tree, only that the bearing twigs are often left six inches long without being nailed to the wall.

### *Apricot.*

95. The *Apricot tree* (*Prunus Armeniaca*, L.; *Icosandria Monogynia; Armeniaceæ*, Juss.) is said to be a native of the whole of the Caucasus, the mountains almost to the top being covered with it. It is supposed to have been introduced into this country in the reign of Henry VIII.

96. In 1629, Parkinson describes six varieties. At least ten varieties are now commonly cultivated. Several of these have been known since the days of Parkinson, particularly the Masculine; and others are mentioned by Rea in 1702, such as the Roman and the Orange.

| | | | |
|---|---|---|---|
| | Masculine. | | Transparent. |
| | Moorpark apricot. | | Peach apricot. |
| | Orange apricot. | | Breda. |
| | Royal orange. | | Brussels. |
| 5. | Roman. | 10. | Turkey apricot. |

The *Masculine* is generally first ripe. It is a small roundish fruit, red next the sun, and, when ripe, of a greenish yellow on the other side. It has a quick high flavour, but in general is rather tartish. The tree is a good bearer.

The *Breda* is a large roundish fruit, becoming of a deep yellow when ripe; the flesh soft and full of juice, and of an orange colour within. It is considered as among the best of the apricots, and the tree is a liberal bearer.

The *Moorpark* is a large fruit, flat shaped, of a deep yellow colour, and very high flavoured. Nicol declares, that one Moorpark is worth three of any other kind of apricot; and it is esteemed by many the richest of the stone-fruit kind. The tree requires a good soil and situation, but deserves them. It is regarded as of English origin, and it receives various names in different parts of the country, such as Lord Dunmore's apricot, the Anson apricot, and the peach apricot. It takes its name from Moorpark in Hertfordshire, a place celebrated by Sir William Temple in his account of English gardens at the close of the 17th century. (Miscellaneuus Works, vol. ii.)

97. The stocks commonly preferred for apricots are those of the muscle plum; but Mr Knight has observed, that they succeed better, and are more durable, on stocks of their own kind, that is, on apricot stocks: this he found to be the case, in particular, with the Moorpark apricot. The apricot being an early tree, the budding is performed any time from the end of June to the end of July; the bud is inserted about six or eight inches from the ground. The apricot is sometimes twice budded; that is, one variety is budded on another. The tree is said in this way to be kept more dwarf. When apricot trees are wanted as *riders*, or temporary trees, to fill the wall, they are of course budded on stocks four or five feet high. The best plants for dwarfs are such as have two strong branches, expanding as widely as possible from each other, and inclined at an angle of about 30°. But it very frequently happens, that there is only one main shoot, and this is headed down to six or eight inches, to obtain a supply of lateral wood. October is the best time for planting, and the end of February for heading down. The young shoots are laid in horizontally, or nearly so, and are not shortened till November following.

The fruit being produced partly on spurs, but chiefly on young wood of the former year, during summer care is taken to pick wood-buds from these spurs, and to lay in and protect a sufficiency of new wood for next season. In June, the superfluous and fore-right shoots can be displaced with the finger and thumb; late in the season a knife must be used. The young shoots cut off, it may be mentioned, may be used for dyeing a fine cinnamon colour. Some good fruit, it must be observed, however, is produced from the curzons or spurs upon two-year-old shoots. The shape of the buds indicates those likely to be fruitful, and which of course are to be preserved. The winter pruning is done any time from October to March. Not only all decayed and very old wood is as much as possible removed, but some of the most naked parts of the bearers of the two last years are cut out, so as to make room for a supply of new wood. The retained shoots are commonly shortened a little, and are always cut next a wood-bud, which is to act as a leader. The full grown apricot tree is managed much in the same way as the peach; but its late or autumn shoots do not agree with being shortened; when wanted as bearers, therefore, they are laid in at full length to the wall. The small and subordinate, or late shoots of the apricot, are more apt to be destroyed by frost than those of the peach tree. On this account, the pruning is often delayed till the end of January, when it can be seen which shoots are alive, and which have perished.

98. When the fruit is over-crowded, it is thinned, but cautiously, in the early part of summer. In the beginning of July it is finally thinned, and the best of the thinnings may then be used for tarts. Some gardeners recommend thinning the Moorpark to a fruit to every foot square, and the smaller kinds of apricots to a fruit to every eight inches; but, in general, the thinning is not carried so far. As the fruit approaches maturity, it is nailed close in to the wall, in order to its gaining as much reflected heat as possible. In this country, apricots begin to ripen in the end of July, and they continue till peaches be ready. Before the introduction of the new style, they were sometimes ready early in July, and hence received the name of Mala *præcocia*, to which epithet our English name may be traced.

Apricot trees are generally placed against an east or a west wall; the heat of a full south wall being apt to render them mealy before they become ripe. In the northern parts of the island, however, a south-east or south-west aspect answers best. In some of the warmer districts of England, several varieties of the apricot, particularly the Moorpark, transparent, Breda, and Brussels, are frequently planted as espalier trees, the horizontal branches being tied to the rail, but the bearers left loose. Occasionally some of these, especially the Breda and Brussels, are tried in the form of dwarf standards; and in fine seasons, they yield the highest flavoured fruit.

When an apricot tree has been greatly mismanaged, it may be cut down very much, as it sets out stronger branches than a peach tree, and these may soon be trained so as to fill the former space. The strong branches of this tree are very apt to throw out gum at places where any accidental hurt has been received: the usual remedy is to cut out the diseased part, filling up the space with pitch and rosin melted together, or merely with a little tar, or any sort of mild paint.

Apricots are seldom forced, as they do not in general answer expectation in this way. The Moorpark, however, is sometimes seen on the flued wall along with peach trees; and dwarf or espalier plants of the early masculine and Brussels, are occasionally introduced into the border of the cherry-house or the peach-house, with success.

*Plum.*

99. The *Plum tree*, (*Prunus domestica*, L.) is completely naturalized in this country, but can scarcely be said to be indigenous to Britain: it is however admitted into our Flora by Sir J. E. Smith, and is figured in English Botany, plate 1783. There are many varieties, of which some of the oldest and best marked are *P. præcox*, the primordian; *damascena*, the damask or damson; *juliana*, the St Julian; *pertigona*, the perdrigon; and *cerea*, the magnum bonum. Parkinson enumerates no fewer than sixty sorts. Miller describes only about thirty.

100. The following are the kinds chiefly cultivated at present:

| | |
|---|---|
| White primordian. | Apricot plum. |
| Early damask. | Mirabelle. |
| Black damask. | Drap d'or. |
| Precoce de Tours. | White imperial, or magnum bonum. |
| Maître Claud. | Red imperial. |
| Monsieur's plum. | St Catherine. |
| Imperatrice. | Orleans. |
| White Perdrigon. | Fotheringham. |
| Blue or Violet Perdrigon. | Wine-sour. |
| Red Perdrigon. | La Royale. |
| Queen Claudia, or true green-gage. | La Roche-corbon. |
| White gage. | Coe's golden drop. |
| Blue gage. | |

The *White primordian*, which is also called St Barnaby's plum, and sometimes Jaune-Hâtive, is the earliest plum we have, commonly ripening in the end of July. The fruit is small, of a longish shape, sugary, but without much flavour. One tree on a wall is reckoned enough, the tree being a free bearer.

The *Early Damask*, or Morocco, immediately succeeds the white primordian. The *Precoce de Tours* and *Maître Claud* are well flavoured plums, and the trees grow freely, and bear well as standards.

*Monsieur's Plum*, or the Wentworth, is a large fruit, somewhat resembling the white magnum: the tree is a copious bearer, and answers very well as a standard: the fruit is much used for tarts and in sweetmeats. The *Imperatrice* is remarkably late, seldom ripening on standards till the end of October.

The *Perdrigons* are melting, sugary, and perfumed fruits; the trees are not very free bearers, but are in many places planted as espalier and dwarf standards.

The *Queen Claudia* of Rouen, or Verte bonne, seems to be the proper *Green-gage*; "the best (says Mr Nicol,) the most generally known, and most highly esteemed of the plum kind." A few trees of this sort are generally trained to a south-east or south-west wall; but in a sheltered situation, and where the soil is a rich deep loam, with a dry bottom, the fruit acquires a higher flavour when produced on standards. The *white* or yellow gage, and the *blue* or red gage, though inferior to the green, are much cultivated.

Tho *Drap-d'or*, golden drop, or cloth of gold plum, is a good fruit; but it requires a wall, and the tree is not in general a plentiful bearer.

The *White Imperial*, or white magnum bonum, has also several other names, as yellow magnum, Holland magnum, Mogul plum, and egg plum. It is a very common fruit; of a large size; sweet, but with no great flavour; excellent for tarts and sweetmeats: the tree grows freely, and seldom fails to bear, either on a wall, or as a standard.

The *Red Imperial* is likewise called red magnum bonum; it is also a large fruit, and of fine appearance; but it is principally used for baking and preserving: the tree is a free bearer as a standard. The *St Catherine* has a rich sweet juice, and is fit either for the dessert, or for being used in confectionary.

The *Orleans* is a middling good plum, of which there are several varieties, as the old or red, the new, and white. The tree is a vigorous grower, and great bearer: it succeeds perfectly as a standard, but is sometimes placed against a wall: it is well suited for a market fruit-garden.

The *Fotheringham*, or sheen plum, is a beautiful large red fruit, of considerable flavour; "there is hardly any plum that excels it," says Forsyth: the tree answers equally well for a wall, or as an espalier or standard.

The *Wine-sour* is a plum said to be of Yorkshire extraction; it is not much cultivated, but seems deserving of attention; it it very late, and chiefly used for preserves.

*La Royale* is an excellent plum, of a red colour; the tree, however is generally a dull bearer. The *Roche-corbon*, or red diaper plum, is large and of high flavour.

*Coe's Golden Drop* is a late ripening plum, the merits of which have within these few years been attended to, in consequence of a recommendation by Mr Knight in the first volume of the Horticultural Transactions of London. This gentleman considers it as a new variety, while others allege that it has been known for many years. The tree is distinguished by the great size of its foliage, the leaves being often five inches long and three broad. The flesh of the fruit is of a golden colour when ripe; on the side next the sun, the skin is dotted with violet and crimson. It is beautifully figured in Hooker's *Pomona*, t. 14; and is there announced as superior to any late plum at present in the British gardens. It keeps many weeks: Mr Knight mentions, that he suspended some of the fruit by their stalks in a dry room in October, and that they remained perfectly sound till the middle of December, and were then not inferior, either in richness or flavour, to the green gage, or the drap d'or. This variety requires a wall, but succeeds extremely well on a west aspect.

The *Bullace-plum* is the fruit of a distinct species of Prunus, *P. insititia*, which grows naturally in hedges in England. It is often planted in shrubberies or lawns; it is a great bearer, and the fruit is excellent for baking or preserving. There is a variety with wax-coloured fruit, called the White bullace. The *Myrobalans*, or cherry-plum, is by some considered as only a variety of the common plum; but others rank it as a distinct species: Willdenow describes it under the title of *P. cerasifera*.

101. If the wall be high, or above ten feet, a plum tree is allowed about twenty-four feet in length; if it be low, perhaps thirty feet, horizontal training being in this case adopted. An east, south-east, or south-west aspect is found to be better than a full south exposure, in which last the fruit is apt to shrivel and become mealy. Several kinds bear

well as espalier trees; and many as standards. Even in some parts of the Highlands of Scotland, the yellow magnum and the green-gage trees may be seen thriving luxuriantly, and bearing excellent crops of fruit. The late Mr Hunter of Blackness, a zealous Scottish horticulturist, describing the garden of Macdonald of Glenco, says, "The magnums were large, well shaped, free from gum, and of a rich yellow colour all over; the gages of the true brownish and green colour, and completely ripened; and these were growing on standards, in the heart of Lochaber, where the snow on the tops of the hills was visible to us from the garden, on the 23d of September." (*Scot Hort. Mem.* i. 179.) It is to be observed, however, that in such situations, the blossom had probably not expanded till late in the spring, when the danger of frost was over. In the lower and milder parts of the country, plum blossom frequently requires protection as much as that of the apricot or the peach; indeed, the calyx drops sooner, and the blossom is in this respect more tender. In favourable seasons, it may be added, plums are plentiful much farther north; a degree at least.

Plums produce their fruit, partly on the former year's wood, but chiefly on small spurs, rising along the sides, and at the end of the branches, when of two years growth or upwards. These spurs continue long in a fruitful state. There is no necessity, therefore, for securing a supply of new shoots annually, as in peach and nectarine trees. During the summer, fore-right shoots are displaced with the fingers, and side shoots are laid in horizontally, or in a sloping direction, where there is room for them. Useless wood-buds proceeding from spurs are at the same time removed. In this way little winter pruning is required; only some extended spurs, and a few supernumerary shoots, are to be cleared away. The cuts must always be clean, and the knife sharp; plum-trees, like other stone fruits, being very apt to throw out gum and to canker. In regulating mismanaged trees, the lopping off of large branches is, however, sometimes practised; if the air be excluded by some mild paint or other plaster, the wound frequently closes, and new branches set out, which bear fruit in two or three years. For wall plum trees, many gardeners prefer the fan mode of training; but some train in the horizontal manner, being of opinion that this is the best way to check luxuriance of growth, and throw the trees into bearing. When the fruit come in close bunches, some are thinned out, in the beginning of July, when the stoning is over, to allow the rest to acquire full size; and care is taken to lay in the young shoots close to the wall, so that the sun and air may not be intercepted, but may have access to ripen and give flavour to the fruit.

The finer varieties of plums are budded or grafted on plum stocks raised from the stones. Young trees bear transplanting very well, four or even six years after they have been budded or grafted; so that they are often ready to bear the year after being planted. Great pains, however, should be taken, to raise the roots at full length, and to replace them in their new situation without bruising or other injury, and without much exposure to the air.

### *Cherry.*

102. The *Cherry tree* is the *Prunus cerasus*, L.; *Cerisier* of the French, who make three subdivisions, *Griottier Bigarreautier*, and *Guignier*.—It has been generally said that cherries were introduced into England by the fruiterer of Henry VIII.; but Professor Martyn has shown that they were known much earlier. Lydgate, in his account of the London cries in the middle of the 15th century, mentions that

> "Hyt (supposed white) pescods one began to cry,
> "Straberys ripe, and cherries in the ryse."

*Ryse* is a word not yet obsolete in Scotland, signifying spray or twigs; and on the stalls of the Edinburgh fruit market, cherries may sometimes be seen "in the ryse," or at least stuck on the thorns of hawthorn sprigs, in order to catch the fancy of children. The white pescod is a kind of plum.

103. Parkinson's list in 1629 contains about thirty varieties of cultivated cherries, several of which are still known, and in esteem, as the mayduke, heart, amber, and morello, but others have entirely disappeared. Miller enumerates only twenty-one; and of these it is not necessary to notice more than one half, being those commonly cultivated.

| | |
|---|---|
| May-duke. | Carnation cherry. |
| Archduke. | Morello |
| Harrison's heart. | Lundie guigne. |
| Hertfordshire heart. | Black coroun. |
| White heart. | Tartarian cherry. |
| Black heart. | Kentish. |

Of the *May-duke*, Nicol observes that we have no cherry equal to it, and that the tree thrives in all situations. It does very well as a standard; but against a good wall, and with a southern aspect, the fruit becomes considerably larger, and, contrary to what happens in other fruits, it seems to acquire a higher flavour. It ripens early in June; and before the change of the style, it was often gathered in May: this was particularly the case with a small variety called the Early May.

The *Archduke* is also called the Late duke: it is a good cherry when ripened on a wall; but the tree does not answer well as a standard.

*Harrison's heart* is a large cherry, of good qualities, and the tree bears freely. The *Hertfordshire* has a firm flesh and excellent flavour: it is a late cherry, not ripening till August. The *Carnation cherry* has received its name from the fruit, being variegated red and white: it is a late cherry, and requires a good wall.

Though the taste of the *Morello* cherry, approaching that of the mulberry, is not agreeable to many, yet when ripened on a wall in the full sun, it acquires a size and richness of flavour superior to any other: The tree grows freely, and bears well.

The *Lundie guigne* is of a dark colour, and nearly as large as maydukes which grow on standard trees: it receives its name from Lundie in Fife, the seat of Sir James Erskine, where the original trees still remain. The *black coroun* resembles the black heart; it is an excellent fruit, and the tree is a healthy grower and great bearer. The *black* and the *white Tartarian* cherries are much cultivated at Petersburgh, and were introduced from Russia about 1797: the fruit is of good flavour, and ripens early; and the trees produce plentifully. The *Kentish* cherry is chiefly planted in cherry orchards, and in market gardens: the flowers being late in expanding, they generally escape the spring frosts, and afford a plentiful crop: the fruit, however, is fit only for tarts.

104 That indefatigable and truly meritorious horticulturist, Mr Knight, has lately added to our list three new cherries raised from seed; they have been called the Elton, the Black Eagle, and the Waterloo.

The *Elton* is the offspring of a blossom of the graffion, or ambrée of Duhamel, fecundated by the pollen of the white heart; it is distinguished by a very deep tinge of crimson in the petals, and by the extraordinary length of its fruit-stalks. The pulp is very juicy, and of delicate flavour. The tree grows vigorously, and is a free bearer.

The *Black Eagle* was from the graffion, with the pollen of the mayduke, and the tree and its fruit resemble the mayduke in a considerable degree.

The *Waterloo* was of the same origin. "It sprang (says Mr. Knight) from the largest and finest ambrée cherry that I ever saw; and I imagine it was the best fed; for it stood alone upon a tree, which was well capable of bearing at least half a dozen pounds of cherries." The Waterloo is somewhat later than the black eagle. It is nearly as hardy as the mayduke; and it has been observed to acquire tolerable perfection even in cloudy and rainy weather. On approaching maturity, one side presents a dark livid colour; but in ripening, it acquires a rich and deep red colour, nearly black. It is larger than the black eagle, and more conic towards its point.

All of these three varieties possess valuable qualities, and deserve the attention of cultivators in every part of the country. The only plants of these yet brought to Scotland, as far as we know, are in the garden of Sir George Mackenzie, Bart. at Coul in Ross-shire, where, as it is situate far to the northward, their qualities in regard to climate will be put to the proof. They who possess opportunities should also attempt the production of new kinds. The cherry, it is believed, *sports* more extensively in variety when raised from seed than almost any other fruit; and Mr Knight justly remarks, that it is probably capable of acquiring a higher state of perfection than it has yet attained.

105. The finer kinds of cherries are trained against the wall, chiefly in the fan manner: they are placed about twenty-four feet distant from each other, and, at the first planting, a temporary tree is usually put in between each. When favoured with a south aspect, they not only produce early, but large and excellent fruit, highly worthy of a place in the dessert. To prolong the cherry season, some of the duke and heart varieties are generally placed against a west wall. The morello, being chiefly wanted for preserves, has frequently a north aspect assigned to it. This variety in so far differs in habit from the others, that it is produced rather on the young wood of the former year than on spurs; it is necessary, therefore, at the time of pruning, to have a supply of young wood in view. Cherry-trees are sometimes trained on espalier rails; and in this case, as in wall-trees, it is a great object to keep up a stock of young wood, or at least a quantity of young spurs, or curzons. The branches are generally tied to the rails by means of willow-twigs, or strands of bass-matting. All stone-fruit trees being liable to become gummy at places where they are galled, attention is necessary that the tyings do not injure the bark. Cherries, it may be added, succeed much better as half-standards or dwarf standards than as espalier-trees.

It is a general rule to bud or graft cherries at the height where the head is intended to begin. Some prefer having only two main branches for a wall cherry-tree; but three branches are, in general, found more commodious. Miller suggests, that budding heart cherries on stocks of the birdcherry (*Prunus padus*), might have a similar effect as grafting apples on paradise stocks; that not only might the tree be thus kept in less compass, but rendered more fruitful.

In prunning cherry-trees, the shoots are not shortened, for they produce many fruit-buds at the extremities. It is a common remark of practical gardeners, that cherry-trees dislike the knife. The branches therefore are trained at full length, superfluous fore-right shoots being displaced by the hand in the early part of summer. Much fruit is produced on small side-spurs proceeding from wood two or three years old; these side-spurs are therefore carefully preserved.

When the fruit begins to colour, it is assailed by blackbirds, jays, and other birds. The most effectual remedy is found in hanging a net in front of the tree, or over it, if it be an espalier or dwarf-standard. In gathering the fruit, care should be taken not to break the fruit-spurs, which are very brittle: to avoid the risk of this, some gardeners are at the pains to cut the fruit-stalks with a pair of small scissars.

### *Apple.*

106. The *Apple-tree* (*Pyrus Malus, var. sativa*, L) belongs to the class Icosandria, order Pentagynia, and natural order Rosaceæ of Jussieu. The crab-tree, *P. malus*, is a native of various parts of Britain, and is figured in English Botany, t. 179. Like the wild pear, it is armed with thorns. Many of the cultivated kinds have been imported from the continent at different times; and many others have been raised from the seed in this country. Ray, in the close of the 17th century, described seventy-eight sorts, then accounted good: several of these still retain their character, but many more have either lost it, or have entirely disappeared. The costard-apple, which was then so commonly sold in London that dealers in apples were styled costard-mongers, is not now known. At this time among the favourite cider apples were the redstreak, the golden-pippin, the gennet-moil, the white and red masts or musts, the fox-whelp, and the stire; all of which, as remarked by Mr Knight, are now fast hastening to decay and extinction. Several new apples, however, possessed of excellent qualities, have of late years been brought into notice; and so many amateurs of gardening are now engaged in raising new varieties from seed, that there seems little reason to apprehend a deficiency. This is as it should be; the apple being doubtless the most useful of the fruits freely produced in this country.

107. Forsyth, in his Treatise on Fruit-trees, describes no fewer than 196 varieties, exclusive of many, of which he gives the names only, without descriptions. In this place only a few of the finer apples can be noticed; such as are commonly cultivated in gardens, as wall or espalier trees, or as half and dwarf standards. The other standard apples used for baking, or in the manufacture of cider, will be treated of under the article ORCHARDS.

Golden pippin,
Balgone pippin,
Nonpareil,
Scarlet nonpareil,
Ribston pippin,
Oslin pippin,
Hawthorndean,
Margaret,
Jenneting,
Nonsuch,
Margil,
Quince apple,

Aromatic pippin,
Royal Russet,
Codlin; Royal, Kentish, Carlisle, and Keswick.

Newton pippin, and Spitsenberg.

Rennets, grey, golden, and Canadian.
Violet apple.

The *Golden pippin* is a well known excellent fruit, ripening late in autumn; when fully matured it keeps long, and forms, during winter, one of the choicest dessert apples; it is generally small, but beautiful, and the juice is sweet and high flavoured. The tree requires a light but good soil; if the subsoil be wet, it is extremely apt to canker. It is rather of low growth; against a wall, however, it grows freely, and produces abundance of fine fruit. The golden pippin is highly praised by French horticultural writers, under the name of Reinette d'Angleterre. Miller notices the general falling off of this fruit, and the subject has been enlarged upon by Knight: the fact cannot be denied: the former ascribes it to the practice of grafting on free-stocks instead of crab-stocks; the latter, we believe with more reason, to the natural decay of the variety through old age. The *Balgone pippin*, so named from the seat of Sir James Suttie in East Lothian, much resembles the golden pippin, and to all its excellencies adds the advantage of larger size. The tree grows luxuriantly against walls, and appears at present to be in health and vigour. It deserves the attention of the horticulturists of South Britain.

The *Nonpareil* is one of the best apples known, and the chief of the russet tribe: it is rather a flat-shaped fruit, with a sharp, pleasant, high-flavoured juice. It is scarcely ripe till the end of November; but if well ripened, it keeps till May, or later. The tree grows to a large size; and in a good soil, such as a hazelly loam, it bears pretty freely. It is very generally trained against a wall; and in the northern parts of the island, it requires not only a wall, but a good aspect. The *Scarlet nonpareil* ripens more freely than the former; and the fruit becomes larger, and more smooth and plump, being at the same time highly charged with the flavour peculiar to the nonpareil: it is in season in January and February.

The *Ribston pippin* is an excellent apple; when well ripened, it adds to the dessert; for kitchen use it is unrivalled. The tree grows freely in almost every situation, and is a good bearer. The fruit is of a greenish-yellow colour, with red or brown streaks on the side next the sun. It keeps very long, remaining quite firm till April or May. Mr Nicol is justly in raptures with it: "It may be called a universal apple for these kingdoms; it will thrive and even ripen at John-o-Groat's, and it deserves a place at Exeter or at Cork." It was long supposed to have been raised at Ribston Hall in Yorkshire; but it is now ascertained to be a Normandy pippin, introduced early in the 18th century.

The *Oslin pippin* is sometimes called the Original, and sometimes the Arbroath pippin; by Forsyth it is named Orzelon. This is a very good apple, excelled in flavour only by the nonpareil, over which it has the advantage of ripening in a worse climate. It does not keep: indeed it should be eaten from the tree, and it is known to be fit for use by its acquiring a fine yellow colour. It is particularly described by Dr Duncan, senior, in the first volume of the Scottish Horticultural Memoirs. The tree grows freely by cuttings, provided each cutting include a knot or bur. The Doctor mentions, that of fifty branches detached early in the spring, more than one half blossomed and produced ripe fruit the same year; they continued fruitful for the next two years, and promised to form permanent fruit-bearing trees. The Oslin has been for time immemorial cultivated at St Andrews and Arbroath, where there were formerly magnificent establishments for monks, by whom it was probably introduced from France.

The *Hawthorndean*, or White Apple of Hawthorndean, derives its name from the romantic seat, in Mid Lothian, of the poet and historian Drummond, at which he was visited by the celebrated Ben Jonson. It is a summer apple, but does not keep long; it is juicy and good, excellent for kitchen use. The tree is a free grower, and bears quickly and plentifully; it is however but short-lived, generally shewing symptoms of decay when twelve or fifteen years old: it is well calculated, therefore, for a temporary tree in any situation, and for this purpose it is much employed.

The *Margaret apple* is also called Magdalene apple; it is an early fruit, of good flavour, but does not keep long. The tree is of middling size; commonly productive.

*Jenneting*, or Geniton, as Dr Johnson has it, is generally supposed to be a corruption of June-eating. It is a small fruit, but very early ripe; certainly however not in June, nor earlier than August. It is perhaps inferior to the Oslin, Margaret, and one or two other early apples; but no one possessed of a healthy jenneting tree in full bearing would willingly part with it.

The *Nonsuch* is a well known pippin; the tree is rather subject to the canker, but it generally bears more or less every season.

The *Margil* is a very good late apple, fit for the dessert in January; the fruit is much improved when the tree is trained against a wall.

The *Quince apple* is a small fruit, shaped like the quince; the side next the sun of a russet colour, the other side yellowish; it is an excellent apple for about three weeks in September, but does not keep much longer. The tree is of low growth.

The *Aromatic pippin* receives its name from its fine flavour; the side next the sun is of a bright russet colour. It ripens in October, and is fit for use from December to February.

The *Royal russet*, or leathercoat russet, is so named from the deep russet colour of the skin; it is a large fruit, of an oblong figure, broad towards the base: it is an excellent kitchen fruit, and may also appear in the dessert; it keeps till April. The tree grows to a large size, and bears very freely.

The different varieties of *Codlins* are chiefly baking apples, although they may also occasionally be taken to the table: they are early; but none of them are good keeping apples. The trees are great bearers, and make commodious half and dwarf standards in gardens; the latter are frequently trained around hoops to support their branches. An account of the valuable properties of the Carlisle and Keswick codlins is given by the Right Hon. Sir John Sinclair, in the first volume of the Scottish Horticultural Memoirs. The codlins are frequently propagated by slips, suckers, or layers, trees thus procured yielding fruit much more quickly than grafted trees.

The *Newton pippin* and *Spitsenberg apple* are two American sorts, which have of late years become favourites in some parts of this country. The former was introduced from Long Island, New York: it is a beautiful and excellent apple; it ripens best on a wall, but in favourable seasons it succeeds on espalier rails, or even on dwarf standards. The Spitsenberg is also a very good fruit, with somewhat of the pine-apple flavour; the tree requires a sheltered situation and a good soil: it is observed to thrive better on a west than on a south wall.

The *Grey rennet*, Reinette grise, is a middle-sized fruit, of a deep grey next the sun, but on the other side intermixed with yellow; a juicy apple, of a quick flavour, yet sugary: it ripens in October, but does not keep long. The *Golden rennet*, Reinette dorée, is a very good apple, ripening in the end of September, fit either for the table or the kitchen, and keeping till February. The *Canadian rennet* is called by the French horticulturists Reinette de Trianon: it is a large fruit, of a yellow colour, with a tinge of red: it keeps till February.

The *Violet apple*, Pomme violette, is a middling large fruit, of a long shape; pale green on one side, but deep red next the sun; flesh delicate, juice sugary, with a slight flavour of the sweet or March violet. The tree grows vigorously, and the fruit ripens in the end of October.

The *Eve apple* is originally from Ireland, but now very generally cultivated in the west of Scotland. The tree is nearly as ample a bearer as the Keswick codling; and it is peculiarly well calculated for forming small standards, to be trained either hollow, or like a cylinder or a cone, the tree growing close and compact, and the fruit spurs being regularly distributed along every part of the branches. The apple is of a fine colour, and well tasted, fit either for table or kitchen use. It keeps nearly four months. The tree produces fruit the second year after being grafted; and, like the burknot, it may be propagated by cuttings or by layers.

Several excellent and well known garden apples are not included in the list above given, in order to avoid prolixity; such as the summer and the winter Thorle; different varieties of Pearmain; the Wine apple, or Queen; the red and the white Calville; Wheeler's Russet; Holland pippin; the Strawberry apple; the Devonshire Quarenden, the Crofton, and the Kerry pippin. It cannot be too often inculcated, that the choice of varieties of fruits, and especially of apples and pears, ultimately to be employed as standards and dwarf standards in gardens, ought to depend very much on *experience*,—on observing which kinds succeed best in the particular soil and situation in question.

108. As formerly mentioned, several new apples have of late been brought into notice. Of these, the following have deservedly acquired a good character: The Yellow Ingestrie pippin, the Downton pippin, and the Wormsley pippin.

The *Yellow Ingestrie pippin* was raised a few years ago by Mr Knight, from a flower of the orange pippin dusted with the pollen of the golden pippin. It is similar in form and colour to the latter, which it almost rivals also in richness and flavour: it ripens in October, but does not keep. The tree is very productive.

The *Downton pippin*, named from Mr Knight's seat, had the same origin; and also possesses very good qualities in certain upland situations; but in the low grounds about London it is not good.

The *Wormsley pippin* is another of Mr Knight's apples, a very large fruit, and, in the consistence and juiciness of its pulp, nearly resembling the Newton pippin; it ripens in the end of October, and keeps for some time.

The apple called *Hughes's new golden pippin* possesses the finest qualities; but we suspect it will be found to be, not a new fruit, but a French apple, cultivated in Normandy, and not unfrequently shipped for this country at Charante.

Some varieties are cultivated chiefly by way of curiosity; particularly the *Fig-apple*, which is remarkable for producing no seeds, and indeed for having no proper core; it is said also to shew stamens and pistils only, or to be destitute, or nearly so, of petals. The *Dwarf rennet* is also deserving of notice; when grafted on a paradise stock, the tree scarcely exceeds in size a large plant of gillyflower. It is therefore sometimes kept in pots, and forced, and placed in a growing state on the table. The fruit completely resembles the common French rennets. To these may be added, the *Pomme d'Api*, or Apius's apple, a very small fruit, of a yellowish colour, but bright red next the sun; and the *Pomme de deux ans*, or John apple, remarkable for having apples and blossoms on the tree at the same time.

109. Apple trees intended for full standards are grafted on free stocks, or crab stocks; those for espalier rails or walls, on paradise and codlin stocks. A young grafted apple tree should have three branches; and, if intended for a wall-tree or espalier, the centre branch only is cut down, perhaps to a foot in length, to encourage the setting out of a succession of branches. The fruit of the apple tree is produced on small side and terminal spurs, or short spurs or curzons, from an inch to more than two inches long, proceeding from branches two, three, or four years old, the same wood continuing fruitful for a number of years. The nonpareil, and some other varieties, indeed, yield a few fruit from shoots of the former year; but this is not usual. Espalier and wall trees are pruned twice in the season, in summer and in winter. In May and June, foreright and other superfluous shoots are taken out, a few being laid in, to supply wood where wanted. Any time between December and March, a selection of these is made; and unfruitful, decayed, or cankered branches being cut out, new branches are led along in their place. At the same time, old rugged spurs, and useless snags, are taken clean off close by the trunk, applying any mild ointment to the wound. On walls from nine to twelve feet high, the fan-training is preferred; but on walls under nine feet, the horizontal method is often adopted. About twenty-five feet are allowed to each tree. Standard apple trees receive, and indeed require, but little attention. The ground is dug over, lichens and mosses on the trunks or branches are destroyed, dead branches are cut out, and such as cross each other so as to rub together. When a standard or a dwarf standard is heavily loaded with fruit, several clefted or forked stakes are stuck into the ground, and made to support the drooping branches, which are otherwise apt to break down. Standards in gardens are placed generally thirty feet apart; espalier trees on dwarf stocks, fifteen feet apart; on free stocks, perhaps twenty-five feet.

110. The apple tree grows and thrives on very various soils. It equally dislikes a strong clayey and wet soil, as one that is open, dry, and gravelly; a deep rich cool soil answers best. To lay down more particular rules would be nugatory. It is a fact, that in each particular place, certain kinds of apples are observed to succeed better than other kinds. When therefore the cultivator has discovered the varieties most congenial to the soil and situation, it will be his wisest plan to encourage them, by multiplying grafts of them on his other and less productive trees, or by forming new additional trees of those successful sorts. Where the soil is shallow, and the subsoil bad, it is by following this plan only that large crops of apples can be regularly procured, the new wood of the grafts bearing for a few years, and then giving place to other grafts.

This may be illustrated, by instancing Dalkeith Park garden near Edinburgh, belonging to the Duke of Buccleuch. Formerly few or no apples were here produced, the soil being very shallow, and the subsoil pernicious. But his Grace's gardener, Mr James Macdonald, planted many new trees on this plan:—He formed a small hillock of earth about a foot high, and four or five feet in circumference; on this he placed the tree, carefully spreading the roots, and then covering these with six inches of good earth, and fixing the stem to a stake, to prevent wind-waving. The roots of the trees so planted do not appear ever to have penetrated to the bad subsoil. Still, however, finding that all his standard fruit trees, and particularly apples, would inevitably prove short-lived, Mr Macdonald had recourse to the other plan, of constantly putting on new grafts. He inserts regularly from 2000 to 3000 every year, sometimes placing five or six sorts on one tree. The grafts are of such kinds as experience has taught him to be most fruitful in Dalkeith garden. Apples are now produced in this garden in wonderful profusion, the young wood being often bent down with heavy clusters of fruit, which in many cases are to be seen resting on the ground.

### *Pears.*

111. The *Pear tree* (*Pyrus communis*, L.) is naturalized in some parts of England, and is figured in "English Botany," t. 1784, but can scarcely be accounted an original native. The date of the introduction of the earliest cultivated varieties is not known; for most of them we are indebted to France and the Netherlands. Parkinson enumerates sixty-four, many of which have disappeared. Knoop, in his *Pomologie*, describes and figures above a hundred. Miller has selected eighty, which he describes in his Dictionary, as the best then known in England. Not above one half of those contained in this list are now much esteemed or cultivated. Pears are distinguished, according to the season in which they are fit for use, into *summer*, *autumn*, and *winter pears*. Summer pears must be gathered as they ripen, and eaten from the tree, none of them keeping more than a few days; autumn pears do not keep much more than a fortnight; winter pears are gathered before being fully ripe, in dry weather, and kept, some for several weeks, and others for several months, before being used. They are also classed, according to their general qualities, as *dessert* or *kitchen* pears; and, according as their flesh is firm and breaks, or is soft and melts, into *breaking* and *melting* pears.

112. The following are the best kinds at present cultivated.

*Summer Pears.*

| | | | |
|---|---|---|---|
| | Jargonelle. | | Skinless. |
| | Cuisse madame. | | Prince's pear. |
| | Red muscadelle. | 10 | Summer bergamot. |
| | Green chisel. | | Musk blanquet. |
| 5 | August muscat. | | Longueville. |
| | Little muscat. | | Green Yair. |
| | Summer bonchretien. | | |

*Autumn Pears.*

| | | | |
|---|---|---|---|
| | Brown beurré. | 20 | Great Mouthwater. |
| 15 | Autumn bergamot. | | Red orange. |
| | Gansel's bergamot. | | Great russelet. |
| | Swiss bergamot. | | Red doyenné. |
| | Verte longue. | | Auchan. |
| | Green sugar. | 25 | Muirfowl egg. |

*Winter Pears.*

| | | | |
|---|---|---|---|
| | Chaumontel. | | Easter bergamot. |
| | Colmart. | 35 | Dry martin. |
| | Crassane. | | Louise bonne. |
| | St Germain. | | Marquise. |
| 30 | Echassery. | | Little lard pear. |
| | Winter bonchretien. | | Ambrette. |
| | Virgouleuse. | 40 | Poire d'Auch. |
| | Holland bergamot. | | Swan egg. |

113. The *Jargonelle* (meaning the cuisse madame of the French, whose jargonelle, *vice versâ*, is our cuisse madame) is a well-known fruit, the tree being universally cultivated, either against walls, or espalier rails, or as dwarf standards The flesh is breaking, sweet, and has a slightly musky flavour. It ripens in August, and does not keep; but if two or three trees be planted on an east aspect, the jargonelle season may be prolonged till the end of September.

The *Cuisse Madame* (*i. e.* the French jargonelle) is not nearly so good a fruit as the former; but the tree being a great bearer, the kind is liked for the London market.

The *Red Muscadelle*, or *La bellissime*, is a large beautiful fruit, of a yellow colour, with red stripes; the flesh melting, and of a rich flavour, when not too ripe.

The *Green Chisel*, or Hasting pear, is of a whitish-green when ripe, has a very thin skin, flesh melting and sugary, but when too ripe, mealy.

The *August Muscat*, Royal Muscat, Hanville, or Poire d'Averat, is a roundish flat pear, shaped like a bergamot, skin smooth, of a whitish-yellow colour; flesh breaking, juice richly sugared and perfumed; characterized by Miller, as "one of the best summer pears yet known." The fruit is produced in clusters, and the tree is a great bearer.

The *Little Muscat* is of a longish shape, of a yellow colour, except next the sun, where it is red. On a south or south-east wall it is ripe early in August.

The *Summer bonchretien* is a large oblong fruit, with a smooth and thin skin, of a whitish-green colour, but red next the sun; full of juice, and of a rich perfumed flavour. It succeeds very well on an east or west wall, but as a standard only in good situations, in the milder counties of England.

The *Skinless*, Early russelet, or Flower of Guigne, is a long-shaped reddish coloured fruit, with a very thin skin, the flesh melting, and full of a sugary juice.

*Prince's Pear* is a small roundish fruit, of a yellow colour, but red next the sun; flesh intermediate between breaking and melting; juice high flavoured. The tree is generally a great bearer, and the fruit will keep for a fortnight.

The *Summer Bergamot*, or Hamden's bergamot, is a round flattish pear, of a fine greenish-yellow colour; the flesh melting, and the juice highly perfumed: the tree is a strong and healthy grower, answering either as an espalier or standard.

The *Musk blanquet*, Little blanquet or Pearl pear, is of a yellow colour, full of juice and quite melting; the fruit is produced in clusters, and ripe on the wall in the end of August.

The *Longueville* is very generally spread over the northern part of Britain, where aged trees of it exist in the neighbourhood of ancient monasteries: it is not, however, contained in Miller's list; nor is it mentioned by the French writers. In quality it is surpassed by several of those already mentioned; but still it may be accounted a good summer or early autumn fruit. The longueville of Jedburgh, in Roxburghshire, it may be remarked, seems to be a variety, the fruit possessing the quality of keeping for many weeks: the trees at that place are very old, and evidently the remains of orchards or gardens belonging to the rich religious establishment which once flourished there.

The *Green Yair*, or green Pear of the Yair, is a small green fruit, sweet and juicy, but with little flavour; the tree is a copious bearer, either as a standard or espalier tree. It is supposed to be of Scottish origin, the Yair being an ancient seat on the Border.

114. The *Brown Beurré*, or Red Beurré, is a large and long fruit, of a brownish-red colour next the sun, melting, and full of sharp rich juice, slightly perfumed; indeed it is one of the best autumn pears we have; it must, however, have every advantage of soil and shelter, and a good aspect on the wall. The fruit varies considerably in colour, the

difference seeming to depend on accidental circumstances of soil and vigour.

The *Autumn Bergamot* often gets the name of English Bergamot: it is a smaller fruit than the summer bergamot, but resembles it; the flesh is melting, and the fruit richly perfumed: the tree is a free grower and great bearer.

*Gansel's Bergamot* is of English origin, having been raised from a seed of the autumn bergamot by the late General Gansel at Donneland Hall near Colchester. It is nearly allied to its parent. In good situations, the tree answers excellently as a standard; and if the fruit be gathered in the middle of October, it is in perfection about the middle of November, and continues a month on the wall: it sometimes attains a large size; we have seen one produced at Torry in Scotland, which measured in circumference 14 inches, and weighed, when taken from the tree, 1lb. 10oz.

The *Swiss bergamot* is a round fruit, with a tough skin, of a greenish colour striped with red: flesh melting, and full of juice, slightly perfumed: the tree a copious bearer.

The *Verte longue* (long green pear,) or *Muscat-fleuri*, is a handsome fruit, of good qualities: in a dry soil and warm situation, the tree produces great crops.

The *Green Sugar* pear, or Sucré vert, has a very smooth green skin; flesh melting, and the juice sugary, with an agreeable flavour: the tree is a free bearer.

The *Great Mouthwater*, or Grosse mouille-bouche, is a very good pear; and the tree answers equally well for the wall or the espalier rail.

The *Red Orange* pear is middle-sized, of a round shape, greenish colour, and purple next the sun; the flesh is melting, and the juice sugary, with a slight perfume.

The *Orange Rouge* was formerly the most common pear in France, but it is now much less cultivated.

The *Great Russelet*, or Gros rousselet, is a large oblong fruit, of a brownish colour, becoming dark red next the sun; the flesh tender and agreeably perfumed.

The *Red Doyenné* or Dean-pear is smaller than the common doyenné; it is usually a little turbinated or top-shaped, sometimes, when the fruit is clustered, almost globular, crowned with the persistent leaflets of the calyx; colour yellow; when ripe, red next the sun; ripens from the end of October to the end of November, and continues in perfection a fortnight or three weeks; the flesh is pale-coloured, melting, and, though not very juicy, agreeably perfumed. The tree is a great bearer, even in unfavourable seasons, answering perfectly well either as a standard or espalier. The Dean-pear has been long known in this country, but rather neglected, perhaps on account of Miller's characterizing it generally as "a very indifferent fruit." Mr R. A. Salisbury, however, having recommended the red doyenné in the Memoirs of the Horticultural Society of London, particularly for high and exposed situations, it has risen in estimation.

The *Auchan* sometimes receives the epithet of *grey* or *red:* it is an excellent pear, said to be of Scottish origin: in Scotland the tree is often placed against an east or west wall, but it answers better as an espalier or a standard. It probably deserves more of the attention of English gardeners than it has met with. The tree is a free grower and plentiful bearer, even in light soils. The fruit is sweetish, with a peculiar and rather agreeable flavour. When the name *Auchan* alone is used, this is the kind to be understood: What is called the Summer Auchan is a trifling green fruit, not worth cultivating; and the Black or Winter Auchan is a smaller and later variety.

The *Muirfowl egg* is another pear of good qualities, said to be originally Scottish. It ripens in September, and keeps for many weeks. It is often placed against walls in Scotland, but the fruit from standards is much higher flavoured, though not of so large a size.

115. The finer sorts of winter pears are of French origin; and in this country they require all the aid of a wall with a good aspect, and very considerable attention after they are taken from the tree, several kinds attaining maturity only in the fruit-room.

The *Chaumontel*, or winter beurré, was raised at Chaumontel near Chantilly, where, it is said, the original tree still exists. It is a large rich flavoured melting pear; the skin a little rough; often of a pale green colour, but becoming purplish next the sun; sometimes with a good deal of red. The tree may be considered as in general requiring a wall, and a pretty good aspect: in a few places it succeeds on espalier-rails in good seasons. The fruit is left on the tree till the close approach of winter; it is fit for eating in the end of November, and continues till January. The Chaumontel is produced in great perfection in Guernsey and Jersey, and considerable quantities are yearly commissioned from these islands by the London fruiterers.

The *Colmart*, or Manna pear, is large and excellent; the flesh very tender and melting, and the juice greatly sugared; both in shape and quality, it considerably resembles the autumn or English bergamot: it keeps throughout the winter, and till the end of February. The tree requires a large space of good wall, but deserves it.

The *Crassane* (said to derive its name from *crassus*, thick,) or Bergamot crassane, is a pear of a large size and round shape, with a long stalk; the skin is roughish, of a greenish-yellow when ripe, with a russety coating; the flesh is very tender and melting, and full of a rich sugary juice. It is fit for use from the middle to the end of November, and is one of the very best pears of the season. The tree requires a good wall.

The *St Germain* is a large long pear, of a yellowish colour when ripe; flesh melting, and very full of juice, with considerable flavour. If the tree be planted on a dry soil, in a warm situation, and trained against a good wall, it bears pretty freely: There are two varieties, a spurious, and the true; and it is believed the former is by much the more generally disseminated. The spurious fruit ripens in December, remaining green when ripe, and generally decays by the end of January; unless the soil and season be favourable, it is insipid and watery; it is shorter, and its form is subject to more variations than that of the true variety. The true St Germain keeps in perfection till the end of March, and, for sweetness and flavour, ranks among the very best of the winter pears. It is beautifully figured by Hooker, in the *Pomona Londinensis*, Plate 5.

The *Echassery* is a thick oval fruit, shaped like a citron; skin smooth, and yellow when ripe: flesh melting, juice sugared, with a delicate perfume. In season in December and January. The tree requires a good wall; the fruit is produced in clusters.

The *Bonchretien*, or winter bonchretien, requires even in France all the advantages of a south wall and well prepared border. But although Quintinye and Duhamel mention this as the very best late winter-pear, we would be inclined to consider it as greatly inferior to those already named, judging either from the specimens imported into this country, or from those produced in our gardens. With us it attains a large size, but seldom acquires sufficient maturity to bring forth the characters for which the French authors praise it. The French graft the tree on a quince-stock; but Miller gives it as his opinion, that if it were placed on a free stock, and the branches trained at full length on a good wall, the fruit might be much improved in this country. It is to be observed, that even in France the tree is late of coming into a bearing state, but that it becomes more fruitful as it advances in age. Delauny mentions that the French use the unripe fruit in soups, in place of turnips; and it must be confessed, that those generally produced in this country seem much fitter for that purpose than for appearing in a dessert.

The *Virgouleuse*, or ice-pear, is a large and long fruit, of a green colour, inclining to yellow as it ripens; flesh melting, and full of rich juice; for eating in December, and continues till February. The tree is often accounted a bad bearer; but it has been justly remarked by Miller, that this may frequently arise from gardeners not attending to its nature: it produces vigorous shoots, and the blossom comes principally at the ends of these shoots; if therefore the tree be pruned in the ordinary way, much of the blossom must be cut away; if, however, it be allowed ample space, and the branches be laid in at full length, the tree produces fair crops. In favourable situations, it succeeds on espalier-rails, but it is commonly trained against a wall.

The *Holland Bergamot* is a good pear, of a greenish-yellow colour; the flesh tender, and high flavoured: it must remain on the tree till the approach of frost: it keeps till May.

The *Easter Bergamot*, Bergamotte de Pâques, or winter bergamot, is a large roundish fruit, of a greyish-green colour, with a little red; the flesh between breaking and melting. In this country, the tree must stand on a free stock, and have a good wall, and well prepared border. The fruit is fit for the table in February, and keeps till April.

The *Dry martin* (martin-sec), or winter russelet, is an oblong pear, russety on one side, inclining to red on the other; flesh breaking, juice sugary, with a little perfume; ready in November, and keeps about three months. The tree is generally placed on a free stock; but it succeeds either against a wall or rail, and bears pretty freely.

The *Louise-bonne* resembles the St Germain, and is pretty good when produced against a wall, and from a dry soil; in season in December. The tree generally bears well.

The *Marquise*, or marchioness's pear, is a long pyramidal fruit, of a greenish-yellow colour, with a little brown; the flesh is melting, and the juice rich and sweet. In season in November and December. In this country the tree requires a good wall and favourable aspect.

The *Ambrette* is an oval middle-sized fruit, melting and sugary; when produced from a dry soil and against a south wall, the fruit acquires a flavour resembling the scent of the sweet-sultan or *ambrette* of the French.

The *Poire d'Auch* is described by Forsyth as resembling the colmart, but fuller towards the stalk, and "without exception the best of all the winter pears."

The *Swan-egg* is a very good late pear, for use in November and December. It is egg-shaped, of a green colour, thinly spotted with brown; flesh melting, and abounding with a pleasant juice. On standards or espaliers the fruit acquires a higher flavour than on wall-trees; indeed it is only trained against a wall in high and bleak situations.

116. With the exception of five, all the pears which have now been enumerated and described are of French origin. Of these five, two are considered as of English origin, the Gansel's bergamot and the Swann-egg; and three of Scottish origin, the Muirfowl-egg, Green Yair, and Auchan. Some other Scottish pears, which occur chiefly in country gardens, but are of good quality, may just be named. Such are *Pear-James*, the *Early Carnock*, *Late Carnock* or *Drummond*, *Golden Knap*, *Crawford* or *Lammas*, the *Grey Goodwife*, and the *John Monteith*.

Among English pears little known or attended to, may be mentioned the *Elton pear*, figured in the London Horticultural Transactions, vol. ii. It ripens on standards, for which it is best suited, from the middle to the end of September; but it must be gathered ten days before being ripe, else it is apt to get mealy. When in perfection, it is described as uniting much of the fine flavour of the bergamots with the melting softness of the beurrés. The fruit is without seeds, and indeed almost without internal cavity. The original tree stands on its own roots in an orchard of seedling pears at Elton in Herefordshire. It is about a hundred and fifty years old, but still healthy.

The *Aston-town pear* is regarded as a native of Cheshire, and said to have received its name from Aston-town in that county. The branches of the tree have a peculiar tendency to twist round in growing upwards. The young shoots are pendent, and the blossoms are produced chiefly at the extremities. The leaves are small and oval. The fruit somewhat resembles the swan-egg pear; is of a greenish colour, spotted with russet; when ripe, the flesh is melting, and high flavoured. It is in perfection early in October, but does not keep. The fruit seems to be improved when the tree is trained to a wall; but in order to have fruit in this way, the shoots should be trained downwards according to their natural inclination.

117. Of new pears of any kind, our list is very scanty. The *Wormsley bergamot* has of late years been raised by Mr Knight, from the blossom of the autumn bergamot, stripped of its stamina, and dusted with the pollen of the St Germain. It is a good melting pear, and the tree grows freely in any common soil where other pear-trees thrive; the blossom appears to possess the advantage of being very hardy; the fruit remains on the tree till the end of October, and is in perfection about three weeks afterwards. At this time, we have scarcely any winter keeping pears sufficiently hardy to grow on standards. Mr. Knight, however, confidently predicts, that winter pears will, in the course of another generation, be obtained in the utmost abundance from standard trees; that is, that new varieties, combining perhaps the hardiness of the swan-egg with the valuable qualities of the colmart or chaumontel, will be produced.

118. All the kinds of summer pears ripen, in ordinary seasons, on the different sorts of standards, or on espaliers; the autumn pears, on dwarf standards or espaliers. Espaliers, however, are in both cases preferable to dwarf standards, as the tree may in the former way stand on a free stock, and yet have ample space allowed it. The finer French winter pears in general require a wall, with an east, south-east, or south-west aspect; and in the northern parts of the island a full south aspect. Several of the kinds, however, answer on espalier-rails; and as the fruit ripens more slowly and equably when hanging in the open air, than when assisted by the shelter and reflected heat of a wall, it is found to keep longer. While the espalier-trees are in blossom, and till the fruit be fully set, they require some protection; such as screens of reed or straw, or woollen nets.

A pear-tree, especially on a free-stock, cannot do with less than forty feet of wall. In many varieties the fruit-buds are produced chiefly at the extremities of the new shoots: if the dimensions of the tree must be much circumscribed, therefore, it will often happen, in the ordinary way of training and pruning, that the fruit-buds will be cut away. One well-trained horizontal tree is, on this account, better than two or three upright or fan trees; and there is little danger of keeping the wall covered, however high it be. Miller mentions a summer bonchretien, which extended fifty feet in width, and filled a wall thirty-six feet high, and was at the same time extremely fruitful. The object of the French gardeners, such as Quintinye, was to keep their pear trees within narrow bounds: hence their prolix and confused descriptions of the mode of training and pruning, forming a perfect contrast with the concise and perspicuous directions of Hitt and Miller.

119. For wall pear-trees horizontal training is now very generally preferred to the fan mode; chiefly because, in this latter way, the nearly upright position of the branches encourages the throwing out of numerous strong shoots, in producing which the sap of the tree is exhausted; these shoots are destined to be cut out in the winter pruning, and the middle part of the tree comes in this way to be barren. In the horizontal mode, provision is made for having fruit-bearing wood near the stem, as well as at the extremities of the branches; and it is estimated that, on an average, wall pear trees so trained afford a third more of good fruit than such as are trained in the fan way, or suffered to ramble on the wall as chance may direct. It is a general rule, therefore, that the branches of pear-trees are not to be shortened, unless where wood is wanted to fill up a vacancy; the only effect of shortening being, that in place of small fruitful spurs, rambling and unfruitful shoots are produced. During the summer, foreright and superfluous shoots are displaced with the finger. In this way, no wood buds are left to form shoots next season; and if disbudding be carefully performed, there will be little to do at the winter pruning. It is a rule, that the fruit spurs, especially of the finer French pears, should at all times be kept as close as possible to the wall.

120. But the mode of managing wall pear-trees recommended by Mr Knight (in the London Horticultural Transactions, vol. ii) deserves here particular notice. It will be best understood by describing nearly in his own words, his mode of reclaiming an old St Germain pear-tree which had been trained in the fan form. The central branches, as usually happens in old trees thus trained, had long reached the top of the wall, and had become wholly unproductive. The other branches afforded very little fruit, and that little never acquired maturity. It was necessary therefore to change the variety, as well as to render the tree productive. To attain these purposes, every branch which did not want at least twenty degrees of being perpendicular, was taken out at its base; and the spurs upon every other branch intended to be retained, were taken off closely with the saw and chisel. Into these branches, at their subdivisions, grafts were inserted at different distances from the roots, and some so near the extremities of the branches, that the tree extended as widely in the autumn after it was grafted, as it did in the preceding year. The grafts were also so disposed, that every part of the space which the tree previously covered, was equally well supplied with young wood. As soon, in the succeeding summer, as the young shoots had attained sufficient length, they were trained *almost perpendicularly downwards, between the larger branches and the wall*, to which they were nailed. The most perpendicular remaining branch, upon each side, was grafted about four feet below the top of the wall; and the shoots thus procured were trained inwards, and bent down to occupy the space from which the old central branches had been removed; and therefore very little vacant space any where remained at the end of the first autumn. In the second year, and subsequently, the tree yielded abundant crops, the fruit being equally dispersed over every part. Grafts of no fewer than eight different kinds of pears had been inserted, and all afforded fruit, and nearly in equal plenty.

By this mode of training, Mr Knight remarks, the bearing branches being small and short, may be changed every three or four years, till the tree be a century old, without the loss of a single crop, and the central part, which is almost necessarily unproductive in the fan mode of training, and is apt to become so in the horizontal, is rendered in this way the most fruitful. Where it is not meant to change the kind of fruit, nothing more, of course, is necessary, than to take off entirely the spurs and supernumerary large branches, leaving all blossom buds which occur near the extremities of the remaining branches. In some varieties, particularly the crassane and colmart, the dependent bearing wood must be longer than in others.

The training the bearing shoots downwards, has also been found to throw young trees much sooner into a productive state. Fruit is in this way generally obtained the second year: even the colmart tree, which seldom produces sooner than six or seven years from the time of grafting, yields fruit by this mode in the third season. Mr Knight recommends giving to young trees nearly the form above described in the case of the old St Germain, only not permitting the existence of so great a number of large lateral branches. In both cases, the bearing wood should depend wholly beneath the large branches which feed it; for, in Mr Knight's opinion, it is the influence of gravitation upon the sap which occasions an early and plentiful produce of fruit.

121. To destroy old pear-trees, if they be tolerably healthy, is in any case very injudicious, because, by proper management, they may again be brought into a bearing state. If the soil be bad, it may be mended: if the tree be full of worn-out spurs, new horizontal branches, or new dependent shoots, as above exemplified, may be procured: if the sort of fruit be bad, grafts of more approved kinds may, as we have seen, be introduced. Mr James Smith, gardener to the Earl of Hopetoun, at Hopetoun House, has written a very sensible paper (published in the first volume of the Scottish Horticultural Memoirs) on the cultivation of French pears in Scotland. It contains some judicious remarks on the means of bringing into a bearing state such full grown trees as are nearly barren of fruit, although in a luxuriant state of growth. In the same volume there is a communication from Mr Thomas Thomson, an experienced gardener, on this subject. In order to check unprofitable luxuriance, he particularly recommends cutting some of the roots of the tree, at the distance of about four feet from the stem, especially such roots as incline downwards. He mentions his having brought a crassane tree into a bearing state by cutting it two-thirds through with a hand-saw, below the level of the earth, and above the forkings of the root. From being very luxuriant but barren, it was thus rendered less luxuriant but fruitful, yielding next season, "at one gathering, forty-seven dozen of handsome fruit." If horizontally trained trees have become full of old spurs and breastwood, the most effectual remedy (as described by another judicious Scottish gardener, Mr Alexander Stewart at Valleyfield, in *Hort. Mem.* i. 459) is found in cutting out every second branch on each side, within a few inches of the stem. New shoots are trained along, in place of the former branches; but in the mean time a number of side-shoots from the remaining branches are laid in; these, Mr Stewart remarks, form fine fruit spurs, equal to the young wood from the stem of the tree; and they also tend to lessen the production of breastwood: they are however removed, as the regular new horizontal branches advance. In making use of these side

shoots, it may be remarked, Mr Stewart had very nearly hit on the mode of management now adopted and recommended by Mr Knight.

In managing prepared borders, planted with the finer sorts of pear trees, it is important, that, during the summer, particularly if the soil be strong or inclined to clayey, they be occasionally forked over, or that the light crop supposed to be on this border be frequently hoed. If the season prove dry, and at the same time the soil be light, water is given to the trees. A hollow is formed around the stem, and two or three pailfuls of water poured into it once a-week, or oftener; some *mulch* being at the same time formed to prevent rapid evaporation. In this way the fruit, while in progress, is kept constantly and uniformly in a growing or advancing state. When ripening approaches, the water is withheld, lest the flavour should suffer.

### *Quince.*

122. The *Quince tree* is the *Pyrus Cydonia* of Linné, the *coignassier* of the French. This not being very much cultivated in Britain, it may be mentioned, that the tree is of low growth, much branched, and generally distorted; and that there are different varieties of the fruit,—globular, or apple-quince; oblong, or Portugal quince; and pear-shaped, or pear quince. The quince is a native of some parts of Germany. It was known in England in the time of Gerarde, and probably long before. The fruit has a peculiar, rather disagreeable smell, and an austere taste when raw; but when prepared, it is by many held in esteem. A small portion of it added to stewed or baked apples, is useful for giving quickness and flavour. Quince marmalade is commonly sold in the confectioners' shops. The Portugal quince is the best, but the fruit is produced sparingly. Like the others, it is of a yellow colour; but the pulp has the property of assuming a fine purple tint in the course of being prepared. The quince tree is propagated by layers, by suckers, or by cuttings. It thrives best in a moist soil, but the fruit is superior in a dry one. In this country, the fruit scarcely ripens unless the tree be trained to a wall; and, even then, it is not ready till November.

### *Grape Vine.*

123. The *vine*, or grape tree, (*Vitis vinifera*, L. *Pentandria Monogynia; Vites*, Juss.) it is perhaps superfluous to mention, has a twisted irregular stem, with very long flexible branches, supporting themselves by means of tendrils; the leaves large, lobed, alternate, on long footstalks; the flowers in a raceme, of a herbaceous colour, insignificant in appearance, but fragrant. The berry, or grape, is generally globular; in some varieties, oval; of various colours, green, yellowish, or amber, reddish brown, and black.

124. It has generally been said, that the vine was introduced into this country by the Romans; but from Tacitus we learn, that it was unknown in Britain when Julius Agricola had the command. It was probably first cultivated here in the time of the late Emperors, perhaps about the close of the 3d century.

At the date of the Conquest there seem to have been vineyards in the south and south-west of England. From that period downward to the Reformation, vineyards appear to have been attached to all the principal religious foundations in England; and it is somewhat curious, that from the time of the Reformation to the present day they have in a great measure disappeared. A few, however, have occasionally been formed. From the *Museum Rusticum* we learn, that one was established at Arundel Castle in Sussex about the middle of the last century; and that in 1763, there were in the Duke of Norfolk's cellars sixty pipes of English burgundy, its produce. Professor Martyn of Cambridge has, with his usual industry, drawn together the evidence concerning the culture of the grape vine in Britain in former times, and the practicability of resuming it; and he concludes, that in former times there were many real vineyards in England,—not merely orchards and plantations of currants, as the Hon. Daines Barrington and others have suspected; and gives it as his opinion, that vineyards might still be successful in the southern and western parts of England, in proper soils and situations, if conducted by persons skilled in their management. The earliest and hardiest grapes, or those best suited to the climate, are not, however, well calculated for the making of wine. The miller and small black cluster may do; but they are inferior to the large black cluster, which has an austere taste. Mr Vispré, in 1786, published a dissertation on the growth of vines in England. He proposed to train the shoots, like the runners of melons and cucumbers, near the ground; and he actually found, that the berries thus produced were larger than those of the same kinds trained against a south wall. In the north of France, it is well known, the vines are trained very low, not rising more than four or five feet from the ground.

125. Parkinson, in 1629, describes twenty-three kinds of grape vines, several of which are still cultivated, and in high esteem, such as the Muscadines, and the Frontignacs. The following are the principal kinds which are at this time cultivated in Britain; those which succeed in the open air being distinguished by an asterisk.

*White Grapes.*

| | |
|---|---|
| * White Muscadine, | White Muscat of Alexandria, |
| * White Sweetwater, | White Constantia, |
| * White Frontignac, | White Hamburgh, |
| * Malmsey Muscadine, | Tokay, |
| * Royal Muscadine, | Greek Grape. |

*Red Grapes.*

| | |
|---|---|
| * Brick Grape, | Red Hamburgh. |
| Red Frontignac, | |

*Black Grapes.*

| | |
|---|---|
| * Miller Grape, | Black Frontignac, |
| * Early July, | * Black Hamburgh, |
| * Black Sweetwater, | Alicant, |
| * Small Black Cluster, | * St Peter's, |
| Large Black Cluster, | Claret, |
| Black Muscadine, | * Black Prince. |

The *White Muscadine* is very generally cultivated against open walls in the southern parts of England; and, being an early grape, it ripens well. The berries are roundish, thin skinned, and of an amber colour when ripe; at which time their juice becomes sweet, and of delicate flavour. The bunches are small, but many are produced. Forsyth says, that it is the best vine we have for a common wall, and a great bearer; and Speechly remarks, that it is often cut and eaten before it be fully ripe, but that when well matured, it is an exceedingly fine grape.

The *White Sweetwater* is likewise an excellent early grape, much cultivated in the open air. The berries are round, not of equal size, some being as large as cherries, while others remain nearly as small as mustard seeds; they are thin skinned, and full of juice, which is sugary, but not vinous. When nearly ripe, they become of an amber colour; when clouded with russet, they are in perfection. Nicol remarks, that this grape, like the former, is often cut before it be fully ripe, and that this has occasioned it to be less in repute than it deserves. The shoots are thick and strong, but not long; the leaves very large.

The *White Frontignac* vine is a copious bearer. The berries are round, and of a good size, closely clustered on a long bunch, somewhat *shouldered*. When ripe they are excellent, and remarkable for uniting the qualities of being fleshy, and having a sweet juice and perfumed flavour,—not so powerful, however, as that of the black and red varieties, the last of which has a very strong musky flavour. The ripe berries have a fine white bloom or farina on them, from whence the name is given. It has a place in the vinery, and is also trained against open walls.

The *Malmsey Muscadine* grape has a sweet juice, and high flavour, and the vine is a good bearer. It is commonly planted in the vinery, but succeeds also against the open wall.

The *Royal Muscadine*, or White Chasselas, the d'Arboyse of Speechly and Forsyth, is an excellent grape for the vinery or the hot-house; the bunches large and shouldered; berries round and amber-coloured when ripe; the juice rich and vinous. The vine generally grows remarkably gross and strong, both in wood and foliage.

The *White Muscat of Alexandria*, or Alexandrian frontignac, has large oval berries, which hang loose in the bunches, these being long, and not shouldered; when ripe the berries are amber-coloured; and the juice is then rich and racy; the skins are thick, and the pulp hard, but of a highly musky flavour. It is fit only for the grape-house or pine-stove.

The *White Constantia* berries are tolerably large, rather of an oval shape, of a sweet taste, with only a slight flavour. The bunch is of considerable size, and well formed. This is the kind which has acquired fame at the Cape of Good Hope. It is said to degenerate when transplanted. At Constantia farm it grows in a light sandy loam; the situation is low, but more elevated than other parts of the district. There is likewise a *red* Constantia; and a *black* Constantia appears in some catalogues: but this last has proved to be the same as the black frontignac.*

The *White Hamburgh*, or Portugal grape, grows in large long bunches; the berries are oval, pale white, with a thick skin, and firm pulpy flesh. The vine is a plentiful bearer, and grows very strong both in wood and leaves. It much resembles the Syrian.

The *Tokay*, when well managed, produces both large bunches and large berries, and becomes one of the finest grapes in the vinery. The berries are white, oval-shaped, skin thin, pulp delicate, and of agreeable flavour. The leaves on the under side are covered with a fine soft down like satin. It should be placed in the warmest end of the vinery, and is well suited for the pine-stove.

The *Greek grape* is a high-flavoured and delicate fruit. The berries are of moderate size, somewhat oval, bluish-white; growing close, in middling sized bunches. The leaves of the tree resemble those of the sweetwater, but stand on shorter footstalks; it is a plentiful bearer either in the vinery or hot-house.

The *Brick grape* gets its name from the berries being of a pale red or brick colour; they are thin skinned, with a sweet juice. The bunches are small, but two or three often proceed from the same shoot, so that the vine is, upon the whole, a plentiful bearer. It succeeds on walls and treillages, and is hardly deserving of a place in the vinery.

The *Red Frontignac* is an excellent musky flavoured grape, when fully ripe, of a brownish red colour. The juice of this, says Miller, has the most vinous flavour of all the sorts, and is greatly esteemed in France. It is well calculated for the vinery.

What is called the *Grizzly Frontignac* seems to be only the red in an unripe state, at which time the berries are greyish-coloured, with a few dark stripes.

The *Red Hamburgh*, or Gibraltar grape, grows in large bunches; the berries somewhat oval shaped, of considerable size, thin skinned, red when ripe, juicy, with a rich vinous flavour. It is suited only for the vinery and hot-house.

Of the Black Grapes, one of the most hardy kinds is called the *Miller*, or Dusty Miller, from a white powdery appearance on the surface of its leaves: It is nearly allied to the black cluster grape. It is much cultivated in gardens, and against the front and gable walls of houses in the south-west of England: the fruit ripens freely, and is very good, the skin and pulp being delicate, and the juice sweet and pleasant; the berries are oval, of a middling size, and closely placed to each other in the bunches.

The *Early July* has small black round berries, with large stones; they grow loose on the bunches, which are small but numerous; juice sugary, with but little flavour. It ripens early in September, without fire heat. There is also a White July grape, which is little cultivated.

The *Black Sweetwater* is a small roundish grape, growing close in the bunches; the skin is thin, and the juice very sweet. It ripens early, and is calculated either for the vinery or the wall.

The *Small Black Cluster* resembles the Miller grape, but the leaves are not quite so hoary, and are rather smaller. The fruit is sweet, and of delicate taste. This is extremely common on walls of houses near London.

In the *Large Black Cluster*, the berries are oval, and grow close in the bunch, which, notwithstanding the name, is not large. The juice has a harsh taste, and makes the palate feel rough, as in tasting Port wine; Mr Speechly indeed considers it as the sort used in the manufacture of that celebrated wine.

In the *Black Muscadine*, the bunches and berries are smaller than in the white; it is a very productive kind, and makes a fine appearance, the black berries having a bluish bloom. Fit for the vinery or the hot-house.

The bunches of the *Black Frontignac* are long, and the berries, which are round and of moderate size, are thinly or loosely hung on them. They are of good quality, the juice being vinous, and of exquisite flavour.

The *Black Hamburgh* is well known and generally liked. The berries are somewhat of an oval shape, the skin thick, and the pulp hard; but it is a well flavoured fruit, and the tree bears plentifully. The bunches are large, and handsomely shouldered. It answers very well in the vinery; but, in the open air, it comes to maturity only in very warm situations and in favourable seasons.

The *Alicant*, or Black Spanish grape, forms very long shouldered bunches, the berries being also large and of an oval shape; at first they are red or flame-coloured; but when ripe, they become of a dark brown or black colour; the skin is thick, and the stones large; the pulp soft and juicy, and of agreeable flavour. It is often called the Lombardy grape, and sometimes the Rhenish. It is excellent for the hot-house or the vinery. In autumn the leaves are finely variegated with red, green, and yellow.

* A small quantity of wine was sent some years ago from Portugal to a mercantile house in Leith as a present, which was made from the Constantia grape grown in Portugal. It was a white wine, extremely sweet, but the flavour not particularly good,—altogether quite different from the Cape Constantia wine.

*St Peter's grape* has the berry large, roundish, black; skin thin; the bunches large, handsomely formed, and making a fine appearance at table; the pulp delicate and juicy. The vine is a good bearer, but the grapes are late of ripening. They are apt to crack in the forcing house, or in the vinery. In fine seasons, this kind ripens on a south wall.

The *Claret grape* is distinguished by its harsh sourish taste, and dark claret colour; when the grapes are perfectly ripened in a hot-house, however, the taste is pleasant. The berries are small, and grow close, on small bunches. The leaves are large, and acquire a russet red or claret colour; on which account they have been recommended for making *vine-leaf* wine.

The *Black Prince* is an excellent grape, well deserving a place in the hot-house or the vinery, where it produces both large berries and large bunches. Even on the open wall, in the south of England, it succeeds in favourable seasons: Forsyth mentions, that in this way he has had bunches which weighed a pound and a half, and which ripened in October.

Besides the list already given, two or three others deserve notice.

The *Verdelho*, or Verdellio grape of Madeira, is the kind from which the celebrated Madeira wine is understood to be principally made. The vine grows with great vigour in our grape houses, and is remarkably productive of fruit, frequently yielding three bunches on a shoot. Here, however, the bunches are but small; the berries are also of diminutive size, of an oval shape, green colour, and with a thin skin. The fruit is very acid till it arrive at the last stage of maturity, when the berries become of a fine amber colour, and of a very rich saccharine taste, with considerable flavour. Mr Williams of Pitmaston, near Worcester, has given an account of this variety in the 2d volume of the London Horticultural Transactions; and he expresses his opinion, that in favourable situations in the south-west of England it would succeed on the open wall, especially where the soil is light, dry, and shallow, but that in a deep highly manured soil, it would run too much to wood and foliage. The leaf is dark green, and very thick; and would resist the autumnal frosts, and protect the fruit till a late period in October. The verdelho is much cultivated in the province of Languedoc in France; it is described by Delaunay under the name of *Verdal*, and is highly esteemed at Paris, its berries being accounted the most sugary and delicate in flavour of all the dessert sorts. In France the bunches become tolerably large, and very beautiful; and the berries also acquire considerable size.

The *Raisin de Carmes*, or, as it is sometimes called, *Raisin de Cabo*, is a grape of fine qualities. The fruit is produced in rather loose long bunches; the berries large and of an oval form. The skin is thickish, of a dusky purple colour, covered with a fine bloom; the pulp is firm and extremely rich, though containing a considerable portion of acid. The filaments and anthers frequently remain when the fruit is ripe. The vine needs a high temperature; in the stove it grows freely and bears well, but it requires particular attention at the time of flowering. The wood is rather slender, of a yellowish-brown colour; the leaves small, and pale green. It is figured by Hooker, in the *Pomona Londinensis*, t. 10.

The *Raisin grape* is of a brown or blackish colour; large, oval, fleshy and firm, but with a pleasant juice; forming handsome long bunches. It also is only suited to the hot-house.

The *Syrian grape*, is among the coarsest of the grape kind; but the vine is a good bearer under glass, and produces bunches of extraordinary size. The berries are large, oval, white, with a thick skin and firm pulp; they continue in good condition till January. In this country, Mr Speechly once produced a bunch which weighed 19½lb. and he describes another which was four feet and a half in circumference, and near two feet in length. This last bunch was sent to the distance of twenty miles as a present. Four men were employed, two by turns, carrying the bunch suspended on a pole or staff resting on their shoulders. No doubt one man *could* have carried the bunch, if the weight alone be considered; but it was a great object to transmit it without bruise or injury. This may tend to illustrate a passage in the Sacred Writings (Book of Numbers, ch. xiii.), where the description of this mode of carrying a bunch of grapes has sometimes very unnecessarily excited a sneer.

127. In warmer countries than this, vines that are suffered to grow without pruning attain a large size, their stems assuming the appearance of trunks of trees. Vines that are regularly pruned or dressed cannot be expected ever to arrive at such magnitude. Even in the ungenial climate of Britain, however, they sometimes have a surprising size and expansion. The Northallerton vine, about the year 1785, covered a space of 137 square yards, and the circumference of the trunk near the ground was almost four feet; it was then considerably more than a hundred years old. Lysons, in his Account of the Environs of London, describes a Black Hamburgh vine at Valentines in Essex, the branches of which extended 200 feet, the stem being 1 foot 13 inches in circumference. It sometimes yielded 4 cwt. of grapes in a season. Another Black Hamburgh vine, still more famous for the quantity of its produce, has already been mentioned § 26, as existing in a grape-house at Hampton Court Palace. This season (1816) it yielded about a ton of grapes.

128. New varieties of grapes are of course only to be procured by sowing the seeds. When this is intended, the grapes should be left on the vine till almost in a state of decay, taking care, however, if they be exposed to the open air, to cover them from the attacks of birds. The stones, in this very mature state, become of a dark brown colour; they are to be separated from the pulp, and laid in a dry airy place till spring. Mr Speechly, in his work first published in 1786, recommends the bringing together of flowering branches of two different kinds of grape, calculated to modify or improve each other: the frontignac and other high-flavoured grapes, he observes, may add flavour to other kinds; the white sweetwater may be coupled with the red frontignac, with the Black Hamburgh, or with the white muscat of Alexandria. He boldly augurs, that the best sorts of grapes hitherto known, will at some future day be esteemed only as secondary or inferior. The distinguished Mr Knight supports these views, and indeed has done much towards their accomplishment.

Under the name of *Variegated Chasselas*, Mr Knight has described a new variety which sprung from a flower of the white Chasselas, dusted with the pollen of the Aleppo grape, which last, he remarks, readily variegates the leaves and fruit of the offspring of any white grape. The berries are striped and very beautiful; with a thin skin, and juicy. The leaves become variegated with red and yellow in autumn. It has been found to be a very hardy and productive variety, bearing well in the open air. When gathered in October, and hung up in bunches in rather a damp room, it keeps till February or later.

This active horticulturist has described (*Trans. Hort. Soc. Lond.* vol. i.) still another variety of variegated grape, in which the bunches on the same plant are of different colours. This too he considers as fit for the open air, at least in the south of England: it is very productive, though both the bunches and berries are small. It contains much saccharine matter, more perhaps than any grape, except the *verdelho* of Madeira. Mr Knight therefore considers it as better calculated for the press, in a cool climate, than any we now possess, and observes, that if it were trained to low walls in the warmer parts of England, it would afford a wine of considerable strength.

Several others besides Mr Knight are now engaged in the raising of seedling vines; and in all probability some excellent and hardy kinds will soon be produced; so that another generation may once more see vineyards common in this country. The raising of new vines is by no means a very tedious process. The fruit of the seedling may in general be tasted in the fourth year; while a florist waits patiently for five or six years before his seedling tulips shew flower, and perhaps nurses his breeders as many years more before they *break* to his mind.

129. Vines are often propagated by layers, which, when rightly managed, form good enough plants. Strong healthy shoots from different sides of the stool are bent down, generally in February, and gently twisted or notched: this twisted part is introduced into a flower-pot, filled with fresh mould, and which is sunk an inch or two beneath the surface. In the course of the summer, plenty of roots are sent out at the doubling, and in autumn the offset is separated from the parent plant. In the nurseries near London this mode is much practised; and both parent plant and layers may often be seen bearing fruit, so that the kind can be positively ascertained. Abercrombie describes the mode of forming layers in the open ground; but the advantage of having the plants in flower-pots is evident, as a ball of earth can thus be preserved to the roots. Indeed, the roots of the vine are so liable to be injured in transplanting, that flower-pots should always be employed.

Vines are likewise extensively propagated by cuttings. These are taken off at the usual time of pruning in autumn or winter, and are kept till the following spring, merely by sinking them nearly to the top in dry earth. It was formerly considered of great advantage to have an inch or two of old wood to each cutting; the cutting was from a foot to fifteen inches long, and a single cutting only could in this way be made from a shoot. The Rev. Mr Michell, a philosophical as well as practical horticulturist, first introduced the use of short cuttings, about three inches and a half long, and all consisting of the new wood, if properly ripened, and having only one bud or eye. Plants raised in this way he found to be furnished with more abundant roots, to come sooner into bearing, generally in the second year, and to prove more fruitful, than long cuttings, with several eyes, and a portion of the old wood attached. These cuttings are often planted in a nursery bed in the spring; but they are much forwarded by placing them in pots, into the bark-bed of a stove. Mr. Michell usually planted his cuttings in the naked bark, four or five inches asunder; being short and throwing out tufty roots, they are easily potted when thought necessary. Shoots of strong growth, it may be remarked, are not good for cuttings, having too much pith. Many gardeners are of opinion, that plants thus procured from cuttings become better rooted, and grow more freely, than those from layers.

There is still another and a very speedy mode of propagating the vine, especially the more tender varieties, which will be described when we come to speak of the Vinery.

130. In forming a border for vines, a matter of primary consideration is, that the roots shall not be able to penetrate to a wet subsoil: to guard against this, it is common to take out the earth, and lay lime rubbish, which is firmly beat down, in the bottom. Any fresh and light, but rich soil, to the depth of a foot and a half, or two feet at most, answers perfectly well.

In France and Italy the most experienced vignerons are very scrupulous about permitting any gross or strong manures, such as dungs, to approach the roots of their fine vines, for fear of altering or deteriorating the flavour of the grapes. Rotted turf or clippings of box trodden under foot in the highway, are the manures there preferred. They who apply dungs, are considered as more anxious about quantity than quality. In this country, however, we must partly compensate for the want of a bright sky and hot sun, by giving vigour to the plants by means of manures, even if we should make some sacrifice of flavour. Marshall repeatedly urges the necessity of this, and recommends the digging in of some sheep's droppings, or the cleanings of a poultry-house, every year. Nicol too is a strenuous advocate for applying the essence of dungs, by watering vine-borders with dunghill drainings, which he declares to be the "nectar of vegetable life."

131. In planting vines, it is customary to cut clean at the end the strong root from which the fibres proceed. A hole or trench is then made in the border, corresponding to the length of the main root; this trench is formed with a ridge in the middle; and on this ridge the woody part of the root is laid, the fibres sloping down on each side. If the main root be three inches under the surface of the border, it is deep enough.

132. Hitt long ago recommended the training of the principal stem of the vine in a serpentine form; leading from it parallel horizontal shoots, at the distance of eighteen inches from each other: from these, bearing branches are produced, which are nailed in, in an upright position, by which means, in his opinion, they are less apt to put forth collateral shoots, which rob the fruit. Forsyth has since shewn the advantage to be derived from training the bearing shoots also in the serpentine manner. This, it must be confessed, renders the laying in of the summer wood more troublesome; but, with a little practice, and due attention, all confusion or difficulty of that kind might be surmounted. It is evident that a good deal more bearing wood can thus be laid close to a wall, paling, or trellis, than by the ordinary method. Nicol approves either of the horizontal or the zigzag manner being adopted on low walls or trellises; but for the grape-house he prefers training directly up the roof. It is well known that in vineyards in the wine countries, the standard vines are seldom allowed to rise higher than three or four feet. It is found, that against our walls vines grow much stronger and afford larger grapes when not allowed to exceed four feet in height. They thus enjoy the reflected heat from the earth as well as from the wall. Vines are therefore frequently placed in the low intermediate spaces between peach and nectarine trees.

133. The watering of vines in the open border, in very dry weather, is sometimes necessary; but not oftener, perhaps, than once a week. After the fruit is set, the garden-engine is occasionally used, and water sprinkled over the whole plant, this being found to promote the swelling of the berries.

134. During summer the vine may be said to be constantly in a state of pruning. This consists in the regulation of all the new shoots, selecting the bearers for next year, and displacing all lateral, straggling, and superfluous shoots. In July, when the fruit is formed, the bearing shoot itself is shortened, in order to give vigour to the bunches. The vine is seldom, by judicious gar-

deners, divested of any of its leaves, which seem in this plant almost indispensable to the health and swelling of the fruit.

135. The removal of a small ring of the outer and inner bark from the stem or principal branches, has been found to hasten the production and maturity, and increase the size and flavour of grapes; and this practice is now followed to some extent in the south-west of England. The width of the ring of bark taken out may be from an eighth to a quarter of an inch; the former being sufficient if the plant be weak, the latter proper if it be luxuriant. Care must be taken not to injure the alburnum. The proper time for performing the operation is when flowering is nearly over, and when the berries begin to be formed. In the course of little more than a fortnight, granulations of new bark make their appearance on the upper side of the incision; these gradually increase, till nature has restored the covering of bark. The ring of newly deposited bark is rough, and becomes protuberant; so that a gibbosity remains at the place. The vine-shoot swells, and becomes much larger *above* than below the incision. On vines thus treated, the berries are said to be earlier, to swell much faster, and to become larger and better flavoured, than on neighbouring vines left uncut. In England, the vine usually flowers in the open air towards the end of June or beginning of July. If the circle of bark be removed at either of these periods, the part will be covered with new bark before the ensuing winter, and no injury will be sustained by the vine. In forcing houses, the circle should not be removed till after the vine has flowered, the precise time depending on its state of forwardness. In very old vines it is not recommended that the incision be made on the main trunk, but on the middle-sized branches; and it may either be made on all the principal branches, or only on every other branch.

136. In connection with this practice may be mentioned another, not altogether new, but which has of late been brought into particular notice, in a pamphlet published in 1815 by the Right Hon. Sir John Sinclair, Bart. This consists in entirely removing the parenchymatous outer bark from the stem and principal branches, but carefully preserving the inner concentric bark. The operation is performed in November, or the beginning of December. At that season it is easily done with the common garden knife, and there is then little danger of injuring the liber. The removing of old and rugged bark from vines has long been practised, with the view of preventing the lodging of insects, particularly the red spider; but besides being insured of exemption from these, the decorticated vines are said to make stronger shoots, and the quantity, quality, and flavour of the grapes to be thereby improved. This plan has been followed for several years by Mr King, a fruit-gardener at Teddington, in Middlesex; and as his profit must depend on the quantity of grapes he raises, and the price upon their quality, it is evident that if the practice did not prove useful, it would not be continued by him.

137. Vines seldom produce bearing shoots from wood that is more than one year old, unless the old wood be healthy and well cut back. The great object therefore is, to have abundance of wood of this age in every part of the wall or trellis. The bearing shoots for the following year are commonly left with four eyes each; the undermost does not bear, and consequently only three are expected to be productive; but each of these yields two or three bunches of grapes, which grow from the new shoots of the current year, the fruit-buds being always opposite to the wood buds. Sometimes more eyes are left, and more fruit is naturally produced; but it is not only inferior in size but in flavour. The shoots are laid in about eighteen inches asunder on the wall, to give room to the side shoots. Miller, Forsyth, and Speechly, unite in recommending, for the time of winter pruning, the end of October, when the fruit is all gathered. Hitt proposes to delay it till the end of January, or beginning of February, affirming that vines cut in October make weaker shoots than those pruned after mid-winter. The shoots which were lately bearers are cut back to some good lateral shoot, and a few extended naked old branches are entirely removed, or cut back to some promising young shoots. In either case, the cut is made about an inch above the bud; and sloped backwards from it, so as to convey away the juice which may exude.

If the wounds made in the autumn or winter pruning have not fully healed over, vines are apt to bleed when vegetation commences. Various remedies have been proposed. Hitt recommends, that after wiping the part dry, it should be basted with soot or with unslaked lime. Nicol is for searing the bleeding point, and then smearing it over with hot wax. Mr Knight, from his own experience, recommends a composition of four parts scraped cheese and one part calcined oyster-shells, or lime, to be pressed strongly into the pores of the wood; the sap almost immediately ceases to flow; and if this composition be properly applied, even a large branch may be taken off at any season without detriment from bleeding.

On the open wall or trellis, grapes are very subject to the attacks of wasps. Some of the finest bunches may be saved by surrounding them with bags of crape or gauze. It may be mentioned, that bunches which have arrived at maturity only in the end of October, may be gathered by cutting off the shoots on which they grow: if these be suspended in a cool apartment, the fruit will keep for a month in a tolerably good state.

138. Early in the 18th century a kind of flued walls were first used for the forwarding, or rather for the thorough ripening of grapes, at Belvoir Castle in Rutlandshire, where Hitt, the author of the Treatise on Fruit-trees, was an apprentice: mats were at the same time thrown over the vines at night, to save them from the chilling dews and hoar-frosts that occur in April and May. Since that time flued walls, with moveable glass frames, have been much used; the same vines being brought into bearing every second or third year, and, in the intermediate time, prevented from exhausting themselves, by the removal of the flower-stalks as they appear. Glazed houses for the culture of grapes have also been formed, under the name of Vineries,—to be afterwards described. Speechly remarks, that good crops of grapes may be obtained from vines trained against walls not more than six feet high, by making use of melon-frame glasses, a temporary narrow roof being made to receive the glasses. A slight degree of fire heat, he adds, would be of great advantage; and in no situation, we may remark, would *can-flues*, such as are described in the first volume of Scottish Horticultural Memoirs, be more suitable, these being easily removed, and as easily restored when wanted again.

In a very few places in England, vines are planted in the vineyard form, in ranges, about twelve feet asunder, the shoots being trained in a horizontal direction, to a series of stakes, three or four feet high, placed along the ranges.

139. We must not omit to mention, that one sort of vine may be grafted on another, in the ordinary way: the operation, however, must be performed with great care and exactness. In this way, if a wall have been planted with kinds injudiciously selected, they may, by grafting,

be very speedily changed, preserving all the advantages of having strong well-rooted plants. In a small vinery or vine-frame, various kinds of grapes may thus be inserted on one stock. Speechly mentions a Syrian vine, which in this way produced sixteen different sorts of grapes. The principal advantage of grafting, however, is looked for in the modifying and improving of the various kinds; the weak and tender being grafted on such as are robust and vigorous; for example, the black frontignac, placed on the Syrian, is said to produce well-shaped large bunches, with berries nearly the size of those of the black Hamburgh. This Syrian vine is excellent for stocks; and by some horticulturists, seedling stocks of it, grafted with other kinds, are accounted preferable to cuttings or layers of those kinds themselves. Vine-grafts are gathered at the time of the winter pruning, from bearing branches; and they are kept sunk in light earth till the proper grafting season, which is about three weeks before the stock break into bud. Those in a hot-house must of course be grafted several weeks before those out of doors. The finer sorts are generally grafted by approach.

### *Fig.*

140. The *Fig-tree* is the *Ficus Carica* of Linné, Polygamia Diœcia; belonging to the *Urticæ* of Jussieu; it is the *Figuier* of the French. It is considered as a native of Asia, but it has been cultivated for time immemorial in the south of Europe. It was first introduced into this country in the 16th century. Two very large trees, still remaining in the Archbishop of Canterbury's garden at Lambeth, are reported to have been the first planted in England, and to have been brought hither by Cardinal Pole. They are at any rate of great age. They are of the white Marseilles kind, and still continue to produce fruit.

141. Miller introduced several new varieties of the fig from Venice: he enumerates 14 sorts as deserving of cultivation in this country; but of these little more than one-half are now in repute. Those most esteemed are the following:

| | |
|---|---|
| Brown Ischia. | Malta fig. |
| Black Ischia | Murrey fig. |
| Black Genoa. | Common blue. |
| White Genoa. | Brunswick. |
| Small early white. | Brown Italian. |
| | Black Italian. |

The *Brown Ischia* is a very large globular fruit, of a chestnut colour on the outside, and purple within; pulp sweet and of good flavour. It ripens by the middle of August, and the tree seldom fails to afford a crop.

The *Black Ischia*, also called Blue Ischia, is a very good sort. The fruit is short, of middling size, a little flatted at the crown; when fully ripe, the skin is dark purple or almost black, and the inside of a deep red: the pulp very high flavoured. The tree is a good bearer, and the fruit is ready early in September.

The *Black Genoa* is a long-shaped fruit; the skin of a dark purple, almost black, with a purplish bloom over it; the inside bright red; the pulp high flavoured. It ripens from the middle to the end of August, and the tree is a good bearer.

The *White Genoa* is a large, almost globular fruit, of good flavour; the skin thin, of a yellowish colour when ripe, and light red within. The tree is considered as rather a shy bearer.

The *Small Early White* has a sweet pulp, but without much flavour. It ripens early, and is therefore well suited to our climate: indeed it seldom fails to produce a crop.

The *Malta fig* is a small brown fruit; the pulp sweet, and well flavoured. When permitted to hang on the tree till it be shrivelled, it forms a fine sweetmeat.

The *Murrey fig*, or brownish-red Naples fig, is a large globular shaped fruit, of pretty good flavour; it is distinguished by the murrey-coloured skin. It ripens in September.

The *Common Blue* or purple fig, is of an oblong shape; the tree is a copious bearer; and the fruit ripens in the end of August.

The *Brunswick*, or Madonna, is a long pyramidal fig; the skin brown, the pulp with little flavour. Like the common blue, it is an early kind, and in this respect suited to Britain.

The *Brown Italian* is a small roundish fig, of high flavour; the skin becoming of a brown colour when the fruit is ripe; the inside red. The tree is a great bearer.

The *Black Italian* fig is likewise small and roundish; the pulp high flavoured, and of a dark red colour; the skin purple. The tree bears freely.

142. In this country, fig-trees require good walls, with south-east, south, or south-west aspects, and they occupy a good deal of space. It is proper, therefore, to select only such kinds as are likely to be productive, chiefly the four first enumerated. The trees likewise require careful management. Britain is certainly not the country for fig-trees; yet, with due attention, fresh figs matured on the open walls may grace the dessert from the middle of August to the end of October; and, by means of a fig-house, or even of dwarf fig-trees planted in front of a vinery, the season may be prolonged till December. It may here be remarked, that the fig, in a green or fresh state, being a scarce fruit in this country, is often cut into longitudinal slices at the dessert: a good deal of the flavour is thus lost. Abroad, the person who eats a fig holds it by the small end, and making a circular cut at the large end, peels down the thick skin of the fruit in flakes, the soft interior part forming only a single *bonne bouche*.

A friable loamy soil is best for fig-trees. French writers recommend light and poor soil, even sandy and gravelly; but in such situations in this country, the tree does not succeed; and in any very dry soil the fruit is apt to fall off. If, however, the soil be otherwise good, the recurrence of this last inconvenience may in general be prevented by watering and *mulching*. A free exposure to air and sun is indispensable to the perfection of the fruit.

143. In the public nurseries, fig-trees are often propagated by suckers, and sometimes by cuttings. The cuttings are taken off in autumn, sunk in the ground, and protected with old bark and haulm during winter. Neither cuttings nor suckers form nearly so good trees as those procured by layers, provided the layers be formed of bearing branches. Indeed a single plant thus procured, by *layering*, from a tree in a full bearing state, and from the bearing wood of such a tree, is worth many others.

In general, a young fig-tree is at first trained with three branches, nearly upright, this direction encouraging their rapid growth. If horizontal training be adopted, the two outer branches are afterward laid down horizontally, and from these, upright branches are suffered to rise, at the distance of a foot or sixteen inches from each other. From the central shoot, other shoots spring, and these are successively laid in horizontally, at the distance, perhaps, of two feet from each other. The mode of training, however, generally adopted in this country, and approved by the best gardeners, is the fan-shape; keeping the outer branches nearly horizontal, so as to allow ample space for laying in the central ones. In some instances they are trained in the Dutch mode, with only two low horizontals, and upright shoots from these. In a few places in England, fig-trees are trained to espalier-rails. Sometimes these trees are untied, and during the severity of winter, the branches are laid close to the ground in bundles, and well covered with straw or haulm, over which some earth is heaped. Another method of protecting them, employed both in England and France, is the erecting of two screens of reeds, one on each side of the rail.

144. The fruit proceeds immediately from the eyes of the shoots, without visible blossom; indeed, the parts of fructification are entirely within. In warm countries, two crops are produced yearly, one upon the former year's shoots, and another on the shoots of the same year. In this country, the first of these crops is the only one to be depended on; the second often makes its appearance, but the figs are little larger than peas, when arrested by the cold of approaching winter. Some gardeners direct that these young fruit be carefully swept from the branches at the winter's dressing; but a more cautious observer, Mr Smith at Hopetoun House, has found, that while he frees the trees of all half-ripened fruit, if he can save the very young fruit over winter, they afford, as might be expected, the earliest figs in the following season. While the fruit is ripening, such leaves as cover it should be braced to the wall with small cross-sticks, and not cut off, as is sometimes done.

145. In pruning fig-trees, the shoots of the former year must not be shortened, the fruit being produced at the upper part of these. When a branch becomes naked, or destitute of *laterals*, some advise the cutting it entirely out from the base; but if it be shortened, plenty of young shoots will in general be the result. Nicol remarks, that the most fruitful shoots are short-jointed, round, and not of length proportional to their thickness. The time usually chosen for pruning, is April, or early in May; but some gardeners still prefer the autumn, as recommended by Miller, when less sap issues from the wounded parts.

In preparing the trees for winter, the branches are closely nailed to the wall; and when frost approaches, coverings of bass-mat, straw-screens, or some such means of defence, are employed. Perhaps the best mode of protecting them is described by Mr Smith, in the second volume of Scottish Horticultural Memoirs. He recommends the use of spruce-fir branches, four or five feet long; these are fastened to the wall, each branch by two different points of attachment; and the tree is thus covered as equally as possible. The spruce-fir possesses this advantage, that the branches remain green over winter; and in March, when the days lengthen, the leaves begin to fall off, thus gradually admitting more and more air to the trees as the season advances. By adopting this method, Mr Smith has never failed to have good crops of figs. At Argenteuil, near Paris, the culture of fig-trees is one of the chief employments of the people. The custom there, is to protect the branches by laying them down in the earth, and keeping them covered with soil for the space of two months and a half during winter. The principal pruning is there performed in the spring, by rubbing off the superfluous wood-buds, which are pointed, and leaving the young fruit-buds or embryo figs, which are round. Careful gardeners in our own country likewise perform most of their pruning in this neat and easy way.

146. We must not here entirely pass over the subject of the *caprification* of figs. By this is meant, in eastern countries, the introducing, into the interior of the young fruit, a sort of fly or gnat, which seems to act beneficially, not only by probably carrying in pollen and dispersing it, but by puncturing the pulp, and occasioning a defluxion of nutritious juices. Impregnation is thus not only more certainly accomplished, but the ripening of the fruit is greatly promoted. Caprification is imitated in France, and also occasionally in England, by inserting straws dipped in olive-oil. It has often been remarked, that the pricking of plums or pears hastens their maturation, and renders the fruit of richer flavour. It has been proposed to hasten the maturation of figs, by cutting out circles of the bark of the tree, from near the base of the bearing branches, thus retarding or interrupting the descending circulation of the sap: as in the case of vines above mentioned, § 135, both the outer and inner bark must be removed, but great care taken not to injure the alburnum.

### *Mulberry.*

147. The *Mulberry-tree* (*Morus nigra* of Linnæus; class *Monœcia*, order *Tetrandria*; nat. fam. *Urticæ* of Jussieu) is a native of Persia; but has been cultivated in England since the end of the 16th century. It is generally trained as a standard or half-standard; in a few places it appears as an espalier; and in Scotland it is often placed against a wall. It flourishes most in a rich and deep mellow soil. In old gardens, frequently one or two large standard mulberry-trees, perhaps a century old, may be observed; and these, in the autumn, are covered with fine and large fruit. Where it can conveniently be done, grass should be sown below such old trees: notwithstanding care in gathering, the best of the fruit falls from the tree; and in this way it may be daily collected from the sward, without being injured. On this account, and because of the large size to which the tree ultimately attains, the mulberry is better suited to the lawn than the garden. The fruit ripens in September, and must be used soon after it is gathered, not keeping more than two days.

148. Young trees seldom prove fruitful; and Professor Martyn has stated the true reason, to wit, that monœcious trees, while young, bear male flowers or catkins principally, and of course produce little or no fruit. Mulberry-trees purchased from public nurseries, are not likely soon to prove fruitful, being generally layers from small stock plants, or stools, which have never fruited. The true way to procure fruitful plants, is to take cuttings, in the spring, from fruit branches of bearing trees, endeavouring to have a part of two years growth to each cutting. These may be about a foot and a half long, and planted about a foot deep, in a sheltered place: if covered with glasses, and regularly watered, they strike the more certainly. Mr Knight has observed, that by grafting a young mulberry with a cion from a bearing branch of a full grown tree, a plant is procured which will bear fruit in the course of three years. As mulberry grafts do not *take* readily in the common mode, approach-grafting (§ 70.) is to be preferred.

The fruit being produced chiefly on the young wood, no pruning is applicable to standard mulberry-trees, farther than removing cross branches which rub on each other. Wall mulberry-trees are of course treated like the peach-tree.

149. A circumstance connected with the welfare of these trees may here be deserving of notice. The leaves of the black mulberry, not less than those of the white, forming a favourite food of silk-worms, they who amuse themselves with the breeding of these insects, often go to the gardens of their acquaintances, and collect leaves from the mulberry trees, without supposing that they are doing mischief; probably the proprietor of the trees may be as little aware of the evil: but the truth is, that wherever there is a leaf, there is a bud preparing for the next year; and when the leaf is plucked off, the bud perishes. If the successive

leaves be withdrawn, it is evident that the tree must soon be exhausted, and unable to put forth buds in the spring. In this way we have seen black mulberry trees of considerable size, destroyed in a very few years. The white mulberry (*Morus alba*, L.) is often cultivated in the shrubbery; of the leaves of this, as already noticed, the silk-worm is equally fond: by increasing the number of white mulberry plants, and robbing them only moderately of their leaves, the other kind may be saved.

*Medlar.*

150. The *Medlar-tree* (*Mespilus Germanica*, Linn.; *Icosandria Pentagynia*; *Rosaceæ*, Juss.) is a native of the south of Europe, but appears to be naturalized in hedges in England, and is therefore figured in "English Botany," t. 1523. The variety now commonly cultivated is called the *Large Dutch Medlar*, the fruit of which is large, approaching in shape that of an apple. The *Nottingham Medlar*, or English Medlar, is a smaller fruit, but of a more poignant taste, and by some preferred on that account.

151. Medlars are propagated by grafting or budding the variety wished for, upon seedling medlar stocks, sometimes on hawthorn stocks. The tree is of a middling size; it is chiefly trained in standards; in a few places in espaliers. It is managed very much in the manner of the apple-tree, only the tree is kept rather more thin of wood. The flowers appear late in May. The fruit remains on the tree till the end of October, and is afterwards kept in the fruit-room till it mellow, and acquire a buttery softness, or be "rotten ripe," when only it is fit for the table. This may not take place till past mid-winter: if soft medlars be wanted more speedily, their maturation is forwarded by depositing them in moist bran for a few days.

Two or three medlar trees in the garden are sufficient, more being generally planted in the pleasure-grounds.

*Small Fruits.*

142. We now proceed to notice what are called *Small Fruits*, Currants and Gooseberries, Raspberries and Strawberries.

153. *Currants* and *Gooseberries* belong to the genus *Ribes* of Linné; *Pentandria Monogynia*; *Cacti* of Jussieu. The genus is divided into *Ribesia* or Currants, without spines; and *Grossulariæ* or Gooseberries, with spines. Currants and gooseberries are northern fruits; they seem to have been unknown to the ancient Greeks or Romans. Even yet they are not very generally cultivated in Italy or France; one obvious reason being, that these countries possess a climate suited to much finer fruits. Currants were comparatively but lately introduced into Holland; yet from the industrious Dutch gardeners have we derived improved and large-fruited varieties, both red and white, which have deservedly banished all others from our gardens.

*Red and White Currants*

154. Our common *red* currant is *Ribes rubrum* of Linnæus; and our *white* currant is merely a variety of this. R. rubrum grows naturally in different places in England and Scotland, and is figured in English Botany, t. 1289. Having been long cultivated, several improved varieties have been obtained. The kinds chiefly planted at present are, the large red; the champagne; the pale red, sometimes called grizzly; the long-clustered red; the large white Dutch; the white crystal; and the pearly. The finer and larger bunches, both of the white and red currant, are used in the dessert, particularly late in the season: more commonly, however, the red is made into a jelly, with an equal weight of white sugar; and the white is much in request for the making of wine.

Currant bushes are propagated chiefly by cuttings. These are commonly prepared early in the spring. They should consist of last year's shoots, proceeding from bearing branches, and may be from nine inches to a foot in length. They are planted in a border of light earth, about four or five inches deep. In the spring, if the weather prove dry, they are occasionally watered till the leaves be expanded. In the course of the summer, all the shoots are displaced excepting three: indeed, some gardeners prevent the growth of more shoots, by extracting, at the time of preparing the cuttings, all the eyes or buds but three. In autumn these young bushes are transplanted, and sufficient space allowed them to grow for two years, during which time, if neat bushes be wanted, they are repeatedly pruned or trained. The currant thrives best in a rich loam, and in a free situation. The usual season for transplanting is October or November. They are often placed by the sides of walks or alleys, and allowed to remain many years; but it is better to plant them in quarters by themselves, and to renew them every seventh or eighth year, young bushes yielding fruit more plentifully, and of finer quality. When considerable plantations of currant bushes are formed, much ground is occupied by them, the distance between the rows not being less than seven or perhaps nine feet. But in these spaces coleworts may be planted in October, to be used in the early part of spring, before the currant trees come into leaf. If the ground be not cropped in this way, it should lie rough all the winter.

155. Mr Macdonald, gardener at Dalkeith-House, raises currants, both red and white, of the finest quality. A good deal depends on the way in which he manages the bushes, especially during the ripening of the fruit. He prunes the bushes at the usual season of mid-winter, shortening the last year's shoots down to an inch or an inch and a half. Next summer the plants shew plenty of fruit, and at the same time throw out strong shoots. As soon as the berries begin to colour, he cuts off the summer shoots to within five or six inches before the fruit. This is commonly done with the garden shears, with which a man may go over half an acre of bushes in a day. Sun and air thus get free access, and more of the vigour of the plant is directed to the fruit: the berries are found not only to be of higher flavour, but larger than usual.

156. Currant trees are sometimes trained against a wall. Two branches are led in a horizontal direction along the bottom of the wall, perhaps half a foot from the surface of the earth, and the growth from these of all upright shoots, which will admit of being arranged at the distance of five or six inches from each other, is encouraged. The fruit is produced plentifully on spurs or snags some years old, either on wall or standard bushes; but the largest berries are afforded by young wood, and this is therefore to be occasionally supplied. On a south or south-west wall, the fruit is about three weeks earlier than on standards; and on a north or east wall, if the fruit be defended from birds, by means of netting, it will remain good till October; if matted over when ripe, it will endure even till November. Sometimes a few standard bushes are likewise matted up, and on these the fruit will sometimes hang, in pretty good condition, till the approach of frost. On espalier rails the fruit comes early, and of fine size and flavour. Currants, it may be remarked, should be gathered only when in a dry state; if collected in rainy weather, they lose their flavour.

*Black Currant.*

157. The *Black Currant* (*Ribes nigrum*, Linn.) is also considered as a native of Britain, and is described and figured as such in English Botany, t. 1291. It is very generally cultivated, though not in great quantity, in private gardens. The berries have a very peculiar taste, which however to many people is not disagreeable. In England, they are used in puddings and tarts. A well known jelly is made from them; and if a small proportion only of sugar be used, an agreeable rob is formed. The flavour of the young leaves in spring is strong; a small leaf, laid for a few minutes into an infusion of bohea tea, communicates its flavour, which has been compared to that of green tea.

The black currant bush agrees with a damp soil better than the red. The management of both is much the same; only the shoots of the black are not cut to spurs as in the red, the fruit being produced in a different way. The plants are regularly pruned every winter, from a third to a fourth part of the old or exhausted wood being cut out annually, and the straightest and best placed shoots being preserved. In summer, all superfluous growth is displaced, especially from the centre of the bushes. The black currant-tree produces more fruit as a standard than when trained against a wall; but in the latter way, the berries are considerably larger.

*Gooseberry.*

158. The *Gooseberry-bush* (*Ribes grossularia*, Linn. rough-fruited gooseberry, Eng. Bot. t. 1292, and *R. uva crispi*, L. common or smooth-fruited, Eng. Bot. t. 2057,) if not a native plant, is at least completely naturalized in this country. It often appears in woods, and not unfrequently on the walls of ruinous buildings; but to these places the seeds may no doubt have been carried by birds. The culture of this fruit has for a number of years been particularly attended to in the north-west of England; and the size and beauty of the Lancashire gooseberries have procured them the first character. In the south of Europe, we believe, the fruit is generally small and neglected; and when foreigners witness our Lancashire berries, they are ready to consider them as forming quite a different kind of fruit. In France, the gooseberry is called *groseille à maquerau*, from its being used as a seasoning to mackerel.

159. The varieties of the fruit are very numerous, perhaps not fewer than two hundred. They are distinguished by names not less sonorous, nor less fanciful and unmeaning, than those bestowed by the Dutch on their tulips and hyacinths; such as, Glory of England, Glory of Eccles, Bank of England, Nelson's Victory, &c. Many new ones are constantly coming into notice, and others are falling into neglect. They are classed according as their colours are red, green, yellow, or white. The names of a very few of each of these, which are at present most in esteem, shall be mentioned.

*Red.*

| | |
|---|---|
| Old Ironmonger, | Smooth Red, |
| Early Black, | Hairy Red, |
| Damson, or dark red, | Red Champagne, |
| Large Rough Red, | Nutmeg, |
| Red Walnut, | Captain, |
| Warrington, | Wilmot's early red. |

*Green.*

| | |
|---|---|
| Green Gascoigne, | Green Globe, |
| Green Walnut, | Green-gage. |
| White Smith, | |

*Yellow.*

| | |
|---|---|
| Great Amber, | Sulphur, |
| Globe Amber, | Conqueror, |
| Great Mogul, | Yellow Champagne, |
| Hairy Globe, | Golden-knap, |
| Golden Drop, | Royal Sovereign, |
| Honeycomb, | Tawny. |

*White.*

| | |
|---|---|
| Large Crystal, | White Dutch, |
| White-veined, | White Walnut. |
| Royal George, | |

It must be admitted, that although the large gooseberries make a fine appearance on the table, they are often deficient in flavour, when compared with some of smaller size. Many of them have very thick strong skins, and are not eatable unless thoroughly ripened. Some of the large sort, however, are of very good quality, such as the red champagne and the green walnut. Among these, also, *Wilmot's early red* deserves further notice. It was raised by Mr Wilmot at Islesworth in 1804, and has been cultivated by him very extensively on account of its valuable properties, being early ripe, of excellent flavour, and extremely productive. It usually ripens from the middle to the end of June. For culinary use in the month of May it is larger and better than most others, the skin not being tough, but the whole berry melting to a fine consistence. The gooseberry, it may scarcely be necessary to notice, is used not only for tarts, pies, and sauces, or gooseberry creams, before being ripe; but, when at maturity, it forms a rich addition to the dessert for several months.

Gathered unripe, gooseberries can be preserved in bottles against winter: the bottles are filled with berries, close corked, and well sealed; they are then placed in a cool cellar till wanted. By plunging the bottles after being corked into boiling water for a few minutes, (heating them gradually to prevent cracking,) the berries are said to keep better.

160. Gooseberry-bushes, like currants, are propagated chiefly by cuttings, preferring for this purpose clean and strong shoots of the former year, about a foot in length. They may be planted any time early in the spring. They are trained for two or three years, and should have a stem six or eight inches high. Strong suckers of straight growth are sometimes used, but they are considered as apt to produce suckers again.

In many places little attention is paid either to the soil in which the gooseberry-tree is planted, or to its pruning and management; yet the fruit is greatly improved by attention to these circumstances. The best practical gardeners now prune the bushes so as to form them somewhat like a hollow sphere; no main stem is encouraged, as was formerly done; but the centre is cut out, and eight or ten side branches preserved, according to the size of the plant. All water-shoots of the former season are removed; but any young shoots wanted for branches are left at full length. In this mode of pruning or training, the stem may be short, perhaps half a foot, instead of a whole foot. The bushes may also be planted nearer to each other than such as are allowed to rise many feet in height. They should not, however, be less than five or six feet asunder in every direction, the free admission of light and air being quite necessary. If the bushes be attended to in the month of June, and all central water-shoots and suckers be displaced, the additional light and air thus admitted, will be found very beneficial to the fruit, while the labour of winter pruning will be at the same time diminished. In many gardens gooseberry-bushes are still placed in single rows along the sides of borders; but this is not so good a plan as having a separate quarter for them. They may be planted in November, or any time before February; and the plantation should be renewed every seven or eight years.

161. The plan above described for prolonging the season of currants, by matting up the bushes when the fruit is ripe, it is still more important to adopt in regard to gooseberries, as this fruit forms a more desirable ingredient of the dessert. If some of the late yellow sorts be matted in September, they remain good till November. A few plants of the finer kinds are sometimes trained against a south or east wall; here the fruit not only comes earlier, but attains greater size than usual. They also do very well on a low espalier-rail. In some places, gooseberry-trees on the sides of the borders are trained to a single tall stem, which is tied to a stake: this, though six or eight feet high, occasions scarcely any shade on the border, and it does not occupy much room, nor exclude air; while at the same time the stem becomes closely hung with berries, and makes a pleasant appearance in that state. Some sorts of gooseberry-bushes, and those producing the largest fruit, have a natural tendency to bend their branches downwards. In this case the branches must be supported with small forked sticks, in order to admit air, and to save the fruit from touching the ground.

It may be observed of the currant and goosebery trees in general, that they are very easily raised from the seeds, these often, however, lying a year in the ground before vegetating. The seedling plants generally shew fruit in the third year of their growth, when an estimate of their merits can be formed: it is to be observed, however, that the fruit both of currant and gooseberry seedlings may improve in the fourth and fifth year.

*Raspberry.*

162. The *Raspberry-bush* is the *Rubus idæus* of Linnæus (*Icosandria Polygynia*; *Rosaceæ* of Jussieu) and the *Framboisier* of the French. It is indigenous to several parts of Britain, and is figured in English Botany, t. 2442. The styles being persistent, the fruit has a bristly appearance, from which the name *raspis*, or rasp, has been given. The fruit is very desirable both for the dessert, and for making jam, tarts, and sauces. Eaten fresh with cream and sugar, it makes an excellent supper-dish, and may be had from July to November. It also forms the chief compound in a liqueur called Raspberry Cordial, for which purpose great quantities of the fruit are reared near London

163. The varieties chiefly cultivated are the following: Common red and common white; large red Antwerp; large yellowish-white Antwerp; cane or smooth-stalked, also called reed raspberry; twice bearing white, and twice-bearing red. Some still prefer the common kinds of red and white, thinking that an increase of size in the larger varieties has been purchased at the expence of flavour; but the new varieties are, upon the whole, to be accounted preferable. The second crop of the twice-bearing kind is in general deficient both in flavour and size; but by means of it the raspberry season is prolonged till the beginning of November. It is to be particularly noticed, however, that the fruit should be regularly gathered as it ripens, and should be almost immediately used after being gathered: it will remain good on the bush for a few days after being ripe, but a dish of raspberries, kept in the house for two days, will generally be found to have lost flavour, and possibly to be tainted by maggots.

164. Sucker-shoots rising abundantly afford plenty of plants; but they should always be taken from stools in full bearing. They are planted any time from October to February. The distance is seldom less than three feet between the plants, and the quincunx order is generally adopted, five feet being left between the rows. If the larger varieties be planted, the distances are increased. A raspberry plantation continues good for six or seven years; but after the lapse of that period, it should be entirely renewed: it is generally in perfection the third year after planting; so that a new raspberry quarter should be prepared two years before the old one be grubbed up.

165. During summer raspberry-plants receive little attention. The ground is repeatedly hoed, and a few of the superfluous suckers are sometimes removed. Before winter, the ground is commonly dug and left rough. In some places the stools are dressed at this season, (November;) and a slight crop of coleworts is put between the rows. If this be not done, the general pruning is deferred till February or March, when the decayed stems of the former year are cut out, and the new ones regulated and tied: for there is this peculiarity about raspberry-bushes, that the stems which bear fruit in one year die in the following winter; leaving in their place a succession of new stems, which have been produced during the summer. Where the stools are very strong, six or eight stems are allowed to remain; but in young or weak plants, only half that number are suffered to carry fruit. At the same time, the tender tops, which have been injured by frost and hang down, are cut off. Plants pruned or dressed before winter, it may be observed, sustain most injury from frost; the old stems, when left, affording a degree of protection to the young shoots. In exposed situations stakes are found necessary for supporting the stems; but in general it is thought sufficient to twist the shoots loosely together, and to tie them at top with a strand of bass-mat: Sometimes, the tips of half the shoots on one stool are tied to half the shoots of the next; and in this way a series of festoons or arches is formed, producing a very agreeable appearance, and at the same time affording security against the highest winds.

The raspberry-bush grows freely in any good garden soil; but it is the better for being slightly moist. Although the place be inclosed by trees, and even slightly shaded, the plant succeeds. In an inclosed and well sheltered quarter, with rather a damp soil, containing a proportion of peat-moss, we have seen very great crops of large and well-flavoured berries produced; for example, at Melville House, the seat of the Earl of Leven in Fifeshire. Sometimes a few plants are trained against a west wall, or a trellis or rail, and the fruit here comes more early and of larger size. By training against a north wall, the crop is proportionally retarded.

New varieties of raspberry are easily raised from the seed; and they come to bear in the second year.

*Strawberry.*

166. The *Strawberry* (*Fragaria* of Linnæus) belongs to the same class and order, and natural family, as the raspberry; the plant is called *le Fraisier*, and the fruit *la Fraise*, by the French; and it is the *Erdbeere* of the Germans. Several *species* of strawberry are cultivated in our gardens, and many *varieties*; indeed new hybrid productions are yearly appearing. We shall mention the kinds which are at present most esteemed.

167. The *Scarlet Strawberry*, (*Fragaria Virginiana* of the Hortus Kewensis.) This is the only sort of small strawber-

ry cultivated for the Edinburgh market, a place distinguished for excelling all others in abundance and excellence of this kind of fruit. It is a native of Virginia, and very different in habit from our wood plant, the leaves being dark green, of a more even surface, the flowering stem shorter, and the fruit commonly concealed among the leaves. It is a hardy species, producing plenty of fruit on high and rather bleak situations, near Edinburgh, where the Chili strawberry does not prosper.

168. The *Alpine* (*F. collina*) is larger than our wood species, the stem higher, the leaves broader; the fruit red, (sometimes white,) tapering to a point, and of considerable size. The fruit is of excellent flavour; and being produced from June to November, the plant is well deserving of culture. The summer shoots, it may be mentioned, must not be cut off; for they flower and yield fruit the same season, and it is on this property that the autumn crop depends. From observing this, Mr Knight was led to a new mode of treating the alpine strawberry. He sows the seeds early in the spring, in pots which he places in a moderate hotbed in April. As soon as the plants have attained sufficient size, they are planted in the open ground, where they are to remain. They begin to blossom soon after midsummer, and continue to produce fruit till stopped by the frost. The powers of life in plants thus raised, Mr Knight remarks, being quite energetic, operate more powerfully than in plants raised from seeds even in the preceding year; and he therefore concludes, that the alpine strawberry might with propriety be treated as an annual plant.

169. The *Carolina* (*F. Caroliniana*) is very regular in form, and of a fine red colour; but inferior in flavour to the scarlet. It does not appear to be a distinct species.

170. The *Wood strawberry* (*F. vesca*, Lin.) has been cultivated from time immemorial, and in some places it is still preferred. It is a native of most of the woods of Britain, and figured by Sowerby, t. 1524. There is a variety with white fruit.

171. The *Pine strawberry* (*F. grandiflora*, Hort. Kew.; *F. ananas* of some writers.) The leaves resemble those of the scarlet, but are somewhat larger, and evidently of a thicker substance; the flowers also are larger, and the fruit approaches in size and shape to the Chili, being large, tapering, very pale red on the exposed side, and greenish on the shaded side. When the plants are kept free from runners, this kind is very productive of fruit, and is therefore highly deserving of cultivation.

172. The *Chili* (*F. Chiloensis*, Hort. Kew.) is distinguished by its very thick oval leaves, which, with the leaf-stalks, are set with hairs. The flowers and fruit are both uncommonly large. Some English gardeners speak slightingly of this kind, saying that it is a bad bearer: it has therefore been rather neglected. In the neighbourhood of Edinburgh, however, it proves abundantly productive: 50 Scots pints have frequently been gathered from an acre, by a single person, in the course of a day. It is the only large strawberry cultivated for the Edinburgh market, and is generally sold there under the name of hautboy. The Chili, it may be noticed, has a red berry; while the true hautboy is of a greyish colour.

173. The *Hautboy*, or *Hautbois* (*F. elatior*, Smith, *Fl. Brit.*; *Eng. Bot* t. 2197.) is remarkable for its very large oblong fruit, with a musky flavour. There is a variety called the Globe Hautboy, which is much esteemed, but apt to degenerate.

174 Of late years many new varieties have been raised from seed: Some have for a time acquired a name, and have again been forgotten: others, however, are likely to retain their character. When ripe seed is wished for, the fruit should be allowed to wither somewhat on the plant before being gathered. It may, in passing, be observed, that although, in compliance with popular practice, we term the fruit a berry, it is not such in correct botanical language: a berry (*bacca*) contains the seeds within a pulp; but here we find the seeds on the outside; it is, in fact, a fleshy receptacle, having the surface studded with the seeds.

In Covent Garden market, strawberries are sold in small pottles, the fruit having the calyx-leaf attached. In the Edinburgh market, they are sold in wicker-baskets, each basket containing a Scots pint, or four English pints, the fruit being freed from the calyx-leaves.

175. As it is generally admitted that the market-gardeners in the vicinity of Edinburgh excel in the culture of strawberries, their mode shall here be detailed.

A clayey soil or strong loam is considered as best suited to the strawberry; on a sandy or very light soil it never succeeds. Indeed, as the fruit naturally ripens in June, when drought may be expected, we might conclude, *à priori*, that a retentive soil would be much more proper for it than an open one. New plantations are formed either in September or in the beginning of April, the soil being trenched or at least deeply delved, and at the same time manured. The offsets are always taken from the runners of plants of the preceding year, in preference to those from plants of longer standing. They are placed in rows two feet distant, thus affording sufficient room for delving, or turning over the surface earth between them, a practice which is found very beneficial, both during summer and winter. Three plants are commonly put in together at each place: the distance between each stool or cluster of plants is at least fifteen inches; sometimes a foot and a half. When the weather is dry at the time of planting, they are watered every day till they be well established. For the first year few berries are produced; and the common practice is, to sow a line of carrots, or some such crop, between the strawberry rows. In May the runners are cut off, this being found to promote the swelling of the fruit. Every stool is rendered quite distinct and free from another, and the earth between them is stirred with the spade or hoe. In the dry weather of summer, strawberries are (by some careful cultivators, for it is not a general practice) watered, not only while in flower, and when the fruit is setting, but even when it is swelling off: as the berries begin to colour, however, watering is desisted from, lest the flavour should be injured.

About eighty acres in the vicinity of Edinburgh are occupied by market-gardeners, in strawberry crop, for the supply of the Scottish capital; and the amazing average quantity of 60,000 Scots pints (240,000 English) are yearly sold in Edinburgh and its neighbourhood. In a favourable season, about 75,000 Scots pints (300,000 English) have been brought to market; and it will be remembered, that the berries are freed from the calyx-leaves, which leaves in the English market greatly swell the measure. When the distance is considerable, the wicker baskets are packed over each other in a hamper-creel, and conveyed to town on a light cart hung on springs. The highest price is commonly half a guinea a Scots pint; but this is only got for a few pints at the beginning of the strawberry season: the average price is about 1s.; the lowest 9d. a Scots pint. The berries are picked as they ripen, by women and children hired for the purpose, to whom the strawberry harvest is a profitable time.

As soon as the strawberry season is past, the plants are shorn over, and all runners are again cut off. Towards the end of October, the ground between the rows is delved over. The cultivation of strawberries is thus attended with a good deal of expence, requiring much labour and constant assiduity in digging and hoeing between the plants, clearing them of weeds, cutting off runners and leaves, watering (where that is practised,) and picking the berries for market. They may, with success, be continued on the same land for an indefinite space of time, but the plants must be renewed every fourth or fifth year, and manure at that time supplied. It is however found preferable to change the crop altogether after twelve or fifteen years.

176. Strawberries are generally placed in a quarter of the garden by themselves, and it should be one which is freely exposed to sun and air. They are sometimes, however, planted in single rows, as edgings to borders, and in this way they often produce great crops. In either case, care must be taken to replant them every fourth or fifth year at farthest. The alpine and wood species may be placed in situations rather cool and shady; perhaps as an edging in the shrubbery. In such places they produce their fruit perfectly well, and late in the season, which is desirable.

177. The fruit has evidently received its English name from an old practice of laying *straw* between the rows: in clear weather, the ground is thus kept from drying too much, and less watering is requisite; while, in drenching rains, the berries are preserved from being soiled by the earth. This custom is still followed in some parts of France; and it has of late been partially revived in the neighbourhood of London, through the recommendation of Sir Joseph Banks, contained in the first volume of the English Horticultural Memoirs. When the fruit is formed, some lay tiles or moss around the plants; these answer the same purpose as straw, but certainly not more effectually, and the procuring and applying them must be attended with more trouble.

178. Strawberries are a favourite dessert fruit, and by different means they are brought to table from February till November. By various kinds of forcing (to be afterwards noticed) they are procured from February till June; they are produced abundantly in the open air during the months of June and July; and by means of the alpine and wood sorts, the strawberry season is prolonged till the end of October. The fruit should be used very soon after being gathered. If kept only for a few hours, the flavour is found to have considerably diminished. The berries are generally eaten along with cream and pounded sugar.

179. Strawberries are readily raised from the seed, and new varieties are thus procured. If sown early, they seldom fail to produce flowers and fruit in the succeeding year. In collecting the seeds, it is proper to observe that the berries be perfectly ripe, so that the seeds may be brushed from their surface, or may part with facility.

Having thus given an account of the fruits which are usually cultivated within our walled gardens, in the open air, it may be proper in this place to take some short notice of several other fruits, and nuts, which are occasionally cultivated in the garden, but more commonly in the lawns or pleasure-grounds surrounding it, or in the orchard and its environs; and likewise to mention more particularly some of the native fruits which are still gathered for use in the country.

*Fruits occasionally cultivated.*

180. The *Pomegranate-tree* (*Punica granatum*, L.; *Icosandria Monogynia; Myrti*, Juss.) is a native of the Levant, but naturalized in the South of Europe. It was introduced into England toward the end of the 16th century. At first it was treated as a delicate plant; but now it stands in the open border. It is only, however, in sheltered situations, against a south wall, and in favourable seasons, that it produces tolerable fruit: it acquires indeed a considerable size, nearly that of an ordinary pippin, but is quite deficient in flavour. The tree requires a rich strong soil; in a poor and dry soil, it will not even show flowers. To the northward of London, the fruit scarcely ever approaches maturity. A variety with double flowers is frequently planted against the sides of houses by way of ornament; and when clothed with its scarlet flowers, it is not only very beautiful, but grateful by its odour. The pomegranate is generally propagated by layers. The flowers proceed from the extremities of branches produced the same year. The stronger branches of the former year are therefore shortened, in order to obtain a supply of new shoots. The best time for this pruning is November.

181. The *Olive*, (*Olea Europæa*, L. *Diandria Monogynia*; *Jasmineæ*, Juss.) which constitutes much of the riches of the south of France, Italy and Spain, with difficulty survives in the mildest parts of our island. Protected during winter in the same way as the myrtle, generally by short litter laid around the stem, and by a slight temporary screen of evergreen branches, it sometimes flowers; and in some very warm seasons, it has produced a few unripe fruit.

182. The *Pishamin*, or date-plum, (*Diospyros Lotus*, L.; *Polygamia Diæcia; Guaiacanæ*, Juss.) is chiefly cultivated on account of its fine shining leaves. Its fruit, however, is relished by some. It is the size of a cherry, of a yellow colour, and eaten, like the medlar, in a state of over-maturity or incipient decay. The plant is tender for the first year or two; and even afterwards requires a sheltered situation, and rich but dry soil. It was known in the time of Gerarde, but is still very little attended to in gardens.

183. The *Cornelian cherry* (*Cornus mascula*, L.; *Tetrandria Monogynia; Caprifoliaceæ*, Juss.) was formerly much cultivated as a fruit-tree, and it is enumerated as such in all the old books on gardening. The fruit was used in making tarts, and a rob *de cornis* was kept in the shops. It is now transferred to the shrubbery, where its early flowers, appearing in February and March before the leaves, render it ornamental. The wood is remarkably hard; so that spears were in ancient times formed of it.

184. Besides the common apple, pear, and quince, several others of the Pyrus genus are cultivated. The *Chinese apple* (*P. spectabilis*, L.) is planted in many gardens and shrubberies in the south of England, chiefly on account of its fine show of deep red buds and large blossoms, which appear early in May. It is increased by grafting on crab stocks. Beautiful trees of this kind, some of them above twenty feet high, are to be seen in gardens in the neighbourhood of London. The *Siberian crab* (*P. prunifolia*, L.) is prized chiefly for its elegant little fruit, resembling large Duke cherries, which are very ornamental in shrubberies, in the autumn and early part of winter. The *Small-fruited crab* (*P. baccata*, L.) is planted with the same view. From the fruit of this sort, as we learn from Pallas, the quass or cider of Siberia is made; and we may add, that it makes an excellent preserve with syrup. The *Japan apple*, (*P. Japonica*, L.) blossoms and bears fruit, if trained against a south wall; but the fruit is of no value. The plant requires to be covered with a bass-matt or close straw-net during winter. The *Sorb*, or *Service-tree*, (*Pyrus torminalis* of Hort. Kew.; *Cratægus torminalis*, L.) is a large tree, growing naturally in some parts of England, as in Hertfordshire, from whence the fruit is brought to London in large quantities in autumn. It is figured in Sowerby's "English Botany," t. 298. The fruit is of the shape of the common haw, but larger; of a brownish colour when ripe; if kept till it be soft, in the same way as medlars, it has an agreeable acid flavour. It

succeeds in any strong clayey soil; it is scarcely ever cultivated as a fruit-tree, but is often planted in lawns and about orchards.

185. The *Azarole-tree* (*Cratægus azarolus*, L.; properly a Mespilus) has a still larger fruit, but does not produce it so freely, being a native of the Levant. When fully ripe, the fruit has an agreeably acid taste, for which it is so much esteemed in Italy and the south of France, that it is frequently served up in desserts. It is the *pomette* of the French. In this country it is seldom used.

*Native Fruits.*

186. Of the genus Prunus, we have several species growing naturally in our woods, and by the banks of rivers. The small black cherry or guigne, (*P. cerasus*, Eng. Bot. t. 706,) and the red-fruited variety, commonly distinguished as *Prunus avium*, have already been mentioned, as well as the common wild plum, (*P. domestica*,) which, if not native, is at least completely naturalized. To these may be added the bullace, the sloe, and the bird-cherry. The *Bullace plum* (fruit of *P. insititia*, Eng. Bot. t. 841,) when mellowed by frost, is not unpleasant; indeed it is one of the best of our native productions. It may be made into an excellent conserve, by mixing the pulp with thrice its weight of sugar. It varies with dark purple or almost black fruit, and light or wax-coloured fruit. The *Sloe* (fruit of *P. spinosa*, Eng. Bot. t. 842.) likewise requires to be mellowed by frost. To home-made wines, it is calculated to communicate the colour and roughness of red Port; indeed it is said to enter as an ingredient into the manufacture of this wine. The juice of the unripe fruit forms the German acacia. When the fruit is ripe, the juice affords an almost indelible ink, which is sometimes used for marking linens. Mr Knight (in the London Horticultural transactions, vol. i.) seems to consider the sloe as the original species from which all our cultivated plums have been derived; but on what grounds he passes over the common wild plum and the bullace, which are more nearly allied, he does not enable us to determine. The *Bird cherry*, (fruit of *P. padus*, L. Eng. Bot. t. 1383.) in Scotland the Hag-berry, is, to most palates, nauseous. The fruit is scarcely used, unless occasionally that in Scotland an infusion of it is made in the favourite liquor of the country, whisky.

187. The *Barberry bush* (*Berberis vulgaris*, L.; *Hexandria Monogynia; Berberideæ*, Juss.) is a native of various parts of this country; and is figured in "English Botany," t. 49. The fruit is in considerable demand for preserving; and the berries of the variety without stones are prepared for this purpose. If planted in good soil, and pruned somewhat in the manner of gooseberry-bushes, barberry plants yield both larger bunches and larger berries. In the shrubbery, while in flower, they are ornamental; and the sensitive stamina may afford entertainment; for when the antheræ are ready, if the bottom of the filament be irritated with the point of a knife or a straw, the stamen rises with a sudden jerk, and strikes the anthera against the pistillum. In autumn, the scarlet fruit makes a fine appearance.

188. The *Elder* (*Sambucus nigra*, L.; *Pentandria Trigynia; Caprifoliaceæ* of Ventenat,) is a well known native tree, figured in English Botany, t. 476. In Scotland it is called Bourtree. Elder berries may be included in the list of native fruits; for they are still sometimes gathered for the making of elder wine.

189. The *Mountain ash* (*Sorbus aucuparia*, L.; *Icosandria Trigynia; Rosaceæ*, Juss.; Eng. Bot. t. 337.) is perhaps the most ornamental native tree we possess. It is deservedly planted in pleasure grounds; its foliage, flowers, and berries being all beautiful in succession, and the whole tree forming a fine object. Roanberries are still held in some esteem in the Highlands of Scotland, and in Wales; and in both countries, the boughs of the tree are used in many superstitious ceremonies.

190. Of the genus Rubus, the raspberry has been already mentioned. The *Common bramble* (*R. fruticosus*, L.; Eng. Bot. t. 715.) may be added as one of our native fruits, and not one of the worst. The *Stone bramble*, (*R. saxatilis*, Eng. Bot. t. 2233.) is another: In Scotland, the fruit has a distinct name, Roebuck-berry. *Cloud-berries*, or knotberries, (the fruit of *R. chamænorus*, Eng. Bot. t. 716.) are perhaps the most grateful and useful kind of fruit gathered by the Scots Highlanders: on the sides and near the bases of the mountains, it may be collected for several months in succession. It is not cultivated without difficulty, and it very seldom yields its fruit in a garden. With this may be coupled the *Dwarf crimson bramble*, (*R. arcticus*, Eng. Bot. t. 1585.) This is found only on the highest and wildest mountains of Scotland. The berry is excellent; but it is not easily obtained in sufficient quantity; for though the plant grows freely in gardens, and shews its flowers, it rarely produces its fruit in low situations.

191. Of the cranberry (*Vaccinium*, L.; *Octandria Monogynia; Ericæ*, Juss.) there are various species, three of them native; but the most important is a transatlantic species, which however we may be excused for introducing in this place. It is called the smooth-stemmed *American cranberry*, (*V. macrocarpon*.) This is an addition made within these few years to our list of cultivated fruits. The plant was indeed known; but the opinion given in Miller's Dictionary was general, that "they can only be cultivated for curiosity in gardens, for they will not thrive much, nor produce fruit, out of their native swamps and bogs." To the indefatigable Sir Joseph Banks, we are indebted for pointing out the practicability of cultivating it for use. Wherever there is a pond, the margin may, at a trifling expence, be fitted for the culture of this plant, and it will continue productive for many years. All that is necessary is to drive in a few stakes, two or three feet within the margin of the pond, and to place some old boards within these, so as to prevent the soil of the cranberry bed from falling into the water: then to lay a parcel of small stones or rubbish in the bottom, and over it peat or bog earth to the depth of about three inches above, and seven inches below the usual surface of the water. In such a situation the plants grow readily; and if a few be put in, they entirely cover the bed in the course of a year or two, by means of their long runners, which take root at different points. From a very small space, a very large quantity of cranberries may be gathered; and they prove a remarkably regular crop, scarcely affected by the state of the weather, and not subject to the attacks of insects.

192. The native species of *Vaccinium*, which afford berries in the highlands of Wales and Scotland, are the following. The *Common cranberry*, or moss berry, (*V. oxycoccos*, Eng. Bot. t. 319.) Great quantities of this berry are gathered in upland marshes and turfy bogs, both in England and Scotland. The berries are made into tarts, and have much the same flavour as the Russian imported cranberries, or those procured by cultivation. The *Bilberry*, blaeberry, or whortleberry, (*V. myrtillus*, Eng. Bot. t. 456.) is gathered in autumn for making tarts: in Devonshire the berries are eaten with clotted cream: in the Highlands of Scotland, they are sometimes eaten with milk, but more commonly made into jellies. The *Red bilberry*, or Cowberry, (*V. vitis idæa*, Eng. Bot. t. 598,) is

acid and rather bitter, and decidedly inferior to the cranberry. It makes, however, a very good rob or jelly, which in Sweden is eaten with all kinds of roast meat, and forms a sauce for venison, which is thought superior to currant jelly.

*Nuts.*

The *Nuts* which grow in this country, and which form part of the dessert, remain to be noticed.

193. The *Hazel* (*Corylus avellana*, Lin.; Eng. Bot. t. 723; *Monœcia Polyandria; Amentaceæ*, Jussieu) is a native of Britain, and very common. In September, great quantities of the nuts are collected by the country people, and sent to market. There are several varieties, particularly the White Filberd, and the Red Filberd; the Cob-nut, remarkable for its large size; the Cluster-nut; and the Dwarf Prolific-nut. In some gardens small plantations of dwarf filberd trees are made. The trees are not allowed to rise more than six or seven feet, and they are trained, like gooseberry-bushes, open in the centre. When full grown, the cup thus formed by the expanded branches is about six feet in diameter. Each tree is twelve feet from another. The intermediate spaces are occupied with different crops that require frequent hoeing, the success of the nut trees being much promoted by repeated stirring of the ground. So great is the produce of nuts from small trees managed in this way, that in some parts of Kent such plantations are formed with a view to the supply of the London market. The trivial name *Avellana*, it may be remarked, is derived from a town near Naples, the inhabitants of which have long cultivated the Spanish filberd tree to a great extent, much of their riches depending on the sale of the nuts.

The hazel tree grows vigorously in a strong loam, or in any soil which is somewhat retentive and moist. It is sometimes propagated by suckers, but better plants are procured by layers. In this way only are the different varieties continued: by sowing the nuts, trees may be got for the thickening of a wood, or forming a coppice, but not for cultivating with a view to the fruit. A few trees of the different varieties are ornamental on the side of any bank which may occur in the pleasure grounds. Early in spring, generally about the end of February, the catkins, or male flowers, and the female gems with their bright red styles, are displayed, and make a pleasing appearance at that still dreary season.

194. The *Constantinople hazel* (*C. colurna*, L.) produces nuts which are twice the size of the common hazel nut, and grow in large racemes. It seldom, however, yields its fruit in this country, nor is it much attended to. Indeed a large bush or tree of it is seldom to be met with in our gardens. In the Botanic Garden, Leith Walk, Edinburgh, one of the finest specimens in Britain occurs: it is now (1816) about 25 feet in height, and fifty years old.

195. The *Walnut tree* (*Juglans regia*, L.; *Monœcia Polyandria; Terebinthaceæ*, Jussieu) is considered as a native of Persia, but as having come to us from France, the name *walnut* being regarded as a corruption of *Gaulnut*. The date of its introduction is not known. Large and old trees of it are very common in many parts of England, where it ripens its fruit regularly. In Scotland, however, the fruit comes to perfection only in fine seasons: in ordinary years it attains merely that state in which it is fit for pickling. Several varieties are cultivated, particularly the round and the oval walnut; the large walnut; and the tender shelled. The chief thing to be attended to in the culture of the tree is to induce it to spread its roots near the surface, and to prevent their getting down into cold wet soil. As it generally attains a large size, it must stand in the lawn or park, or a row of walnut-trees may form part of the screen of the orchard. Mr Boutcher of Edinburgh long ago recommended the inarching of a branch of a bearing tree, the quality of whose fruit was known, upon a common stock, and added, that fruit was thus produced in one-third less time. The same idea has lately occurred to Mr Knight, and in this way he has procured plants which proved fruitful in three years. It is evident that the peculiar varieties can only be continued by *layering* and grafting; for large plantations, however, the nuts are sown. The nuts are ready in October, and are gathered by beating the trees with long poles; they may be kept through the winter, by covering them with earth in the manner of potatoes, and mixing some dry mould among them to fill the interstices; for this last purpose, dry sand being preferable.

196. The *Chesnut-tree* (*Fagus castanea*, L.; or *Castanea vesca* of Brown; *Monœcia Polyandria; Amentaceæ*, Juss.) is considered as a native of the southern parts of England, where, at any rate, it has long been naturalized. It has a place in "English Botany," t. 886. It is not much cultivated for its fruit in this country. As a forest-tree it is well known, though perhaps scarcely duly prized. The variety preferred is called the Spanish chestnut. It may be proper to observe, that when fruit is the object, *grafted* trees should be resorted to. The grafting of chestnut-trees has long been practised in Devonshire, and it is now likely to become general. The stocks may be raised from the common nuts, but the grafts are to be taken from bearing branches of such trees as yield the largest and fairest fruit. The timber of these grafted trees is of little value; indeed the tree generally continues in a dwarf state: but the fruit is not only sooner produced, but is of better quality and more abundant. The nuts are not so large as those imported from Spain; but they are more sweet. They may be kept in earthenware jars, in a cellar somewhat damp, or covered with earth or sand, in the manner recommended for walnuts. The French call these grafted trees *marroniers;* and the forest trees, *chataigniers*. The chestnut is suited to the same kind of situations as the walnut-tree above spoken of.

197. The *chinquapine*, or dwarf Virginia chestnut, (*Fagus pumila*, L.) has long been known in English gardens; but the fruit is small, and has not been much attended to.

198. In this country, even in ordinary seasons, several of the fruits which have now been treated of, such as the grape, the peach and nectarine, and the fig, and more particularly the finer varieties of these, are found to be brought to greater perfection, or the trees are more effectually kept in a healthy and fruitful state, by having recourse to a certain degree of artificial heat. If this be true in the south of England, much more may it be affirmed of all that part of the island which lies to the north of York. Glazed houses, under various names, have therefore been contrived for the purpose of forwarding and defending the blossom of the trees, and the setting of the fruit, in the spring, and for ripening the bearing wood for next year in the autumn, the maturation of the fruit itself, at least in the case of peaches and nectarines, being left as much as possible to the influence of the sun and air. The vinery, the peach-house, and the fig-house, ought not, in general, to be considered as *forcing* houses; but as calculated rather to assist the natural efforts of the plant, and to make up for the imperfections of the climate, every possible use being in the mean time made of the natural climate. They may, however, be converted into *forcing* houses, by varying the time of applying the artificial heat; and in this way, not

only cherries and strawberries, but grapes and peaches, may be obtained many weeks before the natural season arrives. The pine-apple, which has not yet been spoken of, requires continually an increased, and even high temperature; while the orange tribe needs little more than to be saved from frost during winter.

The disposition of hot-houses, in regard to the garden and pleasure grounds, has been already spoken of. A suite or range of glazed houses is generally formed together, with only glass partitions between them. In this case the green-house is sometimes placed in the middle, and the stoves at each end, so that, during winter, a person may pass into either hot-house without opening a direct communication between it and the external air, which, on account of the rarefaction of the air within, is ready to rush in.

Hot-houses are comparatively of modern invention. They were unknown in the days of Gerarde and Parkinson, that is, of Elizabeth and James VI. After the civil wars, horticulture seems to have received more attention; but a glazed house, with a furnace and flues, does not appear to have been constructed previous to 1684. Sir Hans Sloane, writing in that year, mentions that Mr Watts, gardener at Chelsea Garden, then recently instituted, had a new contrivance for preserving tender exotic plants during winter: "he makes under the floor of his green-house a great fire-plate, with grate, ash-hole, &c. and conveys the warmth through the whole house by tunnels, letting in upon occasion the outward air by the windows." The green-house was thus converted into a stove, or made to answer the purpose of both. Separate houses for plants belonging to very warm climates were soon found to be necessary; and in 1724, Bradley describes a stove, or conservatory, with flues and every thing in the manner of a modern dry stove. The bark stove was soon afterwards introduced; the heat resulting from the fermentation of tanners bark being employed, however, in the culture of pine-apples before it was applied to ornamental plants of hot climates. Two kinds of stoves are at present in common use, the dry stove and the bark stove.

*Dry Stove.*

199. The dry stove is generally constructed with upright glass frames in front, and sloping glass frames by way of roof, extending perhaps to within four feet of the back wall of the house, which space of four feet is commonly covered with slates. The angle at which the glass is made to slope is usually about 35°. The floor is raised two feet above the exterior surface, in order to give room for the flues, which, if sunk low, do not draw freely. The flues are carried to the extremity of the house, and returned several times, according to the length and breadth of the building. They are constructed of fire-brick, and the covering is composed of square tiles, about an inch and a half thick. In Scotland, where sandstone abounds, the covers are usually formed of flags, two inches or somewhat more in thickness. The flagstones of the Hailes Quarry, near Edinburgh, are excellent for this purpose: the finer laminæ from the quarry at Carmylie, in Forfarshire, commonly called Arbroath pavement, are apt to crack and shiver from exposure to heat. They are generally made about 18 inches deep, and of nearly equal breadth, and horticultural writers have in general recommended these dimensions; but there can be little doubt that the breadth should be nearly double the depth. Mr Stevenson, civil engineer, founding on some experiments made in constructing a drying-house, has strongly recommended this improvement. (*Scottish Hort. Mem.* i. 143. He observes, that "the flues in general use are of too small dimensions; there is not capacity in them for allowing the heated particles of air to expand; so that the heat passes rapidly through such narrow flues, and makes its escape with the smoke, in what may comparatively be called a latent state, without being allowed to act on a surface large enough to rob it of its caloric." He farther remarks, that an apartment heated with flues of a wide, but shallow, form is less liable to sudden changes of temperature, than where the flues are small; and that such flues possess the advantage of seldom or never requiring to be cleaned. The furnace is generally so situated, as that the upper part of the arch is as high as the top of the flue, where the heat is introduced into the house. The height of the body of a furnace, of the usual dimensions, is two feet four inches, varying, however, according to the slope of the ground; the width is nearly the same; the length of it inside three feet; the door a foot square; and the length of the back of the furnace two feet. In the dry stove a stand is erected for supporting shelves, on which the plants are to be placed; the stand and shelves together being called the *stage*. In this stove all kinds of succulent plants, such as cacti, mesembryanthema, stapeliæ, and aloes, are preserved, with many other tender plants which do not require bottom heat.

It may here be noticed, that it having been found that certain parts of hot-houses, where one furnace only is employed, are not heated equally with other parts nearer to the furnace, it has been proposed to convey to these parts heated air from the furnace by means of tinned iron tubes. Nicol and others object to these tubes resting on the flues, as being apt to diminish the evolution of heat from their surface: they might, however, be carried free of them, and certainly deserve further trials. Such tubes, it is to be observed, are only necessary in hot-houses already built. In the constructing of new houses, a small flue, perhaps 2½ inches or a brick square, can easily be carried along in the back wall. Heated air drawn from the furnace into this flue can be conveyed to the opposite end of the house, and there admitted by a valve or door at pleasure. Matters must of course be so contrived, that no smoke can pass into this small flue.

*Bark Stove.*

200. The bark stove is distinguished by having a large pit, nearly the length of the house, three feet deep, and six or seven feet wide. This pit is formed with brick walls, and has a brick pavement at bottom, to prevent the earth from mixing with the tan, which would hinder its heating. It is filled with fresh tanners' bark, well dried; and in the bark, pots containing plants from the East or West Indies, or tropical climates, are plunged. The bark acquires and long retains a moderate heat; but besides this, it preserves a degree of genial moisture, well calculated to keep the fibres of the roots in constant vigour and action. Experience has shewn that a house of forty feet can be properly heated by one furnace. If thought proper, the house may be made large, and there may be two tan-pits and two furnaces, the house being divided in the middle by a glass partition. In this case a higher temperature may be maintained in the one division, than is thought necessary in the other. Over the flues a wooden grate, or crib trellis, is laid; and on this are placed the most tender of the succulent tribes, such as some of the melon-thistles, cereuses, and euphorbiums. The range of temperature which plants can endure in the bark stove is considerable, from 63° to 81° Fahrenheit, or nine degrees above and below the mark *ananas*, on the botanical thermometer. This instrument is hung in the middle of the house, at a considerable dis-

tance from the furnace, and out of reach of the sun's rays.

201. It is not uncommon to give air to such a hot-house only through the day, and to shut it up close at night, perhaps even increasing the temperature in the evening. Judicious horticulturists reverse the practice. Knowing, for example, that in the West Indies, chilly and cold nights usually succeed to the hottest days, they rather imitate nature, by shutting up the house during the day, and throwing it open at night. This practice, however, can only be followed, in our climate, in the summer and autumn seasons.

202. Forcing stoves are of modern invention. In principle, they differ in no respect from the stoves already described; their application only is different. The bark forcing stove has a tan-pit, in which pots of roses, narcissuses, and other flowers, are plunged, in order to their production at an early season. Pots with strawberries, kidney-beans, or perhaps dwarf-cherry-trees, are likewise set in the pit, or on shelves around. Sometimes small borders are formed in this bark-stove, next to the front, and also next to the back wall; a few dwarf fruit-trees are thus introduced, which yield an acceptable addition to the spring dessert. In some places, the more delicate kinds of grape-vines are here also cultivated, and trained along the rafters of the upper sashes.

Forcing stoves are intended chiefly for peaches, nectarines, vines, figs, early cherries, the best sorts of apricots and plums, sometimes apples, and occasionally gooseberries, currants, and raspberries. The whole area of the house is filled with well prepared rich compost, two feet deep. The trees, having been previously trained to near a bearing size, are transplanted into the prepared border. These stoves are begun to be worked early in the spring; and when the crop is gathered, the glass frames are opened wide, or perhaps altogether removed, in order to admit air and rain, and thus harden the annual shoots of the trees. In this open state, the houses remain till after mid-winter, when they are partially shut, in order gradually to prepare the trees for the increased temperature. Different kinds of trees require different modes of management, and also a variation of temperature: in all first-rate gardens, therefore, a separate hot-house is allotted to the peach-tree, called the Peach-house; another to cherries, called the Cherry-house; a third to the production of grapes, called the Vinery or Grape-house, and in some places, a fourth, to figs, called the Fig-house. The difference in the structure of these houses is not considerable.

203. In general it may be remarked, that what is called *forcing* is the more perfectly performed in proportion as less forcing or violence is employed. All the operations of nature are gradual; and a good gardener will always follow these as the safest examples. He will never willingly apply artificial heat before buds have naturally swoln; he will then increase the temperature gradually for some weeks; he will, in particular, guard against any sudden decrease of warmth, it being most necessary towards success, to continue the course of vegetation uninterruptedly, through foliation, inflorescence, and fructification. In all kinds of forcing, it is of importance that free admission of air be given according to the state of the atmosphere; and it too should be given and withdrawn by degrees, especially in the early and cold time of the year: the sashes, or the ventilators, may, for instance, be partially opened by 8 in the morning, top air being given before front air; full air may be allowed about 10; a reduction should take place before 3 P. M., and the whole be closed between 4 and 5, according to the season and other circumstances.

We shall now proceed to notice the peach-house, cherry-house, vinery, and fig-house, in succession; then the pine-stove and appendages; and the orangery. Here we shall take occasion to introduce a short description of the magnificent and commodious suite of hot-houses at Dalmeny Park, near Edinburgh, plans and elevations of which we are enabled to lay before the reader; and we shall subjoin some account of improvements which have lately been adopted or proposed in this branch of horticulture. The cultivation of the melon, being allied to that of the cucumber, will lead us to the kitchen-garden.

### *The Peach-House.*

204. A peach-house intended to be commanded by one furnace, is commonly made about 40 feet long, 10 or 12 wide, and about 14 in height. It has sometimes no upright glass in front; merely a parapet 18 inches high, upon which the rafters immediately rest. In some places the peach and nectarine trees are trained to a trellis next to the glass, none being placed on the back wall; in others the trees are trained only to the wall, or to a trellis placed against it; but in the greater number of cases, small trees are trained nearly half way up the glass roof, and at the same time others of full size are placed against the back wall. The flue passes in front, but at some distance from the parapet, and is returned also at some distance from the back wall; so that both flues taken together, with the space between them, occupy nearly the centre of the house. The old practice of having the back wall itself flued, is now discontinued, *standing flues* within the house being found preferable. Both parapet and flues rest on pillars, so as to allow the roots of the trees free egress to the border on the outside of the house. If early or forced fruit be wanted, the house is made narrower and shorter, so as to give a greater command of temperature. In such houses, either three or four dwarf trees, with intermediate *riders*, are planted; the riders being taken out at the end of four years at farthest. When small trees are also trained in front, three are commonly sufficient there, or nine or ten trees in all. Fire-heat is generally applied about the middle of February, the temperature being for a time kept at 45°; and afterwards gradually increased to 50° or 55° Fahr. The temperature is regulated by a thermometer every morning and evening; during sunshine, air is admitted, to keep down the heat, as near as possible, to the average point. Trees thus forced, generally shew their blossoms in March. While in flower and till the fruit be *set*, gentle steaming is practised, by sprinkling water on the surface of the warm flues. After this, washing the foliage with the garden engine is found very conducive to the health of the plants. When the stones of the fruit are formed, the temperature is raised to about 60°, and the crop is thinned, if thought necessary. Water is now liberally applied to the border. After May, little fire-heat is given, and air is very freely admitted through the day.

Mr Knight strongly recommends the exposing the fruit, when ripening, to the full influence of the sun in warm and bright days, and covering it with the glass roof during cold night air or rains. He has, in the *London Horticultural Transactions*, vol. i. p. 199, described an improved peach-house. The angle of the roof is only 28° in Lat. 52°. In order that the lights may be moved to the required extent with facility, they are made short, and divided in the middle. The back wall does not exceed nine feet high. Two rows of trees are planted; one in front, trained on an almost horizontal or very slightly inclined trellis; and the other on the back wall. The house is 50 feet long, but commanded by a single furnace.

The usual displacing of useless buds and spray, and laying in of new shoots, are operations which must, of course, be attended to, as in the management of peach and nectarine trees on the open wall.

Some of the best fruits for the peach-house are, the red magdalen, the white magdalen, royal George, noblesse, late mignone, early Newington, teton de Venus, and Catherine peaches; and of the nectarines, the Newington, the red Roman, and the violet. But all the kinds formerly mentioned, § 88. are occasionally placed in the peach-house.

*The Cherry house.*

205. The cherry-house, if one furnace only be employed, is nearly of the dimensions mentioned for the peach-house. The cherry-house is always considered and managed as a forcing-house. There is commonly a glass front between two and three feet high; thus giving room in the fore-part of the border for some dwarf trees, either cherry or fig, or perhaps apricot; the principal cherry-trees being trained against a trellis in the back wall. The flue along the front and at each end, is covered with a small horizontal grate or trellis of wood, and on this pots of strawberries or of kidney-beans are forced. For the dwarf trees in front, such as have been kept in pots or tubs for some time, are to be preferred. Forcing in the cherry-house is usually begun about the new-year; but for a month before the fire is lighted, the house is shut at night, so as gradually to accustom the plants to the confined air and increased temperature. At first the temperature is kept at 40°. Till the flower-buds appear, air is admitted, in the day-time, freely; but after this, till the season become mild, with great caution, by the upper sashes only. When the fruit is setting, in the beginning of March, the temperature is kept as steadily as possible about 50°. After it is set, water is given plentifully at the root, and also dashed over the foliage, and air is freely admitted when the weather will permit. When the fruit is colouring, little water is given, the temperature is raised, and as much air as possible is given. When the crop is gathered, the house is generally thrown quite open; in many cases, even the glass-roof is taken off. By much the best cherry for forcing is the common Mayduke.

206. The kinds of strawberries preferred for forcing, are the scarlet, the alpine, and wood strawberry. The plants undergo a course of preparation for a year before they be forced. They should always be taken from the most fruitful plants; and the offsets nearest to the parent plant are to be preferred. During the first summer, they are not only regularly deprived of all runners as they appear, but the flowers are also picked off: vigorous plants, filling the pots, are thus secured for fruiting in the following spring. If the fruit be wanted very early, the plants are placed in a hot-bed frame in the end of October, and there brought to flower, being transferred to the forcing-house when the furnace is set agoing. They generally yield ripe fruit early in March, and continue to afford successive gatherings till the end of April, making a pleasing appearance at this season, and a rich addition to the spring dessert. Water is pretty liberally supplied till the fruit begin to ripen, when it is given sparingly. It may here be remarked, that if strawberry plants which have been prepared as for forcing, be planted in front of a hot-wall, they can scarcely fail to ripen fruit early in May.

207. Of kidney-beans, the best kind for forcing is the early speckled dwarf. The beans are sown, in small pots, (called 24's or 16's,) in many sorts of light rich earth, three beans in each, and placed in the house when fire-heat is begun. As they advance, they require frequent watering, and as much air as circumstances will permit. The pods should be gathered when rather young, as in this way the plants continue longer to yield them.

*The Vinery or Grape-house.*

208. A vinery with two furnaces is generally fifty feet in length, and fourteen or fifteen in width within; the height of the back wall being ten or twelve feet, and of the parapet about eighteen inches. When one furnace only is employed, the length of the house should never exceed thirty or thirty-five feet. The parapet wall is generally supported on small arches or lintels, as already described in the peach-house, so that the vines, which are planted inside the house, may send abroad their roots in search of suitable nourishment. Sometimes the vines are planted without, and introduced through slanting apertures.

209. Very commonly the roof is formed of sashes, which can be let down for the admission of air. In a grape-house described by Mr Knight, (*Hort. Trans. Lond.* vol. i. p. 100,) the air is admitted at the ends, where all the sashes are made to slide; a free current may thus be made to pass through the house. Besides, about four feet of the upper end of every third light of the roof is made to lift up, being attached by hinges to the wood-work on the top of the back wall; and in this way, air is given in hot and calm weather, without any additional shade. Here it may be remarked, with great submission to that eminent horticulturist, that *currents* of air are seldom wanted in hot-houses; they often indeed prove hurtful. To give air, therefore, principally by means of currents seems not a good plan; for the small openings in the roof are not likely to be able to counteract the rush of cold air at the ends. In giving air to vines, it is of great importance to have a free and soft circulation: this will prove highly salubrious to the plants, while, in the same temperature of the atmosphere, a current would be hurtful.

210. In planting a new grape-house, the young vines are put in in February or March, and little or no fire-heat is given; they make strong shoots the first year, but only such as are wanted for trellis are preserved, perhaps three on each plant, and in general these are trained straight towards the roof, ten or twelve inches separate from each other. In September, if the wood be not properly ripened, a little fire-heat is given for this purpose. Next year a good deal of fruit begins to appear; but only a few bunches are permitted to come forward, in order to prove the kinds. In the third year, if well managed, they fill the roof; and if the wood be thoroughly ripened, they may be considered as established plants.

211. We shall here mention an incomparably more speedy mode of storing a new grape-house, which may be adopted wherever a vinery previously exists in the garden, or where there is a friend's vinery in the neighbourhood. This mode is frequently practised at the gardens of Dalkeith House, by Mr James Macdonald, and we have witnessed its complete success.

In the end of June or beginning of July, when the vines have made new shoots from ten to twelve feet long, and about the time of the fruit setting, he selects any supernumerary shoots, and, loosening them from the trellis, bends them down so as to make them form a double or flexure in a pot filled with earth, generally a mixture of loam and vegetable mould; taking care to make a portion of last year's wood containing a joint, pass into the soil in the pot. The earth is kept in a wet state; and at the same time a moist warm air is maintained in the house. In about a week or ten days, roots are found to have proceeded plentifully from the joint of last year's wood, and these may be seen by merely stirring the surface of the earth, or sometimes they may be observed penetrating to its surface. The layer may now be safely detached. Very frequently it contains one or two bunches of grapes, which continue to grow and come to perfection. A layer cut off in the beginning of July generally attains, by the end of October, the length of fifteen or twenty feet. A new grape-house, therefore, might in this way be as completely furnished with plants in three months, as by the usual method, above described, in three years. Supposing the layers to be made on the 1st of July, they might be cut, and removed to the new house on the 9th: by the 9th of October, the roof would be completely covered with shoots, and next season the house would yield a full crop of grapes. It is not meant that they should be allowed to do so, if permanently bearing plants be wished for: on the contrary, they should be suffered to carry only a very moderate crop, as it is pretty evident that the roots could not sustain the demand of a full one; or at any rate, that the plants would necessarily shew their exhausted state, by barrenness in the following season. By this means the more delicate kinds, as the frontignac, may be quickly propagated: we have seen layers of the Gibraltar or red Hamburgh, made in the beginning of July, reach the length of thirteen feet before the end of the month, yielding at the same time two or three bunches of grapes. The more hardy, such as the white muscadine, form still stronger plants in that space of time. Little difficulty is experienced in removing the plants from the pots into the holes prepared for them: if there be fears of preserving a ball of earth to the new roots, the pots may be sunk with them, and then broken and removed; or the plants may be kept in the pots till autumn, when they may very easily be taken out of them without detriment. Mr Macdonald's experience does not lead him to think that plants propagated in this way are less durable than those procured by slower means, and where the roots and branches bear a relative proportion to each other. But supposing they were found to be less durable, it is evident that one may thus very easily keep grape-houses constantly stored with healthy fruit-bearing plants, and that the kinds may be changed almost at pleasure. When it happens that too much bearing wood has been trained in, the plants are relieved, and sufficient sun and air admitted, by thus removing two or three shoots; and supposing these to contain each several bunches of some fine sort of grape, they are not lost, but may be ripened, by setting the pots on the side-shelves, or flue trellis, of the pinery, or any hot-house.

212. The proper management of the grape-house has now become an important part of the duty of a gardener. To lay down particular rules in this place is impossible; a few general hints only can be given. A great deal of useful information on this subject may be found in the excellent Treatise on the Culture of the Vine, by Mr William Speechly, London, 1789; and in the Forcing Gardener, by Mr Walter Nicol, Edinburgh, 1809. These and similar books the gardener should study, as containing the results of experience; but many cases will occur, in which he must depend on his own practical knowledge, and be guided solely by his own judgment.

The forcing of the earliest grape-house is often begun in January. Till all the buds be broke, air is daily admitted by the sashes, and the heat is kept moderate, so that the thermometer may indicate only 50° or 55° in the mornings and evenings, when the sun has no influence. The temperature is then gradually raised, in the course of a fortnight or three weeks, to about 70°. When the flowers appear, it is increased nearly to 75°, and the house is frequently steamed, by sprinkling water on the flues, or on the walk when the sun shines, grapes being found to set best in a strong moist heat. The gardener now selects his bearing wood for next year, and trains the shoots to an upper trellis, a foot above the other, and the wires of which are perhaps two feet apart; while he nips off all lateral and superfluous produce, and at the same time shortens the bearing shoots at an inch beyond the uppermost cluster. While the berries are swelling, water is moderately given. Nicol, indeed, recommends, that it should be given liberally till they begin to ripen; but this has been considered as likely to deprive the grapes of their proper raciness and flavour.

The thinning of the bunches deserves attention. This is sometimes neglected; but in many kinds, without this attention, the berries in the middle of the bunch are apt to get mouldy and to rot; and in all cases where thinning is practised, the berries become larger and more equal in size. In the operation of thinning, particular care should be taken that the left hand, with which the bunch is held, be kept cool, and also quite free from perspired matter. For this purpose, the gardener should have a vessel with pure cold water beside him, into which he may now and then dip his hand, to keep it cool and clean. Without this precaution the berries oftener suffer from being handled, acquiring a rusty diseased look, and not swelling freely.

When the grapes approach maturity, all are agreed that no more watering is proper. Air, however, is freely admitted. In general, a proportion of the foliage, especially on the stubs on which the clusters hang, is removed. The fruit ought to remain till it be fully ripe; but this the impatience of the owners seldom permits. When the fruit is all gathered, the stubs which bore it are cut off, and the new shoots are let down from the upper trellis to their proper places. Watering both of border and foliage is now resumed, and the house is usually left fully exposed to the atmosphere. The general pruning is performed from the middle to the end of October, and time is thus given for the healing of the wounds before forcing be again commenced. At this pruning the loose part of the outer bark on the old wood is carefully peeled off, and the whole plant and the trellises are washed with some penetrating liquid, calculated to destroy the minute eggs of insects. For about a fortnight after this severe pruning the house is kept shut, but it is afterwards freely exposed as before.

The management of the late grape-house entirely resembles that of the early, making due allowance for the difference of season. It is not intended for *forcing* the fruit, but merely for supplying the deficiencies of our natural climate in spring and autumn.

As the vinery may remain without its glass-covers for many months in the year, in some places, especially in the south and west of England, the peach-house is formed exactly of the same dimensions; and, when the peach season is over, the glass frames are transferred to the vinery, and, if the blossoms have escaped, a crop of ripe grapes, of the best sorts, is thus procured in September or October, and the new wood is thoroughly ripened.

### *Fig-House.*

213. The fig-house is generally constructed on the same plan as the cherry house, with fig-trees on the back wall trellis, and either dwarf figs, cherries, or apricots in front, the flues being likewise covered with a small trellis for holding pots of strawberries or kidney-beans. A separate hot-house, however, is but seldom erected for the cultivation or the forcing of figs; a few dwarf trees, such as the

brown Italian, and purple Italian, introduced into the peach or cherry house, being by most people thought sufficient. It has been found by experience, that dwarf standard fig-trees, planted in the middle of a vinery, between the flues, and so under the shade of the vines, bear fruit plentifully, ripening both the spring and autumn crops. This may be seen in the vinery which forms a part of the splendid range of hot-houses at Preston Hall near Edinburgh, designed by Mr John Hay.

*The Pinery.*

214. Three sorts of frames, pits, or houses, are required for the successful or extensive culture of the pine-apple: a bark pit, for nursing the crowns and suckers; a low stove, generally called the succession pit, where the plants are kept till they be ready for fruiting; and a pine-stove or fruiting-house.

215. The *Pine-apple* is the *Bromelia ananas* of Linnæus. (belonging to the class and order *Hexandria Monogynia*, and to the natural family *Bromeliæ* of Jussieu.) Some have supposed it to be a native of Africa; but Linnæus considered it as a Brazilian plant. It was introduced into this country as a curiosity about 1690; and Bradley has preserved to us correct information concerning its first cultivation for the sake of the fruit. In 1724, Henry Telende, gardener to Sir Matthew Decker, at Richmond, had forty ananas, which ripened their fruit by means of the artificial heat arising from the fermentation of tanner's bark; and by the year 1730, pine-stoves, of various kinds, were established in all the principal English gardens.

The name *pine-apple* seems to be derived from the general resemblance of the fruit to some large cone of a pine-tree. The fruit may be described botanically as a kind of pulpy scaly strobilus, composed of a number of coadunate berries. In richness of flavour it cannot be surpassed; and it is one of the greatest triumphs of the gardener's art to be able to boast, that this fruit can be produced in Britain in as high perfection as in a tropical climate. Its culture is however very expensive, the plants requiring constant attention for at least two years, very commonly for three.

216. The following are the most approved varieties:

| | |
|---|---|
| The Queen pine. | The King pine. |
| Brown sugar-loaf. | Green pine. |
| Striped sugar-loaf. | Black Antigua. |
| Montserrat. | Black Jamaica. |

The *Queen pine* is perhaps the most common in this country, and in Europe, as it is the hardiest. The fruit is of an oval or rather tankard shape, of a yellowish colour, but the pulp pale. It grows to a large size, sometimes weighing 3lb.

The *Brown sugar-loaf* is of a pyramidal or conical shape, with a yellow or straw-coloured pulp, and brownish leaves. The plants may be distinguished by the leaves having purple stripes on the inside throughout their whole length. The fruit also grows to a large size. Its juice is accounted less astringent than that of some other varieties, and consequently it may be eaten more freely.

The *Striped sugar-loaf* is so named, from its green leaves being striped with purple; in one sub-variety they are prickly, in another smooth. In colour and flavour, the fruit resembles the Queen pine, and it is nearly as hardy.

The *Montserrat pine* is distinguished by the leaves being of a dark brown, inclining to purple on the inside; and by the pips or protuberances of the fruit being larger and flatter than in the other kinds.

The *King pine* is a large fruit, first raised in this country by Miller; its leaves are of a grass green colour; the pulp is hard, and rather stringy, but of good flavour when ripe.

The *Green pine* is not common; when ripe, the fruit is of an olive hue.

The *Black Antigua pine* is shaped like the frustum of a pyramid. The leaves of the plant have a brownish tinge, and fall down; they have strong prickles, thinly scattered. The pips of the fruit are large, often an inch over; it attains a large size, weighing sometimes 3lb. or 4lb.; it is of a dark colour till it ripen; very juicy, and high flavoured.

The *Black Jamaica* is likewise a very large kind, and similar in habits and character to the black Antigua.

217. In gardens of the first order, the pinery is now generally placed in a detached situation, and the three kinds of pits or houses above mentioned conveniently form a continuous range or suite by themselves; the fruiting-house, being higher in the roof, occupies the centre, and the nursing pit and succession house are placed to the right and left.

218. The *nursing pit* is commonly about three or four feet high in front, and between seven and eight at the back wall, or the difference between the height in front and in rear does not exceed one-third of the breadth, whatever that may be. The front and roof are of glazed frames. These pits are generally furnished with small flues; but as a much less degree of heat (from 55° as the minimum, to 65° or at most 70° Fahr. as the maximum) is required in these than in the fruiting-house; sometimes no flues are employed, the heat being trusted entirely to the fermentation of a dung hot-bed, lined when necessary. When flues are used, tree-leaves or tanner's bark are still proper for receiving the pots, and equalizing the heat.

The pine-apple is propagated, by planting either the crowns or tufts which grow on the fruit, or by the suckers which appear on the fruit-stalk, or which proceed from the base of the plant. The crowns are therefore in general returned to the gardener, after having been presented at table attached to the fruit; and they are kept four or five days longer, till the place of separation be healed over or dried; they may however be almost immediately planted, if the parent plant have not received water perhaps for a fortnight before, in order to heighten its flavour. The stocks also from which fruit has been cut, if thought of superior quality, may be encouraged to set out many suckers, by plunging them in a hot-bed, and regularly watering them; such suckers making excellent plants.

Some writers give nice and curious directions for forming a compost for pine-apple plants; but vegetable mould, such as rotted tree leaves afford, may be considered as perfectly good. Even kitchen garden mould which has not been exhausted, answers very well. If old pasture soil be used, it should be mixed with well rotted dung, and laid in heap for a year before being used, during which time it should be repeatedly turned. The pots used for crowns and suckers are three inches in diameter, inside measure, and 4½ deep, for the smaller plants; 4 inches in diameter, and 6 deep, for the larger; but it is much worse for the plants to have pots too large than too small. Dry shivers or chips of broken pots, or clean gravel, to the depth of an inch, are placed in the bottom of the pots. No water is given for a few days, till the plants shew signs of growing. The principal potting is naturally in July and

August, after the fruiting season. Next April, or as soon as the growing season has fairly commenced, the plants are shifted into larger pots, 5 inches in diameter within, and 7 deep. They are shaded by a canvas sheet for a few days, at least during sunshine; and when the plants begin to grow again, water is given both at root and over the leaves with a fine rosed watering-pot. During winter, it may here be remarked, water is given only once a week, or even seldomer; and it is kept for some time in the pit or stove before being applied. To the roots of young plants, dunghill drainings are sometimes supplied. Minute rules for admitting air are laid down by Speechly, Macphail, Nicol, and Abercrombie: these should be studied by the gardener; but much must still depend on his own experience and sagacity.

219. The *succession pit* resembles in structure the nursing pit. In this, during the second autumn and winter, the plants are kept merely vegetating. If they be maintained in health, it is not expected that they should increase in size, unless perhaps that, having more room, they may swell at bottom: the temperature therefore is kept rather lower than in the nursing pit. When plants are shifted into this, which is commonly when they are about a year old, the business should if possible be completed in one day. The pots now used are 24's, or 7 inches across, and 9 deep. Any injured parts of the roots are carefully cut off, and a few of the oldest or lowest leaves are removed.

220. In the *fruiting-house*, more room, greater height, and at the same time a higher temperature, are required. The pots here used are from 8 to 10 inches in diameter, and 10 inches deep. In the bottom of these fruiting-pots, it is better to put half rotted grass-turf than shivers or gravel. From the time that the plants begin to shew fruit, the temperature is not suffered to fall below 65° Fahr.; it is kept generally at 75°, or at least above 70°: in sunshine it is allowed to rise to 85°, or even 95°, as fresh air can thus be more freely admitted. Water is given very cautiously, sufficient only to keep the plants healthy, but not to injure the flavour of the fruit. Pine-apples should be cut a short time before they attain complete maturity, or be dead ripe. When the fruit changes colour, in most varieties when it becomes greenish-yellow or straw-coloured, and when it also diffuses its peculiar odour to some distance, it may be considered as fit for cutting.

221. A clearer idea of the course of culture, in the nursing pit, succession pit, and fruiting-house, may perhaps be obtained from the following compendious view of the operations, suggested by Abercrombie, in which specific days or months are assumed, merely in order more distinctly to mark the anniversary or relative periods.

NURSING PIT.

1816. Aug. 15. Crowns or suckers planted.
—— Oct. 30. If the plants, from rapid growth, require more room, some are removed to another pit, and the remainder set at increased distances.
1817. Mar. 30. Such plants as need it, are shifted into larger pots. Plants of the same standing are now distributed to houses where the treatment differs, as the plant is expected to fruit at the end of two or of three years. It may be noticed, that the large varieties, such as the black Antigua and black Jamaica, always require three years culture; and that crown and fruit-stalk suckers are seldom so forward as those from the base or root of the plant.

| *Three-year fruiting plants.* | *Two-year fruiting plants.* |
| --- | --- |
| NURSING PIT *continued.* | SUCCESSION PIT. |
| 1817. May. Plants intended to complete a year in this pit, are repotted; having the ball of earth shaken away, and the old root-fibres pruned off. | 1817. Mar. 30. Forward plants from the nursing pit are put into larger pots, and brought for culture here. |
| | —— May or June. Succession pines are sometimes intermediately shifted without disturbing the balls of earth. |
| SUCCESSION PIT. | |
| —— Aug. 15. Plants that have been in the nursing pit the previous year, are shifted and transferred to this house. | |
| FRUITING HOUSE. | FRUITING HOUSE. |
| 1818. Aug. 15. Plants which have remained one year in the nursing pit, and a second year in the succession pit, are removed to this house. | —— Aug. 15 Plants from the succession pit, after being only *one* year in the first and second stages, are shifted into the largest pots, and placed here. |
| 1819. Aug. 1 Such plants ripen their fruit. | 1818. Aug. 1. Such plants afford fruit fit for cutting. |

222 Success in the culture of this fruit, it may be remarked, very much depends on two circumstances; on giving them plenty of room in the nursery pit and succession frame, so that the lower part of the plant may swell out and increase in bulk, without being drawn up; and on keeping the fruiting plants in a continued healthy or vigorous state: for this last purpose, early in the spring the tan of the fruiting house should be stirred, and a fresh quantity intermixed, so as to raise a new fermentation and accompanying heat. In the different pine-stoves it is found very advantageous frequently to white-wash the plaster, and to repaint the wood work.

223. The plants, especially if weak or not healthy, are subject to the attack of a small species of coccus (*C. hesperidum*, Lin.) commonly called the pine-bug. The insects adhere closely to the leaves, often near the base, and seem almost inanimate. Mr Miller recommends turning the plants out of the pots, and cleaning the roots; then keeping them immersed for four-and-twenty hours in water in which tobacco stalks have been infused: the bugs are then to be rubbed off with a sponge, and the plants, after being washed in clean water and dripped, are to be repotted. Mr Muirhead, a gardener in the north of Scotland, has described a similar mode, (*Scottish Hort. Mem.* vol. i. p. 209,) only in place of tobacco juice he directs flowers of sulphur to be mixed with the water. With a bit of bass-mat fixed on a small stick and dipt in water, he displaces as many of the insects as he can see. He then immerses the plants in a tub of water, containing about 1 lb. of flowers of sulphur to each garden-pot full. They remain covered with the water for twenty-four hours, as desired by Miller. They are then laid with their tops downwards, to dry, and are repotted in the usual manner. What share of the cure, in either of these ways, may be due to the sulphur or to the tobacco liquor, does not clearly appear; the rubbing off or loosening the insects is evidently important; and it is not unlikely that immersion, in simple water, so long continued, may alone be sufficient to destroy them. Indeed, the experience of one of the best practical gardeners in Scotland (Mr Hay) leads him to conclude, that even moderate moisture is destructive to these insects. During many years, he regularly water-

ed his pine-plants over head with the squirt, during the summer months: this was done only in the evening; it never injured the plants; and the bug never appeared upon them.

*The Orangery.*

224. This is merely a green-house, and indeed is generally employed in part for protecting ornamental plants and shrubs. In a few places the orange trees are planted in the border soil, in the manner of shrubs in a conservatory. The genus *citrus* includes not only the orange, but the shaddock, lemon, citron, and lime: it belongs to the class and order Polyadelphia Polyandria, and natural order Aurantiæ of Jussieu. In warm countries the trees rise to the height of perhaps fifty feet; here they seldom exceed the size of shrubs. The species may readily be distinguished by the petiole or leaf-stalk: in the orange and the shaddock, this is winged; in the lemon, citron and lime, which are considered as varieties belonging to one species, it is naked. The orange and shaddock fruits are almost spherical, and of the yellowish-red colour known by the name of orange; the lime is spherical, but of a pale yellow; the lemon is oblong, with a nipple-like protuberance at the end; the citron is oblong, and distinguished by having a very thick rind.

225. Of the *Orange* (*Citrus aurantium*, Lin.) there are two principal varieties; 1. The sweet orange, including the China orange, the Portugal orange, and similar kinds; and, 2. The bitter orange, including the Seville orange, and other varieties called *bigarades* by the French. The Seville orange-tree produces its fruit more readily in this country, and has larger and more beautiful leaves than the China orange: the former is therefore more generally cultivated, but the latter also succeeds very well in some places. There are, besides, the willow-leaved or Turkey orange, the dwarf or nut-meg orange, the double-flowering, and many other varieties, some with the leaves variegated yellow and white.

Sir Francis Carew is said, by Mr Lyson, (*Environs of London*, vol. i.) to have introduced orange-trees into this country, in the reign of Elizabeth; but whether he brought plants, or raised them from the seeds of oranges brought home by Sir Walter Raleigh, is not clear; it may be remarked, however, that it has long been known from experience, that in this climate orange plants raised from seed shew no inclination to produce fruit; whereas Sir Francis Carew's yielded plenty of fruit. What is further curious in the history of these early orange trees is, that they were planted in the open border, and protected during winter merely by a moveable shed. They grew on the south side of a wall, not nailed against it, but at full liberty to spread; they were 14 feet high, and extended about 12 feet wide. They were finally cut off by the great frost of 1740, after having stood a century and a half. Professor Martyn informs us, (Miller's *Dict.* in loco), that they had, the year before, been inclosed in a permanent building like a green-house; and he very justly remarks, that the dampness of new walls, and the want of the usual quantity of free light and air to which they had been accustomed, might probably have killed them, even had the great frost never occurred.

226. The orangeries of this country are supplied in two ways; either by plants raised from the seed, and budded, inarched, or grafted by our nurserymen and gardeners; or by small budded trees imported in chests from Italy.

The best stocks are common citrons, this tree making strong straight shoots, and receiving readily either orange or shaddock buds; they are procured by sowing ripe citron seeds. Next to these, Seville orange stocks are desirable; the seeds may be taken from rotten Seville oranges, which are generally the ripest. They are sown in pots sunk in a bark hot-bed, and, about two months afterwards, each plant is transferred to a small flower-pot, about five inches in diameter. They are gradually hardened, by admitting air, till the end of September, when they are transferred to the green-house for the winter. Next spring they are forwarded, by being again plunged in a moderate hot-bed; but after midsummer they are hardened as much as possible, and in August they are ready for budding. The buds should be taken from trees in a bearing state, and which are known generally to afford a good crop, preferring buds from round shoots to those from flat shoots. The plants are again preserved in the green-house through the winter; and in the following spring, they are once more planted in a gentle hot-bed, the stocks at the same time being cut off about three inches above the buds: By this means, the stem of the future tree generally grows up straight in one season.

Trees raised in the way now described, require no less than fifteen or sixteen years to attain the size of those imported in boxes from the Mediterranean. The latter, if they be good plants, if they have not suffered greatly from the voyage, and if they be properly managed on their arrival, will bear fruit in three or four years. But it is chiefly the shaddock and citron that are thus imported. Those stocks which have two buds inserted in them, it is observed, make finer heads than such as have one only. To recover the trees after their being so long out of the earth, requires some care and attention: they are planted in fine vegetable mould, in pots having channel to the depth of some inches in the bottom, so as to drain away superfluous moisture, and are placed in a hot-bed; at the same time, hay bands are wrapped round the stems, to prevent the sun's rays from over-drying the bark.

227. Young orange trees are every season repotted, generally in April, for successive years, till they produce fruit. The earth or compost must be prepared at least a year before, so that any dung mixed with it may be very completely rotten. When the trees become large, that is, six or eight feet in height, they are generally planted in wooden cases or tubs. When old orange trees have been mismanaged, it is found very useful to plunge them into a hot-bed: this is accomplished by planting them in baskets, and sinking these into the bed. The baskets are made of less size than the tubs, and when the trees are restored to these, the baskets are cut away, and the empty space filled with prepared earth. It is a rule to remove, every season, a considerable portion of the earth, taking great care not to injure the roots; its place is supplied with a fresh quantity of the prepared soil.

228. In the orangery, during winter, the trees receive regular but moderate watering, and as much free air as the nature of the season will permit. In May, they are removed to the open air: the place should be sheltered from high winds, and it is found best that the plants should be exposed only to the morning and afternoon sun, and shaded from the mid-day glare and heat. Here they remain till about the middle or near the end of October. They produce their pure white and very fragrant flowers in June; and after the first season of flowering, blossoms and fruit are seen together on the same plant, the latter remaining a year or fifteen months on the tree before it be ripe. The clusters of blossom and fruit are thinned progressively, as there seems to be occasion.

In different places of England, Seville orange trees have of late been planted in the open border, in emulation of Sir Francis Carew's trees, and covered during winter with moveable glass frames. It is found generally indispensable, however, that the walls should be flued, and that some slight fire heat be in this way afforded during severe frosts. The bottom of the border on which orange trees are planted must absolutely be dry; it is necessary, therefore, to lay at least two feet of lime rubbish, or some similar material, beneath the border soil.

229. The *Shaddock* (*Citrus decumana*, L.) is the pampelmous of the French, Delaunay however describing the *chadec* as a large variety of *C. aurantium*: the denomination *Shaddock* was given from the name of the English officer who first conveyed the plant from the East to the West Indies. It is managed like the orange tree, but is somewhat more tender, and must be treated accordingly. In a well-arranged orangery, however, and under the care of a judicious gardener, it produces large and ripe fruit. Even in Scotland this is the case; as at Woodhall, near Hamilton, the seat of Mr Campbell of Shawfield.

230. The *Citron* (*Citrus medica*, L.) is also cultivated like the orange; but being rather more tender, must be less early exposed in the spring, and sooner put under glass in the autumn. The summer situation should be the warmest and most sheltered in the garden. There are several sub-varieties of the citron, particularly one with very large fruit, the *poncire* of the French.

231. The *Lemon* is generally budded or inarched on a citron stock. Its culture is the same as that of the orange; but it is more hardy than that species, and requires more free air during winter. It should also be watered somewhat more liberally. In some parts of England, lemon-trees succeed very well in the open border against south walls: they are sheltered during winter by moveable glass frames, and produce plenty of large fruit, making a pleasant variety on the wall.

232. The *Lime* is propagated and treated much in the same way as the lemon.

233. Having thus given a general account of forcing houses, or hot-houses for producing fruit, taken separately, we shall now describe a range or suite, and at the same time shall illustrate what we say by reference to the plans, elevations, and sections, contained in Plates CCCX. and CCCXI. The magnificent suite of glazed houses represented in the former Plate, it will be observed, is by no means ideal, but exists in the garden of Dalmeny Park, the seat of the Earl of Rosebery near Edinburgh; and the accuracy of the plans may be relied on, Mr Hay, the designer employed at Dalmeny, having, with permission of the noble proprietor, favoured us with them. We shall at the same time give a short description of the garden, and particularly of the walls, as illustrative of some improvements in this branch of horticulture introduced by Mr Hay.

234. The garden at Dalmeny Park lies on the face of a bank having a considerable declivity to the south and southeast. It is bounded on the north by a low hill crowned with trees, perhaps about 40 years old; on the west, by rising ground with trees of the same standing; and on the east, by hollow marshy ground, likewise covered with trees. On the south flows a little rill, the bed of which terminates the slope on which the garden is placed: from this lowest point the ground rises gradually to the south, to some height. Part of this rising ground on the south side of the streamlet is included within the ring fence which surrounds the garden, and is laid out in shrubbery and parterres; through these the walk from the house to the fruit-garden is conducted. The soil of the lowest part consists chiefly of bog or peat earth, admirably adapted for the growth of American shrubs, such as rhododendrons and kalmias. The garden contains about two Scottish acres within the walls. The fruit-tree borders are 18 feet wide, and the walks seven feet broad; the soil beneath the gravel of the walks was prepared with the same care as that of the borders. The walls in general are 14 feet high; the east wall is somewhat more. They are built of bricks manufactured at Leven in Fife, and regular bricklayers were brought from Newcastle for the purpose of rearing them. The whole extent of the south wall, 361 feet in length, is flued, the heat being supplied by twelve furnaces placed on the north side of the wall, six on each side of the central door. The tops of the furnaces are covered with flags, which are on the same level as the soil of the garden; and the stock holes or entrances to the furnaces have hatchway covers, in which are two ventilators to admit air. In this way the furnaces produce no disagreeable appearance. The trees on this wall may, at the same time, be covered with the osnaburg canvas mentioned in § 84. From the corners of the walls, where they meet at right angles, a wall is extended diagonally about 17 feet. This extension is found very useful in breaking the force of the wind when ranging along the walls. At the same time it does away in a considerable degree the formal box shape of the garden, when viewed from the higher grounds in the neighbourhood. The apex of the projecting wall is rounded: here a jargonelle pear-tree is planted; the branches are trained to both sides of the wall, and the fruit of course ripens at different times.

235. The contrivance for watering or washing the foliage of the wall-trees in this garden deserves particular notice. Water is supplied to the garden from a reservoir, situated on an eminence a considerable height above the garden walls. Around the whole garden, four inches below the surface of the ground, a groove between two and three inches deep has been formed in the walls, to receive a three-quarter-inch pipe for conducting the water. About 50 feet distant from each other are apertures through the wall, two feet and a half high and ten inches wide, in which a cock is placed, so constructed, that on turning the handle to either side of the wall, the water issues from that side. It has a screw on each side, to which is attached at pleasure a leathern pipe, with a brass cock and director, roses pierced with holes of different sizes being fitted to the latter. By this contrivance all the trees, both outside and inside the wall, can be most effectually watered and washed in a very short space of time, and with very little trouble. One man may go over the whole in two hours. At the same time, the borders, and even a considerable part of the quarters, can be watered with the greatest ease when required. The conveniency and utility of this contrivance must at once be perceived by every practical horticulturist. The same plan of introducing water is adopted in a garden which Mr Hay planned and executed for Lord Viscount Duncan at Lundie House near Dundee; and, after the experience of several years, it has been greatly approved of. The water at Lundie is conveyed to the garden from a considerable height, and is thrown from the point of the director with great force and to a good distance. A sketch of the cock, pipe, and director, is given in Plate CCCX. Fig. 6; *a* the cock; *b b* the leathern pipe; *e* the director.

236. In the middle of the north wall of the garden is the great range of hot-houses, consisting of seven, a central one, and three on each side. The entire suite extends from east to west 181 feet. The elevation of this fine range is seen in Plate CCCX. Fig. 2. The houses differing considerably in breadth, the eye is not offended with monotonous uniformity; and the addition of a central door, with a diamond-trellis arch, ornamented with tender and

showy climbing plants, is a great improvement in point of appearance. The ground plan of these houses is given at Fig. 1. of the same Plate. The middle division A, with those on the right and left of it, B and C, are peach-houses. On the back wall are placed trellises, to which the principal peach-trees are trained. Small trees are also trained on low sloping trellises in the front, over the flues. The farthest east division D, is what is called a *Double Peach-house;* peach trees being trained on the back wall as in the other houses, and likewise in front on a wire trellis on the roof of the house, reaching upwards as far as the first or under sash only. The trees on the front part of the house may be forced before those on the back wall. To accomplish this, the upper sashes of the house are kept off, thus admitting air freely to the trees on the back wall; while meantime the front trees are inclosed within the first two returns of the flues, by means of moveable shutters made for the purpose, one of them being placed on hinges, and used as a door. Hence the name of Double Peach-house. The partition remains only until the fruit be set; at which time it is removed, and the roof-sashes put on. By these means the fruit season in this house is protracted a considerable time, perhaps a month or more. Fig. 5. in Plate CCCX. is a section of this double peach-house.

The other three divisions of the range, E, F, G, are grape-houses. The back walls are all covered with trellises. A vine is planted in the middle, and trained on the trellis at the top of the house, where in general there is plenty of light in the early time of forcing. The lower part of the trellis is covered with fig-trees, which, as already mentioned, § 213. have been found to succeed very well in such situations. Fig. 3. Plate CCCX. is a section of division F.

In all the houses of this suite, air is given by moving the upper sashes by means of weights and pulleys placed in a cavity in the back wall, as seen at *a a a*, in the sections, Figs. 3, 4, and 5.

Into each of the hot-houses is introduced a three-quarter-inch pipe, coming from an inch one, which passes along the back of the walls. The cocks are of the same kind as those in the walls already described; and the directors, when screwed upon them, water the houses with very little trouble, and are exceedingly useful in keeping under the red spider, and other insects.

237. On the north side of this range, opposite to the middle hot-house, is a mushroom-house, constructed on Oldacre's plan, (to be afterwards described). It has a large and a small pit, with four shelves on the back wall, and three shelves on each of the two ends, all of which may be used for the purpose of raising mushrooms, either at the same time, or in succession. The large pit is partly filled with earth, and kitchen vegetables are kept in it in time of severe frost. Sea cale can also occasionally be forced in this pit. Fig. 4. Plate CCCX. is the section of the mushroom-house, and also of the middle peach-house, the ground plan of the mushroom-house being at H, and of the peach-house at A.

238. On the east side of the garden is situated the melon ground. The garden wall is extended on the north of it to the length of 152 feet, of the same height as the other walls, and flued like the rest of the wall having a south aspect. The pine-stoves are situated here. The ground on which they stand falls considerably from north to south. The furnaces are placed on the south side of the stoves; and, on the same side, there is a narrow nursing pit, four feet broad, the whole length of the house. This pit may, at pleasure, be divided, at the furnaces, into three divisions, D, D, D. The glass-roof of the pit covers the top of the furnaces, and from thence heated air is introduced, by means of apertures with dampers, into either pit as it may be wanted. Heated air can also be admitted from the stove to the small pit, by means of openings in cast iron doors, which can be shut when required. When still more of the warm air is wished to be communicated from the stove to the small pit, the doors are made to lift out altogether, and as the front flue of the stove passes these doors, the heated air has free access to rush in; or it can be admitted from the vacuities between the flue and front wall. As the tan in the small pit is of no great body, and cannot long maintain its heat, the front of the pit is built of brick, with pillars and holes similar to a pigeon house; and there is an inclosed space in front of it, to receive a lining of warm dung, when the heat is wished to be increased. This lining is covered over with flooring, which forms part of the walk, tends to prevent the dissipation of the heat, and gives the whole a neat and clean appearance.

The spaces over the top of the furnaces can at pleasure be converted into distinct or separate forcing places, by putting in the covers of the dampers, and fixing two wooden divisions across, at the extremities of the furnaces. In these places, potatoes may be forced in early spring; or, if a taste for fine flowers be indulged, the single and the double Cape jasmine, (*Gardenia florida*, L.) which are not easily brought to blossom, may here be made to flower, by placing the pots among wet mosses, (*hypnums*,) the moist heat thus supplied proving very congenial to the plant. From the spaces over the top of the furnaces the heated air can at pleasure be directed into either of the two succession houses, being admitted by removing one or other of the covered dampers at *d*, *d*, Fig. 1. Plate CCCXI.

There are niches along the back wall of the pine-stove, nearly opposite to the middle of each sash. They are narrow on the outside, but are bevelled inwards to at least double their exterior width. The bevelled sides are plastered, and covered with a trellis; on these, grape vines are trained, the principal shoot, after reaching the roof, being conducted down the rafter, as far as the first row of pine plants in the back of the pit. To these recesses two sets of shutters are adapted, one for the outside, the other for the inside. During winter the outer shutter is removed, and the inside shutter employed. The vine, after being pruned, is led without, and fixed there during winter, exposed to the cold of that severe season. When brought in to be forced, the inner shutter is of course removed, and the outer shutter put in. The time of forcing these vines may thus, in a great measure, be regulated by the gardener, and made to suit the conveniency of the family. Fig. 1. Plate CCCXI. is the ground-plan of this pine-stove. A is the first succession-pit, containing nine sashes; B the second succession-pit, with ten sashes; and C the fruiting-pit, with eleven sashes. Fig. 2. is the elevation. Fig. 3. is the section; and it will be observed, that, for the sake of distinctness, this section is drawn to an enlarged scale, nearly double that employed in drawing the ground plan and elevation of the stove, Plate CCCXI. At *k* is a moveable gangway, eighteen inches broad over the glass roof of the narrow pit, for giving access to the front of the stove. It may be mentioned, that there are two returns of the flue beneath the pathway at the back of the pit. The heated air is drawn from between these two flues by means of cast metal covered dampers, *b*, *b*, &c. in Fig. 1,; the covers being only put on while the workmen are changing the tan in the pit, or on similar occasions. The small holes seen in the back wall of the ground plan, Fig. 1. *a a*, &c. communicate with the cavities of the flue on the side next to the back wall. Those seen in the *curb* or back wall of the tan-pit *c c*, &c. communicate with the cavity of the flue next to it; and those in the path-way *b b* with the cavity between the flues. In this way, heated air is drawn from the sides of the flues at thirteen places on the back wall of the house, and at ten places on the *curb* of the pit.

The line *e f g h i*, Fig. 3. in Plate CCCXI. extended to the north wall, shews the declivity of the ground on which the pine-stoves are placed. Nearly opposite to the door in the back wall of the pine-stove, there is a door in the garden wall, leading to the pine-shed, where the plants are kept in time of shifting. In front of the pine-stoves, it may be noticed, are situated the general forcing-pit, the melon-pits, and the cucumber frames.

Before leaving the subject of glazed houses, we may notice some improvements which have of late years been proposed.

239. Mr Knight remarks, that where sunshine and natural heat do not abound, the form which admits the greatest quantity of light through the least breadth of glass, and which affords the greatest regular heat with the least expenditure of fuel, must be the best. It is evident that the sun's rays ought to fall as perpendicularly as possible on the glass roof; because the quantity of light which glances off without entering the house, must be inversely proportionate to the degree of obliquity with which it strikes upon the surface of the glass. Mr Knight made many experiments to ascertain by what elevation of the roof the greatest quantity of light can be made to pass through it; and he found that in latitude 52°, the best angle of elevation is 34°. But it cannot be denied, that the rays of the sun will fall, in a directly perpendicular direction, on this inclined plane, only twice in the year, and then for only very short spaces of time: at all other periods, they must fall in an inclined direction, and never perpendicular to the plane of the glass. Without expecting, therefore, that the rays will ever fall precisely perpendicular upon it oftener than twice in the year, it is of importance that they should do so as much as possible, during those periods when the influence of the sun is most desired. Mr Knight, (in *Hort. Trans. Lond.* vol. i. p. 100.) and the Rev. Mr Wilkinson (same volume, p. 162.) do not agree as to the proper inclination of the glass-roof: instead of 34°, proposed by the former, the latter would have the angle 45°. It seems unnecessary to detail the reasons assigned by either writer.

240. It has been remarked by Sir George Mackenzie, that if a form for the glass roof can be found, such that the rays will be perpendicular *to some part of it* during the entire period of the sun's shining, not on two days, but on every day of the year, that form must be considered the best. This form is to be found in the *sphere*; and he proposes the quarter segment of a globe, or a semi-dome; though, to catch the sun at all times, the segment would have to correspond with the greatest segment of the circle which the sun describes. He does not propose to bring each pane of glass into the form of a small segment of a sphere; this would not only be expensive, but unnecessary. The size of a glazed house of this kind, can scarcely, with propriety, exceed a radius of fifteen feet, that is, thirty feet of length for training. The plan, elevation, and section of a vinery, constructed on the principles thus suggested by this ingenious and scientific horticulturist, have been published by the London Horticultural Society, in the second volume of their Transactions; and in Plate CCCXII. we have given these, with considerable improvements since made by the author. It has been found, that the frame for the glass-roof may easily be formed of ribs of hammered iron; each rib consisting of three slips of iron, such as shewn at full size at Fig. 4. The ribs are fixed in an iron plate at the bottom. The distance between them at the base, is about fifteen inches; and when the gores contract to half that width, every alternate rib may stop. The word *gore*, we may remark, is that commonly used for a slip of any material, so cut, as when joined to others, to form a globe or any round figure. The frame-work might also be made of wood; but the wrought iron is not only much cheaper at first, but far more durable. The under frames may be about thirteen feet high; they are rivetted into an iron ring at top, and made fast all round to the coping and upright wall. Iron rods may be placed for supports at *x*, *x*, *x*, *x*, Fig. 3. if thought necessary. The width of the panes at the bottom is about a foot, diminishing to six inches at the second set of ribs; when they begin again at one foot, and contract upwards to four inches. Air is admitted by sliding shutters, which may be glazed, if thought proper, in the parapet wall in front; and also by wooden shutters, moving on pivots, and opened or shut by means of cords along the back wall; and by windows in the pediment roof. The glass-roof itself is immoveable; but the upper part of it may be made into moveable sashes, if required, by forming a sufficient number of ribs with grooves, and fixing stay rods on the under sashes, to receive the upper ones when let down; and Sir George Mackenzie mentions, that, from viewing the structure of the roof of Short's old observatory at Edinburgh, he is convinced that the glass semidome might be made in two parts, and placed on rollers, so as to expose, at pleasure, every plant in the interior to the direct influence of the sun. If it is wished at times, to defend the plants from the sun, a *gore* of canvas may be so contrived as to cover one-half of the glass. The general appearance of such a house (as seen in the elevation, Plate CCCXII. Fig. 1.) is doubtless highly elegant; and it seems pretty evident, that several such houses, tastefully disposed in a garden, would have a much finer effect than one great range, although the latter must necessarily be more economical. Mr Knight, we understand, highly approves of this invention, and is of opinion that it will answer every purpose, better than any form hitherto contrived.

242. It may here be mentioned, that Mr Robert Fletcher, at Bonnyrig, near Edinburgh, a good many years ago, constructed a grape-house, in the form of a regular polygon of 24 sides, having a base 24 feet in diameter. A thin brick wall, two feet high, passes around, forming the proper angles: on this wall rest the couples which support the central or flat part of the roof, which is eight feet in diameter. An iron ring connects the couples at the base as well as at the top. The length of the couples is 10 feet 3 inches. Between these are glazed sashes, 3 feet wide at base, and tapering to 1 foot at top. In this way the ceiling is 8 feet 6 inches from the ground, and the sashes incline at an angle of 40°. The door of the house is to the north; the furnace close by one side of the door; the flue makes a circuit around the house at the distance of 2½ feet from the wall, and the smoke escapes on the other side of the door. Air is admitted, as wanted, by means of three ventilators on the south-west side; but in point of fact air can pass in by many crevices, particularly at the flat part of the roof, and no putty has been used in glazing. The brick wall being founded merely on the surface of the ground, the roots of the vines pass under it in any direction. The soil is dry and rather shallow. In the end of June, Mr Fletcher forms a heap of vegetables, commonly the weeds from his garden, in the centre of the floor of the house: when this heap begins to decompose, some degree of heat is produced, a good deal of vapour rises, and nutritious gases are exhaled: the heap is occasionally fed, so as to keep up the fermentation till about the middle of September. In this house, and under this sort of management, has this ingenious person, for a number of years, raised very good crops of grapes of different sorts, particularly the black Hamburgh, the Lombardy, and the white sweetwater, the berries of all these kinds becoming large and of high flavour.

243. It may also be noticed, that Mr Henderson, nurse-

ryman at Brechin, has constructed a small hot-house, which he styles the *triple meridian*. The narrow end of it is placed to the south, and the roof, which is ridge-shaped, is inclined in the same direction, by a slope of one foot in six. In consequence of the position of the house, one side has the sun's rays approaching to perpendicular at 9 A. M. and the other at 3 P. M.; and, on account of the slope to the south in the roof, the sun's rays are enjoyed partially all the time he is above the horizon. Air is admitted by ventilators. After several years trial, Mr Henderson has found such a construction to answer all his expectations.

If melons be the crop raised, no furnace is necessary. In place of fire heat, the warmth arising from the fermentation of weeds, or a mixture of grass and rushes, is sufficient; proper chambers for holding these, and enabling them to communicate their heat, being prepared within this house. The employment of refuse vegetables in such a melon-house, or in Mr Fletcher's grape-house, must operate as a premium for the destruction of nettles, thistles, and other weeds.

244. At Lord Mansfield's garden at Scone in Scotland, the hot-houses are constructed on a new plan, inasmuch as they have no *upright* front glass, and all the sashes are *fixed*, or not calculated to slide up and down. Air is admitted by ventilators in front, and at the top of the back wall. The houses are 12 feet high; the back wall two feet higher, or 14 feet; and the front or parapet wall only two feet. The advantages of this plan seem to consist in saving the expence, at first, of upright wooden rafters or pillars, and in preventing the breakage of glass, which must to a certain extent be occasioned by the moving of sashes up and down. But it is not to be concealed, that these immoveable sashes are attended likewise with some disadvantages. A liberal circulation of air is sometimes necessary to the health of the young fruit, which, without it, drops off at the time of the first swelling; and an equable exposure to the air is highly important for communicating flavour to peaches and nectarines when just approaching to ripeness. Air admitted, however, only by openings in the front parapet and in the top of the back wall, must in some measure form currents, which, as formerly remarked, (§ 209.) are seldom desirable. Even in avoiding injuries to the glass, the advantages cannot be very considerable, particularly if the moveable sashes be drawn up and down in a steady manner by means of pulleys and weights. Whoever erects a house with a glass roof, must of course lay his account with occasional accidents, whether the roof be fixed or moveable, and one would be apt to think, that the repairs of panes accidentally broken on fixed roofs, could scarcely be accomplished without very considerable risk of increasing the damage, in clambering over them with ladders.

*Gathering and keeping of Fruits.*

245. Fruits in general should be gathered in the middle part of a dry day: not in the morning, before the dew is evaporated, nor in the evening, when it begins to be deposited. Plums readily part from the twigs when ripe: they should not be much handled, as the bloom is apt to be rubbed off. Apricots may be accounted ready when the side next the sun feels a little soft upon gentle pressure with the finger. They adhere firmly to the tree, and would over-ripen on it. Peaches and nectarines, if moved upwards, and allowed to descend with a slight jerk, will separate if ready; and they may be received into a tin cup or funnel lined with velvet, so as to avoid touching with the fingers or bruising. If this funnel have a handle two or three feet long, the fruit may be gathered with it from any low or ordinary wall. The old rule for judging of the ripeness of figs, was to observe if a drop of water was hanging at the end of the fruit; a more certain one is, to notice when the small end becomes of the same colour as the large end. The most transparent grapes are the most ripe. All the berries on a bunch never ripen equally; and it is therefore proper to cut away unripe or decayed berries before presenting the bunches at table. Autumn and winter pears are gathered, when dry, as they successively ripen. The early varieties of apples begin to be useful for the kitchen in the end of June; particularly the codlins and the jenneting; and in July they are fit for the dessert. From this time till October or November, many kinds ripen in succession. The safest rule is to observe when the fruit begins to fall naturally. Another easy mode of ascertaining, is to raise the fruit level with the foot-stalk; if ripe, it will part readily from the tree: this mode of trial is also applicable to pears. A third criterion is to cut up an apple of the average ripeness of the crop, and examine if its seeds have become brown or blackish; if they remain uncoloured, the fruit is not ready for pulling. Immature fruit never keeps so well as that which nearly approaches maturity; it is more apt to shrivel and lose flavour. Winter apples are left on the trees till there be danger of frost: they are then gathered on a dry day.

In all cases the fruit is plucked with the hand, and great care taken to avoid bruising. For collecting the fruit from half standard and full standard trees, a step-ladder is employed. This ladder may be so contrived that the back shall come away by removing a bolt. The same ladder may thus be used for high wall-trees; but in this case two rods of iron should be made to project six or eight inches from the top, to keep it from resting on the branches of the trees, and injuring them.

246. Hitt's method of keeping pears may be shortly mentioned. Having prepared a number of earthen-ware jars, and a quantity of dry moss (different species of hypnum and sphagnum,) he placed a layer of moss and of pears alternately till the jar was filled; a plug was then inserted, and sealed around with melted rosin. These jars were sunk in dry sand to the depth of a foot; preferring a deep cellar for keeping them, to any fruit-room.

247. Miller's plan may also be noticed. After sweating and wiping, in which operations great care must be taken not to bruise the fruit, the pears are packed in close baskets, having some wheat-straw in the bottom and around the sides to prevent bruising, and a lining of thick soft paper to hinder the musty flavour of the straw from infecting the fruit. Only one kind of fruit is put in each basket, as the process of maturation is more or less rapid in different kinds. A covering of paper and straw is fixed on the top, and the basket is then deposited in a dry room, secure against the access of frost, "and the less air is let into the room, the better the fruit will keep." A label should be attached to each basket, denoting the kind of fruit; for the basket is not to be opened till the fruit be wanted for use.

248. Mr James Stewart, an experienced gardener at Pinkie, in Scotland, has long preserved his choice apples and pears in glazed earthen-ware jars, provided with tops or covers. In the bottom of the jars, and between each layer of fruit, he puts some pure pit sand which has been thoroughly dried on a flue. The jars are kept in a dry airy situation, as cool as possible, but secure from frost. A label on the jar indicates the kind of fruit; and when this is wanted or ought to be used, it is taken from the jars, and placed for some time on the shelves of the fruit-room. The less ripe fruit is sometimes restored to the jars, but with newly dried

sand. In this way he preserves colmarts and other fine French pears till April; the terling till June; and many kinds of apples till July, the skin remaining smooth and plump. Others, who also employ earthen-ware jars, wrap each fruit in paper, and in place of sand use bran.

249. Mr Ingram at Torry in Scotland, a very intelligent gardener, has succeeded uncommonly well in the management of the fruit room. For winter pears he finds two apartments requisite, a colder and a warmer; but the former, though cold, must be free of damp. From it the fruit is brought into the warmer room as wanted; and by means of increased temperature, maturation is promoted, and the fruit rendered delicious and mellow. Chaumontels, for example, are placed in close drawers, so near to a stove, that the temperature may constantly be between 60° and 70° Fahr. For most kinds of fruit, however, a temperature equal to 55° is found sufficient. The degree of heat is accurately determined, by keeping small thermometers in several of the fruit-drawers, at different distances from the stove. The drawers are about six inches deep, three feet long, and two broad; they are made of hard wood, fir being apt to spoil the flavour of the fruit. They are frequently examined, in order to give air, and to observe the state of the fruit, it being wiped when necessary. Mr Ingram remarks, that, in Scotland particularly, late pears should have as much of the tree as possible, even although some frost should supervene; such as ripen freely, on the other hand, are plucked rather before they reach maturity.

250. Winter apples are generally left on the trees till there be danger of frost. They are then gathered, when dry, as formerly noticed; and are laid in heaps, and covered with mats or straw, or short grass well dried. Here they lie for a fortnight or more, to *sweat*, as it is called, or to discharge some of the juice of their skin, which thus contracts in a certain degree. After this they are wiped dry with a woollen cloth, and placed in the fruit-room. Sometimes, when intended for winter dessert fruit, they are made to undergo a farther sweating, and are again wiped and picked; they are then laid singly on the shelves, and covered with paper. Here they are occasionally turned, and such as shew any symptoms of decay are immediately removed. Baking fruit is kept in a close but cool place, where the temperature undergoes little variation. It is found to be advantageous to keep each sort separate. Sometimes apples and pears for baking are kept in baskets or hampers. Thick paper is considered a better material for lining and covering such baskets or hampers than straw, and straw is better than hay.

It may be proper to mention, that some entirely disapprove of the sweating of fruit, affirming that it thereby acquires a bad flavour, which it retains, or at any rate that the natural flavour of the fruit is deteriorated. They consider it better to carry the fruit directly from the tree, carefully avoiding all sort of bruising, and to lay it thinly on the shelves of the fruit-room; afterwards wiping, if it appear necessary. The room, they say, should be dry; but the only use that should be made of a stove is, to take off the damp.

As connected with the forcing department, we now proceed to speak of the culture of the melon under frames placed upon a hot-bed.

### *Melon.*

251. The *Melon* is the *Cucumis Melo*, L.; *Monœcia Monadelphia*; and belongs to the natural order *Cucurbitaceæ*; The genus cucumis affords the rich melon for the dessert; the cucumber well known for its cooling qualities; and the coloquintida of the apothecaries. The water-melon, the squash, and the pumpkin, belong to the same natural family, but to a different genus, Cucurbita, distinguished chiefly by the swelling rim of the seed. The melon has been cultivated in England since before 1570; but the precise period of its introduction is uncertain.

252. Many are the varieties of this fruit, but a few only are worth cultivating: particularly different sorts of Cantaleupe, the Romana, Polignac, oblong ribbed, rock, Portugal, and Salonica. The largest kinds are in general of inferior quality, being valuable chiefly to the market gardener, who finds his advantage in having a large and shewy fruit, rather than one whose only merit consists in being high-flavoured.

The *Cantaleupes* are well known, and generally cultivated. In most of them the outer coat is rough and warty. The fruit is of middling size, rather round than long. There are several subvarieties: one has a greenish pulp; another and more esteemed sort has the pulp of an orange colour: there is likewise a scarlet and a white cantaleupe; besides the black rock cantaleupe, and the netted cantaleupe, the last possessing excellent qualities. The cantaleupe has received its name from a seat of the Pope near Rome, where the fruit was either originally produced, or is supposed to have been so.

The *Romana* is an early melon, small in size, but of fine flavour; and the plants are very plentiful bearers. There are two or three subvarieties, of which the large netted Romana is the best; it is of an oval shape, high-flavoured, and at the same time very solid and ponderous.

The *Polignac* is a rich-flavoured fruit, pretty generally cultivated.

The *Oblong ribbed*, sometimes called the musky melon, is of agreeable flavour, and the plants produce abundantly.

*Rock* melons, or carbuncled melons, are of different sorts; with green pulp, scarlet pulp, black and silver rock.

The small *Portugal* melon is an early variety, not destitute of flavour, and it is produced very plentifully.

The *Salonica* melon was little known in this country till recommended by Mr Knight. Its form is nearly spherical, and without any depressions on its surface; its colour approaches that of gold, and its pulp is pure white. It is allowed to remain upon the plant till it be completely matured, for it improves in flavour and richness till it become quite soft, and even shew symptoms of incipient decay. The consistence of its pulp is nearly that of a water melon, and it is very sweet. A full grown specimen of the fruit generally weighs about 7lb.

253. In the cultivation of the melon, it is a matter of much importance to procure proper seed. Some gardeners are so scrupulous on this point, that they will not sow the seeds, unless they have seen and tasted the fruit from which they were taken. It is proper at least not to trust to seeds which have not been collected by judicious persons. Some make it a rule to preserve always the seeds of those individual specimens which are first ripe, and even to take them from the ripest side of the fruit. A criterion of the goodness and probable fertility is generally sought by throwing them ino a vessel containing water; such as sink are considered as good and likely to prove fertile; those that float, as effete. It is remarked of seeds brought from the continent, that they must have more bottom heat, and the young plants less water, than are necessary for seeds ripened in this country, or young plants sprung from these.

The seeds are seldom sown till they have been two or three years kept; from this age till they be five years old, they succeed very well. The plants produced from such seeds are not so luxuriant, and are therefore more tractable and more prolific. The cause is supposed to be, that the albumen of the seed is deteriorated by the keeping, and the plants thus starved, in a certain degree, at their first germination; the fruitfulness of plants in general being promoted by checking their luxuriance. When gardeners intend to sow seeds which have been kept only for one year, they are in the practice of carrying them for some months in the pockets of their small clothes; the warmth from the body being found to promote the desirable maturation or siccity. If, on the other hand, the seeds have been kept for many years, steeping them for some days in weak oxymuriatic acid (chlorine) might probably tend to excite germination.

254. The seeds are sown at two or three different periods of the season; the first sowing taking place early in February, the next about the middle of March, and another later. They are sown in broad shallow pans, or in common flower-pots sunk to the brim in a small hot-bed, called the seed-bed, covered with a one-light frame. Here the temperature is kept as near as possible to 65°; a little air is given in the day time, but during night the frame is closed, and covered with single or double mats, according to the state of the weather. When the plants are about an inch and a half high, they are pricked into nursing pots, three in each, and placed generally in an intermediate frame of two lights, till they shew one or two of their rough leaves, when they are ready for final transplanting.

255. The melon ground, or quarter in which the melon beds are formed, should have a dry bottom, a free exposure to the south, and be sheltered from the north and east. It is desirable also to have it inclosed by a hedge of yew, beech, holly, or privet; and it is an advantage to keep it under lock and key, no kind of plants being so apt to be disordered or injured by the curiosity of ignorant intruders. In many places, the melon ground is formed in the slip, or on the exterior of the garden; and where this is the case, there is generally a cart access, which, considering the quantity of stable-dung required, proves very convenient.

256. The soil or compost for melons is prepared at least a year before it be used, and, like other composts, it is frequently turned over and thoroughly mixed. Two-thirds of fresh hazel-coloured loam, from the surface of an old pasture, and one-third of rotten cow-dung, or of the remains of old hot-beds, form an excellent soil. This compost is generally passed through a screen; but there is no need for its being made very fine.

257. The site of the hot-beds is scooped out to the depth of a foot, that the surface and lights may be kept low. The bed is generally made between three and four feet high, and the back four inches higher than the front. Stable dung and litter are the usual ingredients of these as of other hot-beds; but some use tanner's bark, in which case it is necessary to have a brick pit, or a strong wooden frame erected. The earth is not put on till the temperature become steady and moderate, which it generally does in the space of a week. The beds are covered with large frames, each having three sashes or lights. These are generally about four feet wide, and six feet in length; but sometimes they are made eight feet in length, by three feet wide.

258. In some places, pits are built with brick in the following manner. After the size of the glass-covers is fixed upon, and supposing that a three-light pit is intended, the brick work is made 3 feet 6 inches deep on the fore-side, and 4 feet 6 inches or 5 feet on the back; the bottom part all around, to the height of 2 feet 6 inches, is built with small openings, the more numerous the better: for this purpose no mortar is used in this part of the building; but above it, mortar is used; the walls are the thickness of brick on bed. If three such pits be required, they are placed one in front of another, at the distance of three feet: the whole is surrounded with a wall, the top of which is six inches higher than the open building of the pits, and so far sunk as that the height may not appear offensive to the eye. The pit is filled with tanners' bark or tree-leaves to a little above the open building, and covered with earth as in the common way; and the vacant space around the outside of the pit, to a little above the open building, is filled with stable dung, or with weeds, in the season when these are to be had; for either of them, in fermenting, produces a sufficient degree of heat. When the heat of this lining is abated, and when a continuance of increased temperature is required, the exhausted matter is removed, and a new lining supplied. It may be proper to add, that the eave of each pit should have a small spout to carry off the water, otherwise the lower side of the bed is apt to become too damp.

259. In laying on the earth on the bed at first, a hillock or ridge is formed in the middle, somewhat more than a foot high, the covering in all other parts of the bed not exceeding two inches in thickness. In the beginning of March the young plants are transferred thither with great care, the breaking of the fibres or bruising of the roots being very detrimental. Some are for transplanting as soon as may be, after the unfolding of the third leaf, or in other words the first true or rough leaf; but the more general plan is, to allow two or three of the rough leaves to shew themselves before transplanting. Others put the plants in separate flower-pots for a few weeks, and afterwards turn them out, with all the earth attached, into the melon frame. One plant to each light is generally sufficient, especially of the cantaleupe, or larger melons; but most cultivators put two plants; and some even crowd three under each light. When four leaves are expanded, the top is by many pinched off, in order to promote the setting out of lateral shoots or runners; but some allow the first shoots to extend the length of five or six joints before *stopping* them. Afterwards the points of these lateral shoots are pinched off, to encourage the putting forth of subordinate shoots, from which fruit is to be looked for. But all shoots that are either very luxuriant or very weak are equally useless, and may be removed. A few reed stalks are often spread thinly over the surface of the beds, for the shoots to run upon.

When the plants have established themselves, earth is gradually added, and pressed close down, till the other parts of the bed be almost on a level with the spots on which the plants are situated. This thick layer of earth has one great advantage; it renders very little watering necessary. When water is given, it should scarcely touch the leaves. The heat is regulated by keeping a Fahrenheit's thermometer within the frame; which should as nearly as possible indicate 70°.

If the beds be in good heat, the frames are generally filled with runners in six weeks, and by this time the roots will have extended to the extremities of the beds. Linings are now added; and these being covered with soil, well trodden down, the roots penetrate into it, and thence draw additional nourishment; while, at the same time, the linings assist greatly in keeping up the heat.

260. As there is little opportunity under a glass-frame for the wind to perform its part in conveying the pollen, careful gardeners generally assist by taking off some fully expanded male flowers, and laying them or shaking them over the female flowers, which are situated on the crown of the embryo fruit. Even without fecundation, fruit will

be produced; but it never acquires perfection, and the seeds of such fruit will not germinate. The different varieties of melons, it may be remarked, should not only be kept in distinct frames, but, if possible, at some distance from each other, to lessen the chance of the pollen of one kind accidentally reaching the stigma of another. One fruit is selected on each principal runner, preferring that which is nearest the stem, or has the thickest footstalk; this is encouraged, while the rest are picked off. If the melon be a small-sized variety, sometimes two are permitted on a shoot. It is a general rule, not to leave more than four or five fruit on each plant, if of the larger kinds; or eight or ten, if of the smaller. A more correct way of estimating, perhaps, is to allow each plant only to carry 20 lb. or 30 lb. weight of fruit. It may be mentioned, that where late melons are wanted, an easy way to procure plants is to take some of the superfluous shoots of the first crop; for the plant grows freely by cuttings.

If water be now given, it should be introduced without touching the stems, leaves, or fruit; it is seldom needed more than once a week, even in dry and warm weather. Great attention is requisite in allowing the plants free air as often as possible. Some have contrived bent tin pipes, connecting with the open air, and passing through the body of dung, by means of which a current of slightly warmed air is introduced even in the worst weather. When the weather happens to be very cold, mats are laid over the frames.

261. In the southern parts of Britain, melons are also raised in hot-beds. The plants are at first under hand-glasses; but the shoots or runners are allowed to spread from under the glass, and cover the hot-bed as the season advances. The beds are hooped over, and when heavy rains threaten, they are closely covered with mats. Frames of oiled paper answer very well for the raising of melons. A kind of paper made from parings of skins, and used for packages, under the name of *leather-paper*, is stronger than common paper, and can easily be made so as to possess equal transparency. The leather-paper seems excellently adapted for the purpose.

A piece of clean tile is introduced below each fruit; and during the course of its swelling, it is not uncommon to turn it gently once a week, that both sides may be equally exposed to the sun's rays. But it should not be oftener turned, for fear of twisting and injuring the fruit-stalk, and so preventing the conveyance of nourishment through it. At this time very little water is given, dryness tending to heighten the flavour, and air is as freely admitted as the weather will permit. When the leaves press against the glass, the frame is raised two or three inches; but leaves should never be cut when it can possibly be avoided. Nicol recommends the removing of those which shade the fruit; but it is doubtful whether the advantage arising from the additional sun-light thus acquired, will counterbalance the detriment occasioned by the loss of leaves, these being organs on which Mr Knight found the success of this fruit most essentially to depend.

The fruit should always be gathered before it be dead ripe. It is known to approach maturity, by its beginning to crack near the footstalk, and by the peculiar rich odour it then emits. It is cut, with all its stalk to it, early in the morning, before the sun has had access to it, and it is kept in a cool place till served up. If melons be deficient in external colour, this may be brought on merely by laying them in the frame for a day or two. Melons should in general be eaten exactly when ripe, or *sharp ripe*, as gardeners call it; but rather a day or two before than after maturity.

262. A late crop of melons from seed is often produced in a flued pit. The seeds from this crop are sown in the beginning of July, and the seedlings are planted out towards the end of the month. Tanner's bark, or tree leaves, afford sufficient warmth at this season: indeed, the remains of the bed of bark or leaves on which early kitchen-vegetables, or tender annual flowers, have been raised in the beginning of summer, a little aided by fresh materials, answer all the purposes. No fire-heat is required till September. In the end of October the melons are ready: they are not equal in flavour, certainly, to those ripened under the brighter and more powerful sun of June and July; but are very acceptable at that season of the year,—the more so, that, owing to the caprices of fashion, those in high life chiefly spend the later months of autumn and the beginning of winter in the country, while they waste the summer amidst the smoke of London. The melons which do not ripen are sometimes pickled like mangoes, and are said to make a very good substitute for these.

263. In the first volume of the London Horticultural Transactions, Mr Knight has given a general account of his highly interesting views on the subject of vegetable physiology, and has illustrated this account, by alluding to the habits of the melon, and the mode of culture best adapted to it. This gentleman's gardener, it appears, had not been previously acquainted with the proper management of the melon, and Mr Knight therefore particularly attended to it himself. Experience soon taught him, (what was previously in some measure known,) that much of the flavour of the fruit depends on the plant possessing efficient foliage, that is, healthy leaves, presenting their upper surface to the light, and remaining as much as possible undisturbed in that position. Free use of pegs is therefore to be made, not only with the view of keeping the shoots in their position, but of preserving the leaves upright; and water is to be introduced without touching the leaves, as already recommended.

*Cucumber.*

264. The *cucumber* naturally follows the melon, being not only a species of the same genus, (*Cucumis sativus*, L.) but requiring pretty much the same sort of culture, only the fruit is produced perfectly well in a lower temperature. It is a tender annual, a native of warm climates. It was early known in this country, but did not come into general cultivation till the middle of the 17th century.

265. The varieties most in esteem are the following:

Early long prickly, (green.)
Longest green prickly.
Early short prickly, (green.)
Dutch or white short prickly.
Cluster cucumber.
Smooth green Roman.
White Turkey cucumber.

The fruit of the *Early long prickly* is from 5 to 7 inches long, of a green colour, with few prickles. The plant is a good bearer; and, upon the whole, this is accounted the best cucumber for the general summer crop, the pulp being very crisp and pleasant.

The fruit of the *Longest green prickly* is from 7 to 10 inches in length; it has a dark green skin, closely set with small prickles. This is a hardy sort, but does not come early.

The *Early short prickly* is not more than 4 inches long; the skin green, rather smooth, but with a few small black prickles. This is one of the hardiest and earliest sorts, and is often preferred for the first crop.

The *Dutch* or *white short prickly*, though not much cultivated, is recommended by a very competent judge, the Rev. Mr Marshall, as preferable even to the early long prickly; it has fewer seeds; is evidently different in taste from most other cucumbers, but of agreeable flavour.

The *Cluster cucumber* is a very early sort, named from the circumstance of the flowers appearing in clusters of three or four together; the fruit is seldom more than 5 inches long; it is at first of a fine green colour, but becomes yellowish as it ripens. The stems of this variety are much inclined to climb, by means of their tendrils, upon sticks; the leaves are small, and the plant altogether occupies but little room.

The *Smooth green Roman* is also an early sort; the fruit becomes large and long, and is quite smooth; the plants grow very strong, and require a good deal of room.

In the *White Turkey*, the stalks and leaves are larger than in the other varieties; the fruit also is very long, sometimes from 10 to 15 or even 20 inches; it is quite straight, and has a smooth skin, destitute of prickles; it is produced sparingly, and late in the season. There is likewise a long green Turkey variety, which is sometimes sown for the late crop. Late cucumbers, however, are much less cultivated than the early varieties; most gardeners being of opinion, that those kinds which are best for the early crops are also best for the late.

266. Three crops of cucumbers are generally raised in the year. The earliest are of necessity produced on hot-beds, or in flued pits. Pickling cucumbers are generally raised either on a slight hot-bed or under a hand-glass, and planted in the open air in June. When they have thrown out a few joints, they are topped, in order to encourage lateral or fruit branches; and these are trained on the ground at eight or nine inches apart, and generally kept down by pegs. In some places, the seed is at once sown in drills in the open air; the fruit being produced in August and September, and well adapted for pickling. But drilled cucumbers succeed only in the southern parts of England; in the northern half of the island they will not do. The prickly sorts are chiefly used in the recent state; and the smooth green is much liked for preserving.

The soil recommended by Nicol is composed of three-fourths light rich black earth from pasture land; an eighth part vegetable mould from decayed tree leaves; and an eighth part well-rotted cow-house dung.

For the early crops, the seed is sown about the end of December or beginning of January, on a small hot-bed, covered with a one-light frame. Where there is the conveniency of a stove, this seed-bed is sometimes dispensed with. Seed which is several years old is preferred, being less apt to produce exuberant shoots than what is recent. The plants soon rise, and the seedlings are transferred from this seed-bed to a larger or two-light frame, which serves as a nursery. Here great care is necessary to the giving of air, in order to strengthen the plants, and prevent them from drawing up weak; at the same time, too free access of cold air would probably kill them. When the seed-leaves are about half an inch broad, some of the best plants are pricked into small pots, generally three into each pot, the pots having been previously filled with light rich earth, and sunk into the bed to acquire equal temperature. The plants not potted are pricked out on the surface of the bed, at such a distance from each other, as to permit the lifting of each with a small ball of earth at the time of final transplanting. Less or more water is given, according to the state of the weather, and the warmth of the beds.

The young plants are *stopped* at the first joint. This operation consists in pinching off closely the runner-bud which springs from the axilla of the second rough leaf: it is best performed when the end of the shoot is little bigger than a large pin's head. In this way a stronger and more compact growth is promoted, and the emission of fruitful lateral runners is secured. When the plants have formed one joint, and when the first two rough leaves are from two to three inches broad, which is generally the case in a month, they are ready for final transplanting, or *ridging out*, as it is technically called. There must now be in readiness a fruiting hot-bed, or several beds, covered with two-light or three-light frames. As in the case of melons, a small hillock of earth, somewhat less than a foot high, is formed under the centre of each light, the rest of the bed being covered only to the depth of two or three inches. Into these beds, when of a proper temperature, the plants in pots are placed, preserving the ball of earth entire about the roots; in general, three plants are set in the middle of each hillock. If the plants have not been potted, they are transferred with as much soil adhering to them as may be. The frames are covered with mats at night, which are taken off through the day. Air is given by tilting the upper end of the glass cover, more or less, according to the state of the weather, and of the hot-bed. In a dry season, water is regularly given; and when the heat of the bed declines, linings are applied. As the plants advance in growth, the other parts of the surface of the bed are filled up nearly to an equality with the hillocks. In July, the nightly covering of mats is omitted, and the glass covers are drawn fully off through the day.

When the blossoms appear, some of the male flowers are shaken over the female, as in the case of the melon. So certainly efficacious is this operation, that it is called *setting* the fruit. When cucumbers are grown in drills in the open ground, the impregnation is entrusted entirely to the agency of the winds and of insects.

The subsequent management of cucumbers consists chiefly in admitting air as freely as the state of the weather will permit, and in affording liberal but judicious supplies of water, generally avoiding the foliage; although a sprinkling upon the leaves appears not to be disadvantageous, for we know that cucumbers thrive better in a moist than in a dry heat; and if the red spider appear, water is the remedy.

Sometimes a crop of cucumbers is raised by means of hand-glasses, placed upon cavities containing hot dung. Instead of hand-glasses, oiled paper covers are occasionally used: these remain night and day till the middle of June, and in general answer very well, all danger of frost being then over.

267. For the natural ground crop, or drilled cucumbers, the beginning of June is the proper sowing time. The plan usually followed is this: the ground being made fine and level, shallow circular hollows are formed with the hand, a foot wide, and half an inch deep in the middle. The distance between each hollow is about three feet and a half; the distance between the rows of hollows, between five and six feet. Eight or ten seeds are sown in each cavity, to be afterwards thinned out to three or four. They are watered two or three times a week, according to the state of the weather, preferring the morning or the evening for this operation. Pickling cucumbers are gathered chiefly from the middle to the end of August; and they are best when not more than three inches in length. Cucumbers form a very extensive and profitable article to the London market gardeners. In March they fetch above a guinea a dozen; in August and September they are sold at a penny a dozen. One village (Sandy in Bedfordshire) has been known to furnish 10,000 bushels of drilled cucumbers in one week.

268. Some persons are careless about the seed which they use, or at least are ready to sow any kind that is recommended to them. This is wrong: when one is pos-

sessed of an approved kind, the safest way is to preserve seed of it. With this view, one good fruit is allowed to remain till it become yellow; it is then placed, upright, in the full sun for some weeks, to acquire the most perfect maturation. The individual fruit having most prickles is commonly selected for this purpose. The seeds are afterwards thoroughly washed from the pulp, dried, and tied in paper bags, to remain for a year at least.

269. Curious cultivators sometimes amuse themselves by planting cuttings of late cucumber plants in the beginning of October: these, if placed in a hot-house or a well regulated hot-bed frame, grow freely, and produce fruit about mid-winter. But in order to have cucumbers at this season, a better plan is, to make them succeed melons in a flued pit, these being generally ripened off by the middle or end of October. The seedling cucumbers may be previously reared in small pots beside the melons, so as to be ready to take their places. They are watered once in four or five days, and commonly over the foliage, especially when, as winter advances, the fire-heat is made stronger. All the pruning necessary at this season is, to stop the shoots as they shew fruit, at a joint or two beyond the fruit. A few cucumbers are thus procured at the end of December, or the begining of January.

### *Gourds.*

370. Allied to the melon and cucumber are the different kinds of *gourds*, two or three of which are sometimes cultivated, and may here be mentioned.

The *Pumpkin*, Pumpion, or more correctly Pompion, is the fruit of the Cucurbita Pepo of Linnæus. The pumpkin was the melon or millon of our early horticulturists, the true melon being formerly distinguished by the name of Musk-melon. The pumpkin is now cultivated principally for ornament or curiosity; but in some of the villages of England, the country people plant it on dunghills, at the back of their houses, and train the shoots to a great length over grass. When the fruit is ripe, they cut a hole on one side, and having taken out the seeds, fill the void space with sliced apples, adding a little sugar and spice, and then bake the whole.

The *Water-melon*, or Citrul, (the fruit of the *Cucurbita citrullus*, L.) although it forms both the food and the drink of the inhabitants of Egypt for several months in the year, is little regarded in Britain. It requires the same attention and expence as the common melon; the hot-beds and glass frames, indeed, would need to be even of a larger size. In a few places only, two or three plants of the water-melon are occasionally cultivated with such attention as to procure the ripe fruit.

The *Squash* and the *Warted gourd*, the fruits of the Cucurbita melopepo and C. verrucosa, though commonly cultivated as esculents in North America, are considered in this country only as curiosities. In the same way are viewed the *Bottle-gourd* or false Calabash, C. lagenaria; and the *Orange gourd*, C. aurantia, lately introduced, which last is really ornamental, when trained spirally round a pole, or against a wall, and loaded with its yellow fruit.

The *Succada*, or Vegetable Marrow, is a kind of small green gourd lately introduced. It is raised under a hand-glass, and afterwards transplanted into a good aspect, and trained to a trellis. When the fruit is of the size of a hen's egg, it is dressed in salt and water, squeezed, and served up in slices on a toast.

## KITCHEN GARDEN.

271. The order in which culinary plants are arranged, or treated of, is not a matter of much importance. They may be divided into the cabbage tribe; leguminous plants; esculent roots, either tuberous or fusiform; the alliaceous tribe; spinach plants; boiling salads, including those plants, the stems and leaves of which are generally blanched; fresh salads; plants for soups, and for garnishings; with the various sweet herbs, those used for preserves, and as medicines. The mushroom stands alone, being the only one of the fungi which is cultivated.

Several of the plants may no doubt be considered as belonging to more than one of these divisions; but they shall be treated of under that title to which they seem chiefly allied, and only named under the others. In treating of each article, nearly the same method shall be pursued as has been adopted in speaking of fructiferous plants. The botanical name shall always be given, as the want of this has been found by experience to create considerable embarrassment and uncertainty, in consulting the popular treatises on horticulture published in France and Germany. The class and order of Linnæus or Willdenow, and the natural order of Jussieu, to which the plant belongs, shall also be mentioned; and the French, German, or Italian names shall be set down, wherever it may seem of any importance to mention them. The country to which the plant is indigenous shall be noticed; with the date of its introduction into Britain, if an exotic, or of its being used as food, if a native. Where different *varieties* are cultivated, as of peas, onions, lettuce, or others, the principal varieties shall be enumerated and described. The mode of culture shall then be detailed. The means of keeping or preserving esculent roots and other culinary articles through the winter shall not be omitted; and the way in which each plant is used in the kitchen, it may be proper generally to mention.

### *Cabbage Tribe.*

272. Of all the classes of cultivated culinary vegetables, the cabbage tribe is the most ancient, as well as the most extensive. The *Brassica oleracea* of Linnæus (belonging to the class Tetradynamia, order Siliquosa, and to the natural order Cruciferæ of Jussieu) being extremely liable to sport or run into varieties and monstrosities, has, in the course of time, become the parent of a numerous race of pot-herbs, so very various in their habit and appearance, that to many it may appear not a little extravagant to refer them to the same origin. Besides the different sorts of white and red cabbage, and savoys, which form the leaves into a head, there are various sorts of borecoles, coleworts, and kale, which grow with their leaves loose in the natural way; and there are several kinds of cauliflower and broccoli, which form their stalks or flower-buds into a head. All of these, with the turnip-rooted cabbage, and the Brussels-sprouts, claim a common origin from the single species of *Brassica* above mentioned. This original cabbage-plant grows naturally on the sea-shores, in different parts of England, but it has not been observed in Scotland. It is figured in English Botany, t. 637. It is a biennial plant; the stem leaves are much waved, and variously indented; the colour is sea-green, with occasionally a tinge of purple. Early in the spring the wild cabbage or colewort from the sea-coast is said to be excellent, but it must be boiled in two waters, to remove the saltness.

*Close Cabbages.*

273. *Common white cabbage* (*Brassica oleracea capitata alba*, L.)—some sort of cabbage, as remarked by Mr White, in his History of Selborne, must have been used by our Saxon predecessors, for they named the month of February *sprout-kale*. Cabbage was a favourite vegetable with the Romans; and their Italian kind would doubtless be introduced during the long period of their sway in the south of Britain. To the inhabitants of the north of Scotland, cabbages were first made known by the soldiers of the enterprising Cromwell.

274. Of the common white cabbages there are many subvarieties, some of which are preferable for a summer crop; others for an autumn crop; and a third set, for winter supply. The Small early dwarf, Large early Yorkshire, Early dwarf Yorkshire, Early Battersea, and Early sugar-loaf, are generally preferred for summer use, and are ready from May to July; in some early situations, even in April. The Imperial, Large sugar-loaf, Hollow sugar-loaf, and Long-sided, are excellent for autumn use, and also, in private gardens, for the winter crop. The Large drum, the Scots and the American cabbage, resist the severity of winter, and grow to a large size; but they are better suited to field culture and the feeding of cattle.

275. Very few remarks on the kinds of close cabbages seem requisite. The Long-sided is also called Large-sided; it is an excellent sort, but rather tender, so that it should not be sown till May, nor planted out till July. The Scots cabbage is much cultivated in cottage gardens in Scotland; it grows to a large size, and is seldom affected by the severest frost. The drum is named from its flatness at top, resembling the head of a drum: it is also called White Strasburgh, and of it chiefly the Germans make their sour-krout. The American also grows to a large size, and lasts good till a late period in the spring. The Musk or perfumed cabbage is almost lost, being preserved only in a few private gardens. A small firm cabbage, called the Russian, has also become rare, being very apt to degenerate in this country: it is the least and most humble of the cabbages, but it is hardy, quick of growth, and pleasant to the taste. The French gardeners describe a crisp-leafed early kind, which cabbages in forty days; so that, if planted out in the last week of March, it is ready for cutting in the first week of May.

276. In sowing cabbage-seed, a rich, light, open spot is selected; a covering of earth from an eighth to a quarter of an inch is sufficient for all the brassica tribe. The time of sowing for the early or summer crop is the beginning of August of the preceding year. In about six or eight weeks, or when the plants have got several leaves, they are thinned, and the plants taken out are pricked into beds at three inches distance every way; in this way the transplanted seedlings grow firm and shapely, and keep short-stalked, which is a great property, while those left in the seed bed get more room to establish themselves. Some part of this crop is finally planted out in October and November, and the rest early in the following spring. The plants are set in rows between two and three feet wide, and at least two feet asunder in the rows. Some gardeners, indeed, plant their earliest cabbages considerably closer in the rows, perhaps at fifteen inches between the rows, and eight or nine inches between the plants in the line. This is done merely with the view of securing a full crop; by cutting every second cabbage in April, the others are allowed to have room to come to larger size. By market-gardeners, winter spinach is often sown where the summer cabbages are planted; and when the spinach is cleared off in April, there is thus a crop of cabbage on the ground, which is encouraged, by stirring the earth and drawing it around the plants. These operations, it may be remarked, are not to be omitted in any of the cabbage rows. Indeed, the oftener the ground is stirred, the better is the crop. In the end of April, or beginning of May, the early cabbages naturally begin to turn in their leaves, and to harden in the centre. Some gardeners then bind the leaves close with willow twigs or strands of bass-mat, so as to produce a degree of blanching in the middle; and they are thus a fortnight sooner fit for use.

277. The seeds of cabbages for autumn and winter use are sown in the end of February, or beginning of March. If pricked out into shady borders in May, and allowed to remain there for some weeks, they form more compact plants, and are less apt to have long stalks. In June they are finally transplanted, at the same distances as the early kinds. If the weather prove dry at the time of transplanting, they are watered every evening till they have again taken root. These cabbages come to be fit for use in the autumn months, and they continue good, in sheltered situations, and in ordinary seasons, till February or March. To preserve them from severe weather, some market gardeners trench a piece of ground in ridges in November, and lay the cabbages as close as possible on one side in the trench, covering the stems with earth: the outer part of the more exposed side of the cabbage is generally injured, but the inside remains sound.

The best soil for cabbages is a rich mould, rather clayey than sandy; and it can scarcely be too much manured, as they are an exhausting crop.

In some places, the roots and stems of a portion of the summer crop are allowed to remain in the ground, which is slightly delved and perhaps manured in the autumn. In January or February of the following year, very fine cabbage sprouts are produced, not much inferior in quality to small young cabbages.

278. Young cabbage plants are also used as coleworts or open greens. With this view some of the close-growing middle-sized kinds are sown, such as the large York, or the sugar-loaf. The seed is sown in the latter part of summer at different times, so that the plants may be ready for use during winter and in the following spring.

279. The *Red Cabbage*, (*Brassica oleracea capitata rubra*) is chiefly used for pickling; and the dwarf red variety certainly does make one of the most beautiful pickles that can be presented at table. It is also shredded down in winter salads. In the north of Scotland, a sort of open red cabbage is much cultivated by the common people, under the name of Aberdeen cabbage.

280. Of the *Savoy Cabbage*, (*Brassica oleracea sabauda*,) which is distinguished by having wrinkled leaves, there are two principal sorts, the yellow and the green, the latter being esteemed the hardiest. Savoys are sown about the middle of April, and planted out in June. They may be planted considerably closer than the common cabbage. If savoys are wished before winter, the seed is sown in February, or even in the preceding autumn; in which last case, fine large plants, well cabbaged, are ready for the table in the months of September and October. The later crop affords a supply through the winter, and till February or March: Savoys, far from being injured by moderate frost, are reckoned better when somewhat pinched by it.

The roots of cabbages or savoys, when planted year after year on the same land, are very subject to the attack of a particular kind of grub, the larva of a small fly; the roots swell into knobs, and the plant becomes sickly and stunted. The cabbage ground should therefore be changed every year.

The culinary uses of the close cabbages, are too well known to require notice. The spare leaves or heads are always useful where milch cows are kept; and young open cabbage plants, or such as are just closing in the centre, make excellent coleworts, as already mentioned.

281. The raising of the seed of the different sorts of cabbage, affords employment to many persons in various parts of England. It is well known that no plants are more liable to be spoilt by cross-breeds than the cabbage tribe. Unless the plants of any particular variety, when in flower, be kept at a very considerable distance from any other, also in flower, bees are extremely apt to carry the pollen of the one to the other, and produce confusion in the progeny. Market gardeners, and many private individuals, raise seed for their own use. Some of the handsomest cabbages of the different sorts are dug up in autumn, and sunk in the ground to the head; early next summer a flower stem appears, which is followed by abundance of seed. A few of the soundest and healthiest cabbage stalks, furnished with sprouts, answer the same end. When the seed has been well ripened and dried, it will keep for six or eight years. It is mentioned by Bastien, that the seed growers of Aubervilliers have learned, by experience, that seed gathered from the middle flower-stem produces plants which will be fit for use a fortnight earlier than those from the seed of the lateral flower-stems: this may deserve the attention of the watchful gardener, and assist him in regulating his successive crops of the same kind of cabbage.

In the neighbourhood of all considerable towns, market gardeners and others raise white cabbage and savoy plants for sale, at very easy rates: this proves a great conveniency to those who have only small gardens, and who perhaps require only 200 or 300 cabbage plants.

*Open Kale.*

*Colewort*, *Kale*, and *Borecole*, (*Brassica oleracea*, vars.) are general terms for greens that do not cabbage or form heads, but remain loose and open. The common colewort is plain; the others are generally curled or crumpled.

281. *Common coleworts*, (or Dorsetshire kale), being intended chiefly for winter and spring use, are commonly sown in July, and planted out in August. They are set pretty close together, perhaps not more than eight or ten inches apart every way. They withstand completely the usual frosts of our winters. But young plants of the common cabbages, particularly of the large sugar loaf variety, are now generally used as coleworts, and sold in the markets, under that name, from December to April. So completely, indeed, have these cabbage coleworts supplanted the true kind, which is more hardy, but at the same time coarser, that one of the most popular modern books of gardening (Abercrombie's *Practical Gardener*) describes only the former sort under the title of coleworts.

282. The principal kinds of *kale* are German greens, Scots kale, Buda, Red curled, and Milan.

Of the *German Greens*, a tall growing light coloured kind is preferred, as producing a large quantity of small tufts or loose heads of delicate leaves on the stalk in the spring months, when coleworts are getting scarce. German greens are sown in May, and planted out in June, at eighteen or twenty inches asunder every way. Some are also sown in June, and planted out in August, to be ready for use late in the following spring.

The seed of the *Scots kale*, (Siberian borecole, or choux pancalier), is sown in the beginning of July; and in the course of August the young plants are set out in rows a foot and a half wide, and ten inches distant in the rows. This green bears the severest cold without injury, and indeed is not reckoned good for use till it has endured some sharp frosts.

The *Milan kale* cultivated in this country has a thick stem, the leaves of a dark green colour, and much curled or fimbriated. Milan greens are greatly prized in France, and different varieties are there cultivated. The Anjou kale grows to a large size; as does likewise a sort called Cesarean kale. Neither of these is so tender as the other kinds; but the produce being great, they might probably be found useful in the feeding of cows.

A very tall variety of open kale is described by the late Mr Delaunay, in the last edition of "*Le Bon Jardinier*" published by himself. It is called *Choux palmier*. It frequently rises to the height of six feet, with a straight bare stem, the leaves displaying themselves only at top, and thus producing the appearance of a little palm tree. The leaves are much puckered, and so much rolled back at the edges, that they appear narrow, while at the same time they hang in a curved manner; thus aiding the illusion. This variety is evidently to be considered merely as a curiosity. It was first raised in Italy, and is not very hardy. Another tall sort, sometimes rising nearly to the same height, is described by the same author under the name of *Capousta*, or Russian kale. The leaves are of a fine purple colour, much cut and fringed. This variety is represented as extremely hardy, resisting the utmost severity of a Russian winter.

283. The *Borecoles*, properly so called, are of two kinds, the tall purple and the dwarf purple. But all the curled and cut-leaved kale or colewort plants, are commonly called Borecoles. There is a variegated sort, which is very ornamental when growing, but not so good for the table as those of more ordinary appearance.

All kinds of kale seeds are sown in the beginning of April; the young plants are generally pricked into a nursery bed for a few weeks, to enable them to gain strength; and they are finally transplanted in June or July, in rows three feet asunder, and two feet apart in the rows, giving water, if the weather be dry. A few are generally not planted out till September, that they may afford a supply late in the following spring. The only other attention requisite, is the drawing of earth to their stems before winter, in order to support them in times of snow or storm.

*Brussels Sprouts.*

284. The variety called *Brussels sprouts* may be classed with the kale plants. The leaves come out in small crowns or sprouts all along the stem, and are very delicate when boiled. The culture is nearly the same as that of coleworts in general. The seed is sown in March or April, and the seedlings are planted out in June, preferring showery weather, or watering carefully at root. They grow upright and pyramidal, and may therefore be placed nearer to each other than more spreading kinds. They are earthed up in October, are ready for use by midwinter, and continue good till March or April. Brussels sprouts are much used in London during the spring months; but they seldom appear in the Edinburgh market, nor is the plant so much cultivated in Scotland as it deserves.

*Cauliflower.*

285. Cauliflower and broccoli, (*Brassica oleracea*, var. *botrytis*,) are curious varieties of the cabbage; the flower-buds forming a close firm cluster or head, for the sake of which alone the plants are cultivated. These heads or flowers being boiled, wrapped generally in a clean linen cloth, are served up as a most delicate vegetable dish. *Cauliflower* is a particular favourite in this country. "Of all the flowers in the garden," Dr Johnson used to say, "I like the cauliflower." Its culture, however, had been little attended to till about the close of the 17th century; since that time it has been greatly improved, insomuch that cauliflower may now fairly be claimed as peculiarly an English product. Till the time of the French revolution, quantities of English cauliflower were regularly sent to Holland; and the Low Countries, and even France, depended on us for cauliflower seed. Even now, English seed is preferred to any other.

The two varieties called the early and the later cauliflower, are scarcely different. The first is the kind generally produced under hand-glasses, and the difference consists merely in the seed having been saved from the most forward plants. A variety having the stalks of the head of a reddish or purple colour, has lately been introduced, under the name of Red Cauliflower; and it is reputed more hardy than the other sorts.

286. The seed for the early crop is sown about the 20th August of the preceding year, in frames or beds. In September, the seedlings are pricked, either into a dry border near a wall, where they may be hooped over and defended with bass-mats during the severe frosts of winter, or into common glass frames, with two or three sliding lights. In the month of March they are finally planted out, water being given if the season be dry. They are placed in rows, commonly about two feet and a half asunder, and two feet apart in the rows. If the soil be not rich, less distance may answer. It is a rule, that cauliflower plants should never be set deep in the ground. The subsequent culture consists chiefly in repeated hoeings, and in drawing earth, or manure perhaps, close up to the roots and stems. Cauliflower plants have justly been declared "rough feeders;" in fact, the more liberally the cleanings of stables and cow-houses are supplied, the larger produce may be expected. They also require regular and free supplies of water, at least in dry seasons. As the flower or head advances, some of the large outer leaves are bent or broken over above it, partly to shade it from the sun, and partly to preserve it from too much rain.

287. To diversify the time of forming the heads, some of the early cauliflowers are planted out on different successive occasions. But seeds sown in February or March on a hot-bed, or in the front border of a stove or forcing-house, afford young plants to succeed those kept over winter; and by sowing again in May, pricking into nursery beds in June or the beginning of July, and transplanting proportionally late, this delicate pot-herb is produced till the end of October. Even after this, the cauliflower season is prolonged for nearly two months by various devices. Sometimes the plants are raised with balls of earth, and sunk nearly to the head in the borders of peach or grape houses, or in common glass frames, in sand or very light dry earth; and sometimes they are merely hung up in a shed or out-house, and thus kept for some weeks. They have been preserved in still another way, described by Mr Smith, gardener at Keith-Hall in Scotland, (*Scottish Hort. Mem.* vol. i. p. 129.): He digs a pit, about eighteen inches deep, near the bottom of a wall. On a dry day he takes up the cauliflower stocks in an entire state, and wrapping the leaves round the head, or flower, deposits them in the trench, the heads sloping downwards, and the roots extending upwards, so that the roots of one layer cover the tops of another; he then covers up the whole closely with earth, preserving a slope from the wall, and beating it smooth with the back of the spade, so that rain may run off. In this way, the cauliflower is said to keep good till the middle of January.

288. For the early supply of the London market, very great quantities of cauliflower are fostered under hand-glasses during winter and the first part of spring; and to behold some acres overspread with such glasses, gives a stranger a forcible idea of the riches and luxury of the capital. Two, three, or even four plants are, at first, placed under each glass; in fine weather, the cover is tilted in order to admit air. When the plants are somewhat advanced, in the end of February or beginning of March, the spare plants are removed with a scoop-trowel, and planted out separately, leaving one, or at most two, under the glass. The plants thus left under the covers are ready for market in the end of April or beginning of May, and fetch a high price. A method of producing cauliflower pretty early, and with great certainty, is this:—The plants are set in small pots in the winter season, and kept in any convenient part of the floor of a vinery, or other glazed house. In the beginning of March they are taken out of the pots, with the ball of earth attached, and planted in the open ground. If they be here protected against severe frosts with bell-glass covers, they come into head in the course of April, if the weather prove favourable.

It may be mentioned, that in some places it is not an uncommon practice to sow a little radish seed on the cauliflower ground, a fortnight before planting out the cauliflowers. It is found that the flies, or larvæ, which infest the young plants, prefer the tender leaves of the radish to those of the cauliflower, and that the latter thus escape. Market gardeners often mix spinach seed with the radish, but from a different motive; they thus procure a useful crop soon after the cauliflower is removed. More frequently, however, these gardeners employ the cauliflower ground in producing a late crop of cucumbers for pickling.

When seed is wished for, some of the best early plants are selected, and left to flower, plenty of earth being drawn up to their roots. The seed ripens in September, but at various times, on the different branchlets of the same head, so that it is proper to gather it at successive times, as it appears ripe.

*Broccoli.*

289. *Broccoli* is generally considered as merely a variety of cauliflower. It is indeed nearly allied, and the useful part consists, as in cauliflower, of the clustered unexpanded flower buds; but the broccoli plant is distinguished by its cut leaves, its larger growth, and greater degree of hardiness. There are several varieties of broccoli, two of them particularly distinct, the purple and the white. No culinary plant is so liable to *sport* as broccoli; so that new kinds, slightly different, are continually coming into notice or favour, and as speedily sinking into neglect.

Of the purple, there are several sub-varieties, the early, dwarf, branching, and Cape broccoli, the last but lately introduced. What are called the brown and the black broccoli are likewise slight variations of the purple. They are more hardy, and better suited for exposed situations; but they do not form heads so completely as some other kinds; the tender stems and hearts of the plants, with the small heads on the lateral branches, being the parts chiefly used. The dwarf sulphur-coloured is much esteemed, and cultivated to great perfection near Edinburgh. By many, the sort called green broccoli is accounted the best. The white, Neapolitan, or cauliflower-broccoli plant, is rather more tender than the others, but the flower is at the same time more palatable; it forms a close curdly head of considerable size in the spring months, and the plants do not branch, as most of the purple kinds do. A hardy variety of the white would therefore prove a great acquisition.

290. Broccoli seed is sown in April for an autumn crop, to be planted out in the beginning of June; and, for a spring crop in the following year, the seed is sown late in May, or even in June. The seedlings are afterwards placed in nursery beds, where they remain till the middle or end of July, when they are finally transplanted. A light, but deep and rich soil, in an open situation, is preferred. To those situated near the sea, it may be interesting to know, that sea-weed forms an excellent manure for broccoli. In the second volume of Scottish Horticultural Memoirs, p. 266, Mr William Wood, one of the most successful cultivators of broccoli near Edinburgh, gives an account of his remarkable success with this sort of manure. When drift ware abounds on the shore, he bestows on the quarter next intended for broccoli a very liberal supply, immediately digging it in roughly. The ground is afterwards slightly delved over before planting. From the soil thus treated, very large and fine heads are produced. It may be added, that grubs will not infest the roots, as they are very apt to do when stable manure is used. The broccoli plants are set in lines, two feet asunder, and a foot and a half apart in the lines. Water is given when thought necessary, according to the state of the weather. They are hoed and earthed up like cauliflower plants. Nicol recommends, that, in the end of October, the most forward crops, especially of the tall growing kinds, should be raised and laid over on their sides pretty closely together, placing the heads just clear of one another. If this be done in a dry soil and free situation, the plants are seldom injured by the frost of the severest winters. The heads of winter broccoli generally begin to appear early in January, and they continue till April.

In gathering broccoli, five or six inches of the stem are retained along with the head; and in dressing, the stalks are peeled before boiling.

291. The early purple Cape broccoli, already mentioned as lately introduced into this country, deserves more particular notice. The seed, it was understood, was first brought from the Cape of Good Hope, but the same kind has since been received from Italy. A particular account of the mode of cultivation is given by Mr John Maher, in the first volume of the London Horticultural Transactions, p 116. Three crops are sown: in April, between the 12th and 18th of the month; in May, between the 18th and 24th; and in August, between the 19th and 25th; and by means of these, this kind of broccoli is procured from September till the end of May. The seeds are sown very thin, on a border of light rich earth. In about a month the plants are finally transplanted, at the distance of two feet every way, in a sandy loam, well enriched with rotten dung. Frequent hoeings are given, and the earth is drawn to the stem, as in the case of ordinary broccoli. Mr Maher never pricks the seedlings into a nursery bed. He finds, that the head is by that measure rendered less in size, and more apt to run to flower and seed. A part of the second crop is often transplanted into pots (sixteens), and plunged into the open ground, where the head forms. Against December. these pots are removed into a shed, frame, or pit; and in this way fine broccoli is secured in the severest weather of winter; the head often six or seven inches in diameter. The seed for the third crop is sown in a frame; and about the third week in October the plants are ready for transplanting. A few good plants for affording seed are selected at this time, and planted in a remote part of the garden, covering them with hand-glasses during winter, in the manner of cauliflower.

292. When broccoli seeds are to be saved, plants with the largest and finest heads are selected, observing that no small foliage appear on the surface of the head. Mr Wood, already mentioned, makes it a rule to take up such plants in April, and lay them, in a slanting direction, in a rich compost, (cleanings of old ditches, tree leaves, and rotten dung,) giving, at the same time, a plentiful watering, if the weather be dry. The raising, he thinks, prevents them from producing *proud seed*, or from degenerating. When the heads begin to open or push, he cuts out the centre, leaving only four or five of the outside flower-stalks to come to seed. The centre, it may be remarked, would probably produce the stronger seeds; but the object seems to be, to check the tendency to luxuriancy and consequent sporting in the plant.

### *Kohl-rabbi.*

293. The *Kohl-rabbi* or turnip-rooted cabbage (*Brassica oleracea*, var. *Napobrassica*, not a variety of *B. rapa*, or turnip, as supposed in Salisbury's Botanist's Companion), has large broad leaves, and the stem protuberant like a turnip at the base: there are two varieties, one swelling above ground, the other in it. Both are sometimes used in a young state for the table; but they are not much cultivated in this country. Kohl-rabbi is very hardy, and might probably be advantageously cultivated in the colder parts of the island; for it is found to be a very profitable crop in Sweden and other northern countries.

## *Leguminous Plants.*

### *Peas.*

294. The *Pea* (*Pisum sativum*, Lin. *Diadelphia Decandria*; *Papilionaceæ* or *Leguminosæ*) is an annual climbing plant, so well known as not to need any description. The legumes or pods are commonly produced in pairs; the seeds contained in these are the part of the plant used, and to which, in common discourse, the name *peas* is always given. In some varieties, called Sugar-peas, the inner tough film of the pods is wanting, the pods of such, when young, being boiled with the peas within them, and eaten in the manner of kidney-beans. Concerning the native country of the pea, there is no certainty; it is guessed to be the south of Europe. It has been cultivated in Britain from an early period; but some of the best varieties, such as the sugar-pea above mentioned, were introduced only about the middle of the 17th century.

There are very many varieties, differing in size, time of coming in, colour of flower and fruit, and also in taste: but the principal distinction is as to their being early or late; supposing the sorts to be sown on the same day, the former are ready a fortnight at least before the latter.

295. The early peas are called *hotspurs* and *hastings*. Of these there are different subvarieties, especially the Charlton, Reading, Golden, Double dwarf, and Early frame pea; the last being so called from its being often forced in hot beds, especially for the London market. These being comparatively of dwarfish growth, do not require sticking;

and it is a common remark, that peas supported on sticks yield more, but that those recumbent on the ground ripen soonest. Some of these kinds are generally sown towards the end of October, in front of a south fruit-wall, and at right angles to it, or inclining a point to the east, in order to catch the morning sun. With some slight protection of branches of evergreens or old peas-haulm, the crop survives the winter, and produces young peas by the end of May. Many gardeners prefer sowing in longitudinal rows near the wall, the crop thus ripening more equally. In January and February more peas, of the early sorts, are sown, to follow in succession those sown before winter. Some gardeners are in the practice of raising peas in boxes placed in any hot-house, and planting them out when two or three inches high. They must be handled with care, being very brittle; but, with due attention, few plants fail; and it has long been remarked, that transplanted peas are much more productive of pods or fruit, than such as remain where they have been sown.

296. In March and April full crops of later peas are sown. Some of the smaller kinds are the Blue Prussian, Dwarf marrowfat, and Spanish dwarf. These, if well earthed up, and if the rows be sufficiently distant from each other, succeed very well without sticking. To them may be added Leadman's dwarf, which is smaller than any of them, while at the same time the plant is very prolific, and the pea remarkably sweet. Of the large and late kinds, the Tall marrowfat, the Green marrowfat, the Grey rouncival, and the Sugar pea, have long retained their character; while the Spanish moratto and Imperial egg pea are also in good repute, as hardy plants and copious bearers. The Crown pea or Rose pea is well known; but it is as frequently cultivated for ornament as for use: It is remarkable that Parkinson, in his "Paradisus," ascribes to it a Scottish origin. A new white pea raised by Mr Knight must not be omitted. It is sometimes called Knight's marrow pea; sometimes the Wrinkled pea, the circumstance of the skin of the fruit being wrinkled or contracted, being an obvious mark of distinction. The plant is of luxuriant growth, requiring tall sticks to support it; the pods are large, and the peas are of peculiarly excellent flavour when boiled.

The larger kinds of peas require nearly four feet distance between the rows. They are frequently hoed, and when about three or four inches high, earth is drawn to the rows, this being found greatly to promote their growth. The sticking or supporting takes place when they are about eight or ten inches high. The sticks are of different heights for the respective kinds; three feet is enough for the smallest kinds; the hotspurs and dwarf marrowfats require about five feet; and the larger sorts seven or eight feet. Sometimes double rows of peas are sown, and the sticks placed in the middle, the plants being earthed towards the sticks: Or two rows of sticks may be made to serve three rows of peas, the heads of the sticks being inclined towards each other; but in this way the middle row of peas cannot be earthed up or hoed after sticking. Where branches cannot be procured, two lines of strong pack-thread, on each side of the rows, form a tolerably good substitute. In some places, in very dry weather, the crops of peas are regularly watered when in flower and fruiting.

The small early peas are sweeter and of more delicate flavour than the large kinds. In well ordered gardens, therefore, a small quantity of the hotspur sorts is sown every ten days, from the middle of March till the middle of June, choosing for them a moist strong soil, in order to counteract the effects of the summer heat. It is not reckoned proper to sow peas on land which has been recently manured, as they are, in such situations, apt to run to haulm: This crop is seldom sown, therefore, till the second season after dunging. In large gardens, and particularly in market gardens, instead of delving, a slight plough may be used for turning over the ground; and the one-horse drill for sowing, as recommended by Meager so long ago as 1670.

Among the chief enemies of peas may be mentioned slugs and mice. The former often abound in damp situations, or places surrounded by trees. The remedy usually applied is, the spreading of new slaked lime over the surface of the ground, very early in the morning, when the slugs are abroad. A simple preventive of the attacks of mice consists in being particularly careful, in sowing the peas, to leave none exposed on the surface; if the seed be all duly covered, these animals do not seem to be very expert at discovering the rows.

It is generally thought advisable to change the seed yearly; few gardeners, therefore, ripen their own seed. Indeed, the professed seed-growers possess superior opportunities for saving the kinds in a genuine state; and if they be men of judgment and fidelity, it is better for the gardener to buy from them, than to trouble himself with saving either the seeds of peas, or of any other garden plants, which are apt to degenerate by intermixture of pollen.

### *Beans.*

297. The *Bean* (*Vicia Faba*, Lin.) belongs to the same class and order, and natural family, with the pea. It is the *Fève de marais* of the French. It is perhaps superfluous to mention, that it is an annual plant, rising from two to four feet, with a thick angular stem; the leaves divided, and without tendrils; the flowers white, with a black spot in the middle of the wing; seed-pods thick, long, woolly within, and inclosing the large ovate flatted seeds, for the sake of which the plant is cultivated in gardens. It is a native of the East, but has been known in this country from the earliest times.

298. There are two principal kinds of the plant, the garden bean and the field bean: The first only falls to be spoken of here. Of this there are many varieties. The *Mazagan* is one of the hardiest and best flavoured of the small and early sorts. Mazagan is a Portuguese settlement on the coast of Africa, near the Straits of Gibraltar; and it is said, that seeds brought from thence afford plants that are more early and more fruitful than those which spring from home-saved seed. The *Lisbon* is next in point of earliness and fruitfulness; some indeed consider it as merely the Mazagan ripened in Portugal. The *Dwarf-fan* or *cluster* bean is likewise an early variety, but it is planted chiefly for curiosity: it rises only six or eight inches high; the branches spread out like a fan, and the pods are produced in small clusters. The *Sandwich* bean has been long noted for its fruitfulness; the *Toker* and the *broad Spanish* are likewise great bearers. Of all the large kinds, the *Windsor bean* is preferred for the table. When gathered young, the seeds are sweet and very agreeable; when the plants are allowed room and time, they produce very large seeds, and in tolerable plenty, though they are not accounted liberal bearers. There are several sub-varieties, such as the Broad Windsor, Taylor's Windsor, and the Kentish Windsor. The *Long-podded* bean rises about three feet high, and is a great bearer, the pods being long and narrow, and closely filled with oblong middle-sized seeds. This sort is now very much cultivated, and there are several subordinate varieties of it, as the Early, the Large, and the Sword Longpod. The *White-blossomed* bean is so called, because the black mark on the wing of the blossom is wanting. The seed is semitransparent; when young, it has little of the peculiar bean flavour, and is on

this account much esteemed; it is at the same time a copious bearer, and proper for a late crop. It may be mentioned, that Delaunay, in *Le bon Jardinier*, describes as excellent a new variety cultivated at Paris, which he calls the *green bean* from China; it is late, but very productive; and the fruit remains green, even when ripe and dried.

299. The early sorts, such as the Mazagan and Lisbon, are sown in the end of October or beginning of November, in a sheltered situation, in front of a wall, reed-fence, or other hedge, and in drills about two inches deep. The plants are earthed up in November as they advance. In severe frost, some haulm or fern is laid over them, as in the case of early peas. In March and April, as the beans begin to shew flower, they are kept close back to the fence, by means of lines of pack-thread. When the lower blossoms are fully expanded or beginning to fade, the tops of the stems are pinched off, this being found to forward the production of pods. With this sort of care, a crop is generally procured about the end of May or first of June. Successive autumn and winter sowings are managed much in the same way, being sown in rows, eighteen inches apart, in sheltered borders or quarters. It is necessary to guard against the ravages of mice, which are very apt to attack the new sown rows. Some gardeners sow their winter beans thickly, and cover them with a frame, transplanting them in February or March: in this way they prove very productive.

300. In February and March, full crops of the late and large beans, such as the Windsor, Sandwich, and Long-podded, are planted, in a free and open exposure. The middling sized kinds are allowed two feet between the rows; but the large growing kinds, two and a half or even three feet. The plants in the rows, however, are only five or six inches separate. Sometimes the beans are planted with a blunt setting-stick, observing to close the earth down upon the seed; but drills drawn two inches deep, or a little more, with the hoe, are in general preferred. One of the principal things to be attended to is the earthing up: in performing this operation, it is necessary to take care that the earth do not fall on the centre of the plant so as to bury it; for this occasions it to rot or fail. Nicol says, that topping is not necessary for any but the early crops, and is practised only to make them more early. Most other horticulturists are of opinion that topping improves the crop, both as to quantity and quality; and it is very commonly performed on the late crops as well as the early. The crops of beans, when in flower, it may be remarked, are very ornamental to the kitchen-garden, and render it a pleasant walk, the flowers having a powerful fragrance, not unlike that of orange-flowers. The latest crops in May and June are sown in strong or moist land, as on an arid soil scarcely any return could at this season be expected. For these late crops, the long pods, broad Spanish, and Toker, are preferred. In a dry season, it is found useful to soak the seed-beans for several hours in soft river water, before planting.

An expedient sometimes resorted to, in order to prolong the bean season, may here be mentioned: A bed or quarter of beans is fixed on; and when the flowers appear, the plants are entirely cut over, a few inches from the surface of the ground. New stems spring from the stools, and these produce a very late crop of beans.

In gathering beans for table use, such pods as are too old should as much be avoided as such as are too young, the seeds decreasing in delicacy after they attain about half the size which they should possess at maturity. When beans are to be saved for seed, none of the pods should be gathered for the kitchen, the first pods being the most vigorous, and affording the best seed. The whole plant should be pulled up; and the seeds should be allowed to dry in the pods, these last still remaining on the stems.

*Kidney-bean.*

301. The *Kidney-bean* (*Phaseolus vulgaris*, Lin. Common kidney-bean; and *P. multiflorus*, Willd. Scarlet runner) belongs to the same artificial and natural classes as the pea and the bean. In this country it is often called *French bean*; and it is the well known and favourite *haricot* of France. It is an annual, originally from India; its stem is more or less twining, but in the dwarfish kinds it scarcely shews this propensity; the leaves are ternate, on long foot-stalks; the flowers on axillary racemes; the corolla generally white, sometimes yellow or purple; the pods are oblong, swelling slightly over the seeds; these last are generally kidney-shaped, smooth and shining when ripe, varying exceedingly in colour, white, black, blue, red, and spotted. The date of the introduction of the kidney-bean into this country is not known: it was in familiar use in the days of Gerarde. The unripe pods chiefly are used in Britain; but in France, the ripe seeds or beans are also very much employed in cookery, being dried in the autumn, and kept for winter use.

302. There are many varieties, both of what are called *dwarfs*, and of *runners*. By Dwarfs are meant kinds that do not much exceed a foot in height, and do not need support; by Runners, such as have long climbing stems, and which require stakes. Of the former, the Early white dwarf, Early black or Negro, the Speckled dwarf, Early yellow, and the Battersea and Canterbury white, may be mentioned as principally esteemed. Of the latter, the Scarlet runner is preferred, the pods being tender, especially if gathered young, and being produced in succession for a long time. This was formerly considered as merely a variety of the common kidney-bean; but Willdenow has described it as a distinct species, under the name of *Phaseolus multiflorus*; it is distinguished by its racemes equalling the leaves in length, and by its bracteæ or floral leaves lying close to the stalk; while in the common kidney-bean, the former are shorter than the leaves, and the latter project from the stalk. The scarlet runner is frequently cultivated as an ornamental flower, particularly in forming fancy hedges: when trained near a wall, and led up with lines of pack-thread or spun-yarn, it unites both characters, or is at once shewy and useful. The white runner seems to differ from the scarlet merely in the colour of the blossoms and of the seeds. The Dutch white runner produces long smooth pods, but does not afford so many successive gatherings as the other two.

303. The kidney-bean is too tender for sowing earlier than the middle or end of April. From that time successive crops are sown every fortnight or three weeks, till July: and in this way the young and tender pods are to be had all the summer and autumn. The dwarfish sorts are sown in drills from two to three feet asunder, perhaps three inches separate in the lines, and covered with something less than two inches of soil. As they advance, they are hoed and cleared of weeds, a little earth being at the same time drawn to the stems. As the young pods come to be fit for use, the more regularly and completely they are gathered, the greater is the successive produce. The runners, being rather more tender, are not sown till about the middle of May. As tall slight stakes must be placed for them to climb upon, the distance allowed be-

tween the rows of these is commonly four feet. If the runners be sown in July, they continue to produce pods till stopped by the frost. In dry seasons, frequent watering greatly conduces to the abundance of the crops. For the latest summer crop, the seed is commonly soaked for some hours in milk and water. Mr Marshall recommends laying it in damp mould till it begin to chit or germinate, and then sowing it in watered drills. The white Canterbury is the sort generally sown to produce small pods for pickling.

For a supply of seed, some of the early summer plants, either dwarfs or runners, should be left untouched; the first produced pods being always the best, the whole strength of the plants being thus directed to perfecting the seeds. These will ripen in September. The haulm is then pulled up, and allowed to dry with the pods on it; the seed being found in this way to acquire further maturation.

304. Kidney-beans are easily forced, and they form a very desirable early spring dish. They are sometimes raised in hot-beds; but more generally, and with greater certainty, in hot-houses. They are sown in pots in January and February, and placed on a flat trellis over the flues, on shelves, or in any other convenient situation. Three plants are generally allotted to each pot of a foot in diameter. A light rich earth, or what is called a cucumber mould, is the soil preferred. With frequent moderate supplies of water they make good progress, and afford pods in March, April, and May. The dwarf-speckled is the kind generally used in hot-houses; but, for hot-beds, the early white is perhaps better, as being of more dwarfish growth.

French gardeners have enumerated above two hundred varieties of the haricot, but of these not more than twenty are in esteem. They speak of a new variety called the Yellow Kidney-bean of Canada, which they describe as the most dwarfish, and the earliest of all. The Rice Kidney-bean they mention as a slender runner, rising six feet high, but having seeds which, even when ripe, are not larger than peas. The pods they describe as very good in the unripe state, and quite delicious when prepared under roast fowl.

## *Esculent Roots.*

It is, perhaps, scarcely necessary to explain, that the term *roots* is applied to the tubers of the potato and Jerusalem artichoke only in compliance with popular practice; the true roots of the plants consisting of the small fibres or radicles only.

### *Potato.*

305. The *potato* (*Solanum tuberosem*, L.; *Pentandria Digynia; Luridæ*, L.; *Solanaceæ*, Juss.) may be considered as a perennial plant, as it will continue to spring up for many successive years on the same spot. The stem rises from two to three feet in height, is branched, succulent, and frequently spotted with red; the branches long and weak; flowers white, or tinged with purple; the fruit is a round berry, green at first, but black when ripe, commonly called potato-apple. The part used consists of the tubers, which are produced on runners, proceeding from the stem of the plant.

306. Sir Joseph Banks has satisfactorily shewn, that potatoes were first brought from South America to Spain about the middle of the 16th century, as they are mentioned, under the name of *papas*, in Cicia's Chronicle, printed in 1553, and now a very rare book. They were not introduced into this country till near the close of the century, when they appear to have been brought from Virginia by the colonists sent out by Sir Walter Raleigh, and who returned in 1586; Herriot, one of these colonists, describing the potato, under the name *openawk*, in his account of the country they had visited, preserved in De Bry's Collection of Voyages. It is said, that Sir Walter Raleigh planted them on his own estate near Cork. They were soon carried over into Lancashire; but near half a century elapsed before they were much known at London. Gerarde and Parkinson describe the plant by the title of Batata Virginiana, to distinguish it from the Spanish potato, Convolvulus batatas. It was at first raised only in botanic gardens. Parkinson mentions, however, that the tubers were sometimes roasted, and steeped in sack and sugar, or baked with marrow and spices, and even preserved and candied by the comfit-makers. In 1663, the Royal Society took some measures for encouraging the cultivation of potatoes, with the view of preventing famine. Still, however, although their utility as an article of food was better known, no high character was bestowed on them. In books of gardening, published towards the end of the 17th century, a hundred years after their introduction, they are spoken of rather slightingly. "They are much used in Ireland and America as bread," says one author, "and may be propagated with advantage to poor people."—"I do not hear that it hath been yet essayed," are the words of another, "whether they may not be propagated in great quantities, for food for swine, or other cattle." Even the enlightened Evelyn seems to have entertained a prejudice against them. "Plant potatoes," he says, writing in 1699, "in your worst ground. Take them up in November for winter spending; there will enough remain for a stock, though ever so exactly gathered." The famous nurserymen, London and Wise, whose names have been already repeatedly mentioned, have not considered the potato as worthy of notice in their Complete Gardener, published in 1719; and Bradley, who, about the same time, wrote so extensively on horticultural subjects, speaks of them as inferior to skirrets and radishes.

The use of potatoes gradually spread, as their excellent qualities became better understood. It was near the middle of the 18th century, however, before they were generally known over the country: since that time they have been most extensively cultivated. In 1796, it was found that, in the county of Essex alone, about 1700 acres were planted with potatoes for the supply of the London market. This must form no doubt the principal supply; but many fields of potatoes are to be seen in the other counties bordering on the capital, and many ship-loads are annually imported from a distance.

The cultivation of potatoes in gardens in Scotland, was very little understood till about the year 1740; and it was not practised in fields till about twenty years after that period. It is stated in the "General Report" of Scotland, (vol. ii. p. 111,) as a well ascertained fact, that in the year 1725:6, the few potato plants then existing in gardens about Edinburgh were left in the same spot of the ground from year to year, as recommended by Evelyn; a few tubers were perhaps removed for use in the autumn, and the parent plants were then well covered with litter to save them from the winter's frost. Since the middle of the 18th century, the cultivation of potatoes has made raid progress in that country; so that they are now to be seen in almost every cottage garden.

Professor Martyn, in his edition of the "*Gardener's Dictionary*," has given an account of various notices that occur concerning the introduction of the potato, in the writings of successive horticulturists, and most minute and accurate details respecting its tillage, derived from all the best sources of information, and selected with great judgment and care. To the learned and industrious Professor's labours, and to the article AGRICULTURE in this work, we must refer the inquisitive reader, contenting ourselves in this place, in addition to the short history already given, with some account of the qualities of the plant, of a few of the principal varieties, and of its culture in gardens.

The potato is now considered as the most useful esculent that is cultivated; and who could *à priori* have expected to have found it the most useful among the natural family of the Luridæ, several of which are deleterious, and all of which are forbidding in their aspect! It is at the same time the most universally liked; it seems to suit every palate. So generally is it relished, and so nutritious is it accounted, that on many tables it now appears almost every day in the year. It is commonly eaten plainly boiled, and in this way it is excellent. When potatoes have been long kept, or in the spring months, the best parts of each tuber are selected, and mashed before going to table. Potatoes are also baked, roasted and fried. With the flower of potatoes, puddings are made nearly equal in flavour to those of millet. Bread has also been formed of it, with a moderate proportion of wheat flour; and potato starch is common. To cottagers having a number of children, the potato is of inestimable value. Dr Johnson, in his "Journey," remarks, that before the Scottish peasantry acquired cabbages, they must have had nothing; but with much more reason might it now be said, that they must have been destitute indeed, before they knew the potato. By many cottagers in Scotland, and especially in Ireland, potatoes are cultivated on what are called *lazy-beds*. In constructing these, the manure is laid on the surface; sets of potatoes are placed immediately on it; and a little earth is thrown over all. In this way a very great return is procured.

307. In regard to general qualities, potatoes are of two kinds, mealy and waxy; the former of a loose, the latter of a firm contexture. They are distinguished as to shape, into round, oval or kidney, and clustered; and as to colour, into white and red, or purple. It would be quite an unprofitable task to enumerate the many varieties which have been raised from seed, and have obtained a name for a day. A few of those at present in esteem can alone be named. Kidney potatoes, of various sorts, have long been in repute, particularly the White and the Yorkshire. Red, and White, and Black potatoes, have their admirers. The Early dwarf, Champion, Early frame, Manly, Cumberland early, Fox's yellow seedling, and the Goldfinders, still retain their fame for summer use: but they are perhaps excelled by varieties well known in Scotland by the names of the Ash-leaved, and Mathew Cree's early. The large red-nosed kidney, a white potato with a tinged eye, is a great favourite in the London market, for general culinary purposes: and the Don potato is the kind most esteemed, and most commonly sold in the Edinburgh market. For the feeding of cattle, the Ox-noble, a large round sort with deep eyes; the American cluster; the Yam potato; and Lancashire, or large round rough potato, are held in high estimation.

The raising of potatoes being now considered as rather the business of the farm, in many gardens only a quarter of *early* potatoes is to be found. For the original production of the varieties, called *earlies*, we are indebted to the kitchen gardeners near Manchester. Encouraged by the demand of that populous town, they vied with each other to have potatoes first in the market: they noted those plants that flowered early, saved them, and sowed their seeds; by again watching the earliest of these, they procured varieties which arrive so much sooner at a state approaching maturity, as far as the tubers are concerned, that young potatoes may be had for table two months after planting. The most productive of these, and least apt to degenerate, are such as do not shew a disposition to flower.

308. The potato is chiefly propagated by cuts of the tubers, taking care to leave one or two eyes or buds to each cut, but eradicating all clustered eyes. The best shaped and cleanest potatoes are selected for this purpose. The cuts are the better for being allowed to dry for a day or two before planting. Any light soil, in a free airy situation, suits the potato. Too much manure can scarcely be given, if the quantity of produce be alone looked to; but potatoes of more delicate flavour are procured from ground not recently enriched. About the middle of March some of the early kinds, such as the ash-leaved, are planted on a light warm border. As they are to be taken up soon, sixteen inches between the lines is accounted enough, and seven or eight inches between each plant. They are commonly planted in drills, and covered to the depth of three or four inches. The tubers being small, are generally only cut in two to make sets; but not more than two eyes are left on each set. Rooted shoots, accidentally produced among the stock of early potatoes, have been found to afford a very speedy return. Instructed by this circumstance, some gardeners lay the sets on a floor sprinkled with sand or barley-chaff, till they have sprung four or five inches, thus advancing the growth of the plants as much as possible under a low temperature, so as to avoid all unnecessary expenditure of their excitability. Great care must be taken, however, to preserve their germs and roots from injury in transplanting. By this means the plants are forwarded nearly three weeks in their growth. The young potatoes are fit for use in June and July, and in August the tops of the parent plants change to a yellow colour, indicating maturity. Only a few plants are taken up at once; for the young and immature tubers do not keep good beyond a day or two: it is found better, therefore, to let them remain in the ground till wanted, and in this way they may be made to meet the later sort. About the middle or end of April, the general potato quarter is planted. Two feet is the space commonly allowed between the rows, and from ten to fourteen inches between the plants. For planting, some use the potato dibble; which is an instrument about three feet long, with a cross handle at top for both hands, the lower end blunt and shod with iron, and having a cross iron shoulder, about four inches from the bottom, so that the holes must of necessity be struck of equal depth. The only attention the crop requires is hoeing, and drawing earth to the stems: the oftener this last operation is performed, the greater is the produce. The potatoes are taken up and used in the autumn months; the winter supply being drawn from the fields, as already mentioned. Potatoes are taken up with a fork made for the purpose, and which consists of three or four short flat tines, fixed on a spade handle. The winter store is carefully housed; or, what is better, it is lodged under ground, in pits covered with earth, and with straw during frost.

309. The late or field potatoes, it may be remarked, afford in most places a great part of the supply for spring and summer; and any improvement in the mode of keeping them is deserving of attention. The Rev. Dr Dow of Kilspindie (in the first volume of Scottish Horticultural Memoirs) has described a mode, the advantages of which have in various places been confirmed by experience. The potatoes destined for long keeping he puts into small pits, holding about two bolls each; these are formed under the shade of a tree, wall, or stack of hay, and are covered with earth and straw in the usual way. In the following spring,

about May, when warmth begins, the potatoes are examined; all shoots or buds are rubbed off, and such as shew any tendency to spoil, are laid aside. The pits being cleaned out, are nearly filled with water; and when this is absorbed, the potatoes are returned into it, every parcel or half-boll being watered as it is laid in. A layer of turf is placed with the grass next to the potatoes; a plentiful watering is then given; and the whole is covered with earth to the depth of two feet, and well beaten together with the spade. This operation is repeated once a month, as long as the potatoes are wished to be preserved. Dr Dow states, that he has thus kept them till September, quite plump, and unimpaired in taste; and although, from the liberal supplies of water, we might expect them to be drenched with moisture, he assures us that they continue as mealy as ever.

The potato, although it most fortunately produces its tubers freely in our climate, must be considered as rather a delicate plant. Its leaves are blackened by the first approaches of frost in the autumn. Every body knows how apt potatoes kept in the house or cellar are to be injured by frost. The best means of guarding against this evil in these places are, to bring in potatoes in as clean and dry a state as possible, and, when risk of frost is apprehended, to place over them a covering of straw at least a foot thick.

It is well known, that if any of the larger sorts of potatoes of the former year's growth be kept in the cellar till May or June, they never fail to shoot, producing both roots and runners; but it is not perhaps generally known, that if these be carefully placed in boxes among decayed tree-leaves or other very light vegetable mould, and still kept in the cellar, they will yield a crop of small potatoes about mid-winter. A small supply may thus be procured by way of curiosity; but the potatoes are rather watery, and quite deficient in flavour.

In private gardens of a superior order, the first early potatoes are in some measure forced. In February two or three slight hot-beds are formed, and the potatoes are planted thickly on these. They are hooped over, and covered with mats at night and in bad weather. The more air they have the better, provided frost do not get leave to nip them. They require moderate but regular watering, particularly in March, when there is generally some dry weather. The young tubers are gathered in April and May in succession as they are formed.

310. Many persons amuse themselves with raising seedling potatoes. Some of the largest, first produced, and thoroughly ripened berries, are gathered from several different good varieties; these may be preserved in dry sand till spring; or the seeds may be immediately separated from the pulp, and kept in paper-bags over winter. In April the seed is sown, in any fine light soil, in drills half an inch deep, and perhaps a foot asunder, keeping the kinds carefully separate, and marking them with tallies. When the plants rise, they are thinned out to six inches apart. They are kept clear of weeds, and once or twice earthed up. When the haulm decays, the tubers are taken up; they are carefully preserved from frost during the winter; and being planted next spring, the crop which results will determine the qualities of the different kinds. They should be boiled separately, and regard had to their flavour, mealiness or waxiness, size, shape and colour. When the seed of early varieties can be procured, it is, for different reasons, to be preferred. Mr Knight suspected the cause of these early varieties not producing flowers to be the preternaturally early formation of the tubers, drawing off for their support that portion of sap which should have gone to the production of the blossom. He therefore devised means for preventing the formation of tubers; and when this was accomplished, he found no deficiency in the production of flowers and berries. The means were simple: having fixed strong stakes in the ground, he raised the mould in a heap round the bases of them; on the south side he planted the potatoes. When the plants were about four inches high, they were secured to the stakes with shreds and nails, and the mould was then washed away with a strong current of water from the bases of their stems, so that the fibrous roots only entered the soil, and no runners or tubers could be produced.

311. The disease called *curl* has in many places proved extremely troublesome and injurious. It has given rise to much discussion, and to detail all the various opinions would be a useless task. It may, however, be remarked, that the experiments of Mr Thomas Dickson (*Scottish Horticultural Memoirs*, i. 55.) shew, that it arises from the vegetative powers in the tuber planted having been exhausted by over-ripening. That excellent horticulturist observed, in 1808 and 1809, that cuts taken from the waxy, wet, or least ripened end of a long flat potato, that is, the end nearest the roots, produced healthy plants; while those from the dry and best ripened end, farthest from the roots, either did not vegetate at all, or produced curled plants. This view is supported by the observations of a very good practical gardener, Mr Daniel Crichton at Minto, who, from many years experience, found (*Id.* p. 440.) that tubers preserved as much as possible in the wet and immature state, and not exposed to the air, were not subject to curl. And Mr Knight (in *Lond. Hort. Trans.* for 1814) has clearly shewn the beneficial results of using, as seed-stock, potatoes which have grown late, or been imperfectly ripened, in the preceding year. Mr Dickson lays down some rules, attention to which, he thinks, would prevent the many disappointments occasioned by the curl. He recommends, 1. The procuring of a sound healthy *seed-stock* (stock of tubers for planting) from a high part of the country, where the tubers are never over-ripened 2. The planting of such potatoes as are intended to supply seed-stock for the ensuing season, at least a fortnight later than those planted for a crop, and to take them up whenever the stems become of a yellow green colour, at which time the cuticle of the tubers may be easily rubbed off between the finger and thumb. 3. The preventing those plants that are destined to yield seed stock for the ensuing year, from producing flowers or berries, by cutting off the flower-buds; an operation easily performed by children, with a sickle, at a trifling expence.

Mr John Shirreff (in the same volume, p. 60.) takes a general and philosophical view of the subject, applying to the potato the doctrine by which Mr Knight had accounted for the disappearance of the fine cider fruits of the 17th century. The maximum of the duration of the life of every individual, vegetable as well as animal, is predetermined by nature, under whatever circumstances the individual may be placed: the minimum, on the other hand, is determined by these very circumstances. Admitting, then, that a potato might reproduce itself from tubers for a great number of years in the shady woods of Peru, it seems destined sooner to become abortive in the cultivated champaign of Britain; insomuch, that not a single healthy plant of any sort of potato that yields berries, and which was in culture twenty years ago, can now be produced. Mr Shirreff concludes, therefore, that the potato is to be considered as a short-lived plant, and that, though its health or vigour may be prolonged, by rearing it in elevated or in shady situations, or by cropping the flowers, and thus preventing the plants from exhausting themselves, the only sure way to obtain vigorous plants, and to ensure productive crops, is to have frequent recourse to new varieties raised from the seed. The same view, it may be remarked, had occurred to Dr Hunter, who, in his "Georgical Essays," limits the duration of a variety in a state of perfection to about fourteen years. A fact ascertained by Mr Knight deserves to be particularly noticed: it is this; that by planting late in the season, perhaps in June or even in July, an exhausted good variety may in a great measure be restored; that is, the tubers resulting from the late planting, when again planted at the ordinary season, produce the kind in its pristine vigour, and of its former size.

*Jerusalem Artichoke.*

312. The *Jerusalem Artichoke*, or tuberous-rooted sunflower, (*Helianthus tuberosus*, L.; *Syngenesia Polygamia frustranea; Corymbiferæ*, Juss.) is a perennial plant, originally from Brazil. It has the habit of the common sunflower, but grows much taller, often rising ten or twelve feet high. Though its roots endure our hardest winters, the plant seldom flowers with us, and it never ripens its seed. The roots are creeping, and have many tubers clustered together, perhaps from thirty to fifty at a plant. These are eaten boiled, mashed with butter, or baked in pies, and have an excellent relish. The plant was introduced into our gardens early in the 17th century; and before potatoes became common, it was much more prized than at present. The epithet *Jerusalem* is a mere corruption of the Italian word *Girasole*, or sunflower; the name *artichoke* is bestowed from the resemblance in flavour which the tubers have to the bottoms of artichokes. As the potato is the *pomme de terre*, this is the *poire de terre* of the French.

The plant is readily propagated by means of the tubers. They are cut in the manner of potato sets, and planted, in any light soil and open situation, in the end of March. They are placed in rows, three feet asunder, and a foot or fifteen inches apart in the rows. In September they are fit for use; and in the course of November they are dug up and housed, being kept in sand like carrots. Sometimes they are left in the ground, and dug only as wanted, being best when newly raised. The only disadvantage is, that in this way they cannot be had in severe frosts. It is not very easy to clear the ground of them where they have once grown; and on this account, some gardeners devote a by-corner to them, and allow them to remain from year to year, taking up only what is wanted for the occasional use of the family. But the tubers thus produced are not so clean or well flavoured as those produced on newly delved ground by yearly planting.

*Turnip.*

313. The *Turnip* (*Brassica Rapa*, L.) is a biennial plant, growing naturally in some parts of England, and figured in "English Botany," t. 2176. The root-leaves are large, of a deep green colour, very rough, jagged and gashed. In the second season it sends up a flower-stalk, four or five feet high, having leaves which embrace the stem, very different from the former; smooth, glaucous, oblong, and pointed. The cultivated variety with a swelling fleshy root has long been known. Of this there are several well marked subvarieties, distinguished as garden or as field turnips. To the former belong the Early Dutch, Early Stone, and the Yellow; to the latter, the Large White, the Globe, the Swedish, the Red-topped, and the Tankard or oblong.

314. For the supply of the table during the early part of summer, some of the early Dutch turnip is commonly sown. If the weather prove dry, regular watering is proper. For a general crop, the large green-topped white turnip is accounted excellent, as being soft, juicy, and sweet. One of the kinds with which the London market is often supplied is the stone turnip, a hard sweet sort, seldom of a large size. The yellow is now perhaps less cultivated than it formerly was; but the yellow Dutch may still be considered as one of the best kinds for winter use, as no frost hurts it, and it is of excellent flavour. It is a very distinct variety, the flesh being yellow throughout; whereas, in the other varieties, any difference of colour is only in the rind. The red or purple-topped turnip was formerly much cultivated; but the green-topped has now in a great measure superseded it, though less hardy. The general crop is often sown towards the end of June, when refreshing showers may be expected. It not uncommonly occupies the ground from which early peas have just been removed. But as turnips are most desirable for the table in a young state, a small sowing is commonly made once a month from April to August. If sown earlier than April, the plants are apt to run to seed. To divide the seed more equally when sown broadcast, a little fine earth is mixed with it in sowing. It is frequently sown in drills, an inch deep, and somewhat more than a foot asunder. If rain do not occur, frequent watering is of great advantage to the young crops. A light sandy loam, not recently manured, is best for turnip; in a rich garden soil, the roots are apt to become rank and woody. When the root-leaves are about an inch broad, the plants are hoed; and, if they have been sown broadcast, thinned to six or eight inches distance from each other. When young turnips are daily drawn for the table, they may be allowed to stand somewhat closer, the proper degree of thinning being accomplished by pulling for use. If sown in drills, they may stand at five inches from each other in the lines. Turnips bear transplantation with difficulty; yet in moist and rainy weather, spots where the seed has failed may be filled up. When showery weather has made the leaves spring too much, so as to threaten the production of a flower-stem, it is sometimes found useful to tread them down, by placing the foot gently on the centre of the plant. In some gardens, turnips are sown on a slight hot-bed in February, and thus forwarded by two or three weeks; but the beds must have as much air as can possibly be given.

315. For winter use many families prefer the Swedish turnip, which may either be stored or remain in the ground. The stone and the yellow are also very hardy. The surplus of the garden crop, it may be remarked, may advantageously be given to milch cows; and, if the turnips be slightly boiled, no disagreeable flavour is communicated to the milk.

316. If seed is to be saved, it is of advantage that the plants be transplanted, it being thought, that from those so transplanted a progeny having sweet and tender roots may be procured; while from the untransplanted stock-turnips, larger but coarser roots may be expected. It is very important, at all events, to have the plants intended for seed-stock kept at as great a distance as possible from all others of the brassica genus. This seclusion of the seed-stock plants is often more completely accomplished by seed-farmers, than it can possibly be in private gardens.

317. The turnip-fly, or beetle, (*Haltica nemorum*), is very destructive to the crop when in the seed-leaf. One of the easiest remedies is to sow thick, and thus ensure a sufficiency of plants both for the fly and the crop. Mr Archibald Gorrie, a Scottish gardener of merit, has found, from repeated experience, that if quicklime be slightly dusted over the crop while yet in the seminal leaf, no attack will

be made. A preventive is often found in sowing late, the young beetles being compelled to feed on other herbage, and disappearing before the turnip expands its leaves.

If garden turnips be carefully packed in the store-house, and covered with plenty of straw, they keep in good order till March or April. Some are in the practice of cutting the top close off, but others prefer keeping up the power of growing. In some places both the green tops and the small roots of stored turnips are entirely cut off. It may be mentioned, that when turnips are left in the ground over winter, the top leaves form tender greens very early in the spring, which are particularly good for eating with salted meat.

*Navew.*

318. The *Navew* or French turnip is a variety of the *Brassica Napus*, Lin. or Rape, which grows naturally in different parts of Britain. (*Eng. Bot.* t. 2146). It is the most esteemed *navet* of the French, (who have no appropriate name for our round turnips,) and the *Steckrüben* of the Germans, in some places called *Teltower Rüben.* The root is small, and oblong or carrot-shaped; of excellent flavour: "two of these in seasoning," says Justice, in his Scots Gardener's Director, "will give a higher relish than a dozen of other turnips." It was anciently used throughout the south of Europe, and was more cultivated in this country a century ago than it is now. It is still in high repute in France, Germany, and Holland. It is put whole into soups, and is merely scraped, not peeled. It is remarked by Mr James Dickson, (one of the Vice-Presidents of the London Horticultural Society, but better known as an excellent cryptogamic botanist,) that, "stewed in gravy, the navew is excellent, and being white, and of the shape of a carrot, when mixed alternately with these upon a dish, it is very ornamental." In the paper alluded to, (*Lond. Hort. Mem.* i. 27.) Mr Dickson has given different receipts by an eminent French cook in London, for dressing the navew. It succeeds in any soil, either moist or dry; but in a dry light soil the flavour is highest. In strong garden soil, the roots get as large as parsnips, and resemble them considerably; but they are coarse, and deficient in flavour. The seed is sown in April, and the plants are thinned out to about five or six inches apart. The navew is sold in Covent Garden market, but chiefly to foreigners, who prefer it much to the turnip. For seed, some of the best plants are selected, and planted as remote from other brassicæ as circumstances will permit.

*Carrot.*

319. The *Carrot* (*Daucus carota*, Lin.; *Pentandria Digynia*; nat. ord. *Umbelliferæ*) is a biennial plant. In its wild state, it is a common weed in this country, growing by the road-sides, and known by the name of *bird's-nest*, from the appearance of the umbel when the seeds are ripening. It is figured in *English Botany*, t. 1174. The root of the wild carrot is small, dry, of a white colour, and strong flavoured. The root of the cultivated variety is succulent, and commonly of a yellow or an orange colour; it is universally known, and very generally relished, when cooked in various ways.

Several varieties are cultivated, particularly the Orange carrot, with a large long root, of an orange-yellow colour; the Early horn and the Late horn carrot, of both which the roots are short and comparatively small; and the Red or field carrot, which acquires a large size.

320 Carrots are sown at two or three different seasons. The first sowing is made as early perhaps as new-year's day, or at any rate before the first of February, on a warm border, or in front of a hot-house. Some employ a gentle hot-bed for this first crop; while others only hoop over the border, and cover it with mats during frost. The main crop of carrots is put in in March or April; and in June or July a small bed is sown, to afford young carrots in the autumn months. In some places a sowing is made a month later, to remain over winter, and afford young carrots in the following spring. These, however, often prove stringy, but they are useful in flavouring soups. In light early soils, it is better that the principal crop should not be sown sooner than the end of April or beginning of May; for in this way the attacks of many larvæ are avoided. For the early crops the horn carrot is best; for the principal crops, the orange variety is preferred; but the red is also much cultivated.

The seeds having many forked hairs on their borders, by which they adhere together, are rubbed between the hands with some dry sand, so as to separate them. On account of their lightness, a calm day must be chosen for sowing; and the seeds should be trod in before raking. They are sown either at broad-cast, or in drills a foot apart. When the plants come up, several successive hoeings are given; at first with a three inch, and latterly with a six inch hoe The plants are thinned out, either by drawing young carrots for use, or by hoeing, till they stand eight or ten inches from each other, if sown by broad-cast, or six or seven inches in line. The hoeing is either performed only in showery weather, or a watering is regularly given after the operation, in order to settle the earth about the roots of the plants left.

Carrots thrive best in light ground, with a mixture of sand. It should be delved very deep, or even trenched, and at the same time well broken with the spade. If the soil be naturally shallow, the late horn carrot is to be preferred to the orange or red. When manure is added to carrot ground, it should be buried deep, so that the roots may not reach it, else they are apt to become forked and diseased. In general it is best to make carrots the second crop after manuring. From the Scottish Horticultural Memoirs, however, (vol. i. p. 129.) we learn that pigeons'-dung, one of the hottest manures, far from injuring carrots, promotes their health, by preventing the attacks of various larvæ.

A considerable quantity of carrot-seed, for the supply of the London seedsmen, is raised near Wethersfield in Essex; but much is imported from Holland. Cautious gardeners generally *prove* this and some other kinds of seeds, such as onions, before sowing. This is easily done by putting a sprinkling in a pot, and placing it under a hot-bed frame, or in a forcing-house. Other gardeners transplant a few good roots, and raise their own seed: in this case it is better to gather it only from the principal umbel, which is likely not only to afford the ripest and largest seed, but the most vigorous plants.

321. Carrots are taken up at the approach of winter, cleaned, and stored among sand. They may be built very firm, by laying them heads and tails alternately, and packing with sand. In this way, if frost be excluded from the store-house, they keep perfectly well till March or April of the following year. Some persons insist that the tops should be entirely cut off at the time of storing, so as effectually to prevent their growing; while others wish to preserve the capability of vegetation, though certainly not to encourage the tendency to grow.

Carrots are now cultivated on an extensive scale in the field. They are excellent for milch cows or for horses; so that the overplus of a garden may always be turned to good account.

From old Parkinson we learn, that carrot leaves were in his day thought so ornamental that ladies wore them in place of feathers. It must be confessed that the leaves are beautiful. If during winter a large root be cut over about three or four inches from the top, and be placed in a shallow vessel with water, over the chimney-piece, young and delicate leaves unfold themselves all around, producing a very pretty appearance, enhanced no doubt by the general deadness of that season of the year.

*Parsnip.*

322. The *Parsnip*, (*Pastinaca sativa*, L.; *Pentandria Digynia*; nat. ord. *Umbelliferæ*), is a biennial plant. The wild parsnip is not uncommon by the way sides near London, and in many parts of England, chiefly on calcareous soils: it is figured in *English Botany*, t. 556. The garden variety has smooth leaves, of a light or yellowish-green colour, in which it differs from the wild plant, the leaves of which are hairy and dark green: the roots also have a a milder taste: it does not, however, differ so much from the native plant, as the cultivated does from the native carrot. It has long been an inmate of the garden, and it was formerly much more in use than it is now. It was, in Catholic times, a favourite Lent root, being eaten with salted fish. It is doubtless a highly nutritious esculent, and the increase of its cultivation might be useful to the labouring class in England. In the north of Scotland, parsnips are often beat up with potatoes and a little butter; of this excellent mess the children of the peasantry are very fond, and they do not fail to thrive upon it. In the north of Ireland, a pleasant table beverage is prepared from the roots, brewed along with hops. Parsnip wine is also made in some places. If the crop prove too large for the use of the family, the superfluous part (as has been remarked of turnips and carrots) will be found to be very acceptable and useful to a milch cow.

The soil preferred for parsnips is a light loam, but almost any soil will do, provided it be pretty deep; the parsnip requires, however, a stronger soil than the carrot. The quarter should be trenched, or at least deeply dug, in order that the roots may have liberty to strike freely downwards. The seed is sown, broad-cast, in March, either alone, or together with a proportion of radishes, lettuces, or carrots, and in light soils it is well trodden in: the salad plants being soon removed, or the carrots drawn young, do not materially hinder the growth of the parsnips, which spread and swell chiefly in the latter part of the summer. The parsnips are hoed out to about eight or ten inches asunder, or in strong ground a little wider; and the hoeing is repeated as often as the growth of weeds may render it proper. When the leaves begin to decay, the roots are fit for use. They are taken up as wanted during the winter, the root not being in the least injured by frost. About the beginning of February, however, the remaining part of the crop is raised and stored among sand, as the roots become stringy as soon as the new growth takes place, and the flower-stalk begins to form. In some places, the whole crop is taken up in the end of October, and either stored in sand like carrots, or placed in covered pits in the manner of potatoes. If two or three large roots be transplanted to a sheltered border, they will not fail to ripen their seeds, and to afford a sufficient supply: it is proper to tie the flower-stems to stakes, as they grow high, and are apt to be broken over by the wind. Seed that is more than a year old should never be sown.

In the first volume of the Scottish Horticultural Memoirs, (p. 405), Dr Macculloch has described two varieties of parsnip, which are cultivated in the Channel Islands, and there attain extraordinary size,—the *Coquaine* and *Lisbonaise*. The former runs deep into the soil, perhaps three or four feet; the latter becomes thick, but remains short, and is therefore suited to shallow soils. The French writers describe a variety having the root of a yellowish colour, more tender, and of a richer taste than the common kind: they call it the Siam parsnip.

*Red Beet.*

323. *Red Beet* (*Beta vulgaris*, L. *Pentandria Digynia*; *Atriplices*, Juss) is a biennial plant, a native of the seacoast of the south of Europe. It was cultivated by Tradescant the younger in 1656. It was formerly called in this country *beet-rave* (or beet-radish), from the French name *bette-rave*. The leaves of the cultivated sort are large, thick, and succulent, generally red or purple; the roots large, perhaps three or four inches in diameter, and a foot in length, and of a deep red colour. They are boiled and sliced, and eaten cold, either by themselves or in salads; they also form a beautiful garnish, and are much used as a pickle. The roots of a variety having green leaves are by some accounted more tender than those of the red-leaved sort, and are on that account preferred. Others prefer those with dark red leaves, provided these be small and few in number. There is a short or turnip-rooted variety, also of a purple colour, and used for the same purposes. From its mode of growth, this is much better suited than the others to heavy or to shallow soils.

Red beet requires a light but rich soil, of considerable depth, and which has not been recently manured. The ground should be trenched, or very deeply delved, and at the same time broken small with the spade. The seed is sown in April, in drills, an inch deep, and fifteen inches asunder. If sown in March, many of the plants are apt to send up flower-stalks, and so become useless. Kitchen gardeners often sow red beet along with carrots and onions; and drawing these two last for the market when young, they leave the beet alone to occupy the ground.

324. In lifting beet for the winter stock, care should be taken that the roots be not anywise broken or cut, as they bleed much. For the same reason, the tops or leaves are cut off at least an inch above the solid part of the root. They are cleaned, and laid in close rows along the floor of the cellar or store-house, sometimes without any covering of sand, taking care, however, to exclude frost; but more frequently packed with sand in the manner of carrots.

If a few strong roots of red beet be left standing in the rows, or rather be transplanted to some convenient spot, they will next year shoot up and produce seed. The flower-stems should be tied to stakes, to prevent their breaking over. It is scarcely necessary to add, that they should be removed as distant as possible from flowering plants of the green variety, or of the white species.

325. From a variety of the garden beet, having a red skin but white flesh, sugar is prepared in some parts of France and the Netherlands; a manufacture which was introduced during Buonaparte's government, when West India sugars were utterly prohibited. A small species of beet has been cultivated for a good many years in France, under the name of *Castelnaudari*, but which is very little if at all known in this country. It is described as possessing a fine flavour, something like that of a hazel-nut. It is ready for use in August. The colour of the root is the same as that of common beet-rave; but its leaf is smaller, rounder, and rather of a livid hue.

The *White Beet*, although stated by some writers (as Salisbury, in the "Botanist's Companion") to be only a variety of the red, is in reality a very distinct species, *Beta*

*Cicla* of Linnæus; but as the leaves and not the roots of this species are used, it will fall to be treated of under the section *Spinach plants*.

*Skirret.*

326. The *Skirret* (*Sium Sisarum*, L.; *Pentandria Digynia*; nat. ord. *Umbelliferæ*) is a native of China. It has been cultivated in our gardens since the middle of the 16th century, and was formerly more esteemed and more in use than it is at the present day. In the "*Systema Horticulturæ*, by J. W. gent. 1682," *skirwort* is declared to be the "sweetest, whitest, and most pleasant of roots." It is a perennial plant; the lower leaves pinnated; the stem rising about a foot high, and terminated by an umbel of white flowers. The root is composed of fleshy tubers, of the size of the little finger, joined together in one head: these form the part of the plant used. They are considered wholesome and nutritive, but, having a sweetish taste, are not relished by many persons. They are generally boiled and served with butter like parsnips. In the north of Scotland, the plant is cultivated under the name of *crummock*. It is the *chervis* of the French.

Any light deep soil is found to answer for skirret. If the ground be naturally moist, so much the better. In very dry soils, or during long-continued drought, watering is proper. The seed is not sown sooner than the beginning of April, lest the plants should run to flower the first season, when the tubers would become harsh and stringy. Repeated thinning and hoeing are proper, as in the case of similar crops. When the leaves begin to decay in autumn, the tubers are considered as fit for use; but they are generally left in the ground, and taken up as wanted. Sometimes the plants which remain over winter are dug up in the spring, and the side-shoots, each with an eye or bud, are transplanted for a new crop. These are commonly put in with the dibble, and covered over head with an inch depth of soil. But the tubers yielded by plants propagated in this way are not so large as those of seedling plants.

*Scorzonera.*

327. *Scorzonera*, or garden viper's grass, (*Scorzonera Hispanica*, L.; *Syngenesia Polygamia Æqualis*; *Cichoraceæ*, Juss.) is a native of Spain, the south of France, and Italy. The stem rises two or three feet high, with a few embracing leaves, and is branched at top; the lower leaves are eight or nine inches long, and end in a sharp point; the flowers are yellow. It was cultivated in gardens in this country in the end of the 16th century. The tap root is the part used; it is carrot-shaped, about the thickness of one's finger; tapering gradually to a fine point, and thus bearing some resemblance to the body of a viper: it has a dark brown skin, but is white within, and abounds with a milky juice. The outer rind being scraped off, the root is steeped in water, in order to abstract a part of its bitter flavour. The plant is not, in the present day, much cultivated.

The seeds are sown in any cool deep soil, generally in drills, about a foot separate, where they are to remain, after being thinned out to four inches apart. The plant is perennial; but the roots are fit for use only the first autumn and winter after sowing, while as yet no flower-stem has risen; the roots, like all others, becoming tough when the flowers are produced. To avoid the risk of the plants running to flower the first season, the seed is not sown till the middle of April. If a few strong plants be left, they yield seeds freely the following year; or the plant may be propagated by slips in the manner of skirrets; but the roots thus procured are not so good or tender as those from seed. In some gardens, the roots are lifted in November, and stored in the manner of carrots; in others, they are left in the ground, and taken up during winter as wanted.

*Salsify.*

328. *Salsify*, or purple goat's-beard, (*Tragopogon porrifolius*, L.; *Syngenesia Polygamia Æqualis*; *Cichoraceæ*, Juss.) is a biennial plant, a native of some parts of England, but not common; figured in *English Botany*, t. 638. It is the *salsifis* or *cercifis* of the French. The root is long and tapering, of a fleshy white substance; the herb smooth, glaucous, and rising three or four feet high; the leaves resembling those of the leek, as intimated in the trivial name; the flowers of a dull purple colour, closing soon after midday; the seed, as in other species of goat's-beard, remarkable for having attached to it a broad feathery crown. It has been cultivated for a century past in our gardens, but Gerarde and Parkinson do not mention it; while they recommend the yellow goat's-beard, *Tragopogon pratensis*, which is now neglected. Salsify roots, boiled or stewed like carrots, have a mild sweetish flavour. The stalks of year-old plants are sometimes cut in the spring, when about four or five inches high, and dressed like asparagus. Salsify is at present, however, but little attended to.

It is sown in April, and thinned, like similar crops, to six or eight inches apart. A mellow and deep soil affords the best plants. They may remain in the ground all winter, and be taken up as wanted. If two or three roots be left, or be transplanted in the autumn, they will afford abundance of seed the following year.

*Radish.*

329. The *Radish* (*Raphanus sativus*, L.; *Tetradynamia Siliquosa*; nat. ord. *Cruciferæ*) is an annual plant, originally from China. It is mentioned by Gerarde; and was probably known in England long before his time. The leaves are rough, lyrate, or divided transversely into segments, of which the inferior less ones are more remote; the root fleshy, fusiform in some varieties, in others subglobular; white within, but black, purple, or white on the outside; the flowers, pale violet, with large dark veins; pods long, with a sharp beak.

There are two principal varieties, distinguished by the shapes of the roots already mentioned: 1. With fusiform roots, the long-rooted or spindle-rooted radish, the *rave* of the French; 2. With subglobular roots, the turnip-rooted radish, the *radis* of the French. The roots of both are used principally in the way of salad, in winter and the early part of spring. Formerly the leaves were often boiled and eaten; but now the roots only are employed; and as they are always used raw, the plant might, without impropriety, have been ranked under the title of *Salads*.

330. Of the spindle-rooted kind, the subvarieties much in cultivation are, the small-topped or short-topped purple, the leaves of which occupy little room; and the pink or rose-coloured, or, as it is frequently called, the salmon radish. There is also an early dwarfish short-topped red, and an early short-topped salmon radish, sown for the first crops, and used for forcing. Of the turnip-rooted kind, there are several subvarieties. The small turnip-rooted white or Naples radishes, when they appear in the green market in spring, are not unfrequently mistaken for young turnips: they should be eaten young, when crisp and mild, being, when full grown, rather hot and harsh. There is also a small turnip-rooted red radish, and the queen radish, both red and white. The black turnip-rooted or Spanish

radish (*raifort* of the French) has a dark coloured skin, but is white within; though rather coarser than the others, it is much esteemed for autumn and winter use.

Radishes are sown for the earliest crop in the beginning of November, in a sheltered border, or in front of a pinery or green-house; and they are ready for drawing early in March. More seed is sown in December or January: and sowings are continued once a fortnight till April, so as to secure a succession of young roots as they may be wanted.

Any sort of light soil answers, but it should be of sufficient depth to allow the long roots to penetrate easily. A slight covering of fern (*pteris*) is found very useful in the early spring months, when sharp frosts occur: this covering may be raked off in the day-time, and restored at night, without much injury to the leaves of the young radishes. When very dry weather occurs in the end of March, the crops are regularly watered. They who wish to have large radishes are sometimes at the pains to prick a number of holes with the finger, and to drop a seed into each hole. Only a little earth is then tumbled into it, the greater part of the hole being left vacant. The root is thus induced to swell, and long and semi-transparent radishes are procured, Some gardeners mix spinach seed with their later sowings of radishes; so that when the radishes are drawn, the other soon covers the ground. Others sow lettuce and onions along with radishes. If radishes are to be drawn when small, they are allowed to stand at two inches only apart; otherwise they have twice that space or more allowed them. When crowded, they are apt to become stringy in the root.

331. The turnip-radish is sown in February or March, and the plants are thinned out to about six inches with a small hoe. The red and the white queen radish, and the black Spanish radish, are sown from the middle of July to the middle of September, and thinned out in the same manner. They are fit for use in the beginning of September; and before hard frost comes on, they are generally taken up, and stored among sand like carrots, the tops being cut close off: in this way they are ready for use throughout the winter.

The dwarf early short-topped red, and early short-topped salmon radishes, are easily forced on a hot-bed: if the seed be sown by the middle of November, the radishes will be fit for drawing by the end of December, and will afford a supply for a month. Care must be taken to have a sufficiently thick layer of earth, to hinder them from penetrating into the dung.

The seed of any of the sorts is easily procured by transplanting a few of the best and most characteristic plants of the respective kinds: the sorts should be placed as far from each other as possible, to prevent commixture of pollen.

It may be noticed, that the young and green seed-pods are sometimes used for pickling; and are perhaps scarcely inferior to nasturtiums.

It may also be mentioned, that Delaunay, in his *Bon Jardinier*, 1815, describes a new sort of turnip-radish, introduced of late years into France from Egypt; it is remarkable for being of a yellow colour. It has more poignancy than any of the kinds, except the black; and experience has shewn that it may be produced, in the Paris gardens, at almost any season of the year.

## *Alliaceous Tribe.*

### *Onion.*

332. The *Onion* (*Allium Cepa*, L. *Hexandria Monogynia*; *Asphodeli*, Juss.) is a biennial plant, well marked by its fistular leaves, swelling stalk, and bulbous root. Neither the native country of the plant, nor the date of its introduction into this island, are known. There are several varieties in cultivation. One of the chief of these is the Strasburgh, which is of an oval shape, attains a considerable size, and keeps very long. The Deptford onion may be considered as a subvariety of the Strasburgh. The white Spanish onion grows to a large size, and is of a flat shape. Allied to this is the large silver-skinned onion, the most beautiful of all the varieties: the small silver-skinned is preferred for pickling. The globe onion is likewise much cultivated, being a good keeper; and the Reading and the Portugal are frequently sown.

333. For the principal crop, the seed is sown in February or the beginning of March, according to the state of the weather, and the dryness of the ground. The onion delights to grow on light but rich ground, which has not been recently manured: it should be well delved, broken fine, and exactly levelled. In heavy land, it is thought better to sow in the end of March or beginning of April. The seed is either sown at broad-cast or in shallow drills; a very slight covering of earth is given, and the bed is merely smoothed with the rake; the more that onions grow on the surface, the better they prove. The usual proportion of seed is about an ounce to a pole of land. Market gardeners sometimes sow thicker, with the view of drawing young onions, which are called cullings, or in Scotland *sybies* (from *ciboules*.) A small quantity of lettuce seed is frequently sown along with onions; and very fine lettuce plants are thus procured, without materially injuring the onion crop. A first hoeing is given when the plants have advanced three or four inches in growth, and they are then thinned out with the hand to about four inches apart. Another hoeing is given, generally about a month or six weeks afterwards, according to the kind of season; and the broad-cast plants are then singled out to about six inches square, and those in drills to about four or five inches in line. After the onions have begun to swell, the hoe cannot be used, and any large weeds are drawn out with the hand. If the weather be dry at the time of thinning, a plentiful watering is necessary for settling the earth to the roots of the remaining plants. About the end of August the crop is ripe, which is known by the leaves falling down. The onions are then drawn, and laid out on a dry spot of ground, such as a gravel walk, and occasionally turned. In a fortnight they are generally found sufficiently firm and dry for keeping; and they are then stored in a garret or loft, (never in a cellar,) and excluded as much as may be from the air. They are still very apt to grow; and to prevent this, some are at the pains to select the finest bulbs, and singe the radicles with a hot iron. In many places they are strung in bunches, and suspended from the roof of the loft.

334. The secondary crop of onions is sown in August or the beginning of September, and called the Michaelmas or winter crop. They are thinned in the usual way; and weeds must be carefully kept down, as they spring up very rapidly at this season of the year. In the spring months, when the keeping onions fail, part of these autumn sown onions are drawn for use: the remainder form bulbs, which are ready in the early part of summer. In the course of May, however, some bulbs will be observed pushing a flower-stem: these are cast out; and to check this tendency, and divert the growth to the bulb, the crop is *laid over*, as it is called. This operation is described by Nicol in his "Kalendar." Two people, with a rod or rake-handle, walk along the alleys, holding the rod so as to strike the stems an inch or two above the bulb, and bend them flat down. Winter onions, thus managed, may be

taken up about the end of June, and are generally firm and keep long.

In order to procure firm diminutive bulbs, proper for pickling, some seed should be sown late in the spring, perhaps about the middle of April, in light and very poor land. It should be sown pretty thick; and the seedlings need scarcely be thinned, unless where they rise absolutely in clusters. The bulbs thus treated are generally of a proper size for pickling in August. The small silver-skinned variety, it has been already mentioned, is well adapted for this purpose.

It may here be noticed, that such of the keeping onions as have sprouted in the loft are sometimes planted in a bed early in the spring, especially by market-gardeners. In a short time they appear fresh, throwing out long green leaves. They are then sent to market, tied in small bunches, and sold as a substitute for *scallions*, and under that name.

335. It has long been known, that young seedling onions might be transplanted with success. Even Worlidge, in his little treatise on gardening,* published in the end of the 17th century, praises this mode. The practice has of late years been revived, and recommended in England by Thomas Andrew Knight, Esq. and in Scotland by Mr James Macdonald, gardener to the Duke of Buccleuch at Dalkeith. Mr Knight's plan is, to sow the onion seed, at the ordinary autumn season, thick under the shade of a tree, and to transplant the bulbs the following spring: he thus procures onions equal in size and other qualities to those imported from Spain. Mr Macdonald, again, transplants the young spring sown onions. He sows in February, sometimes on a slight hot-bed, or merely under a glass frame; and between the beginning of April and the middle of the month, according to the state of the weather, he transplants the young seedlings, in drills about eight inches asunder, and at the distance of four or five inches from eath other in the row. It is evident, that, hy thus having the crop in regular rows, hoeing may not only supersede hand-weeding, but may be more effectually performed. The bulbs, thus enjoying the great and well-known advantages of having the surface-earth frequently stirred, swell to a much larger size than those not transplanted; while in firmness and flavour they are certainly not inferior to foreign onions. At the same time the transplanted onions remain free from wire-worm or rot, while those left in the original seed-bed are frequently much injured by both. The beds destined for these onions, having probably been under a winter crop, are deeply delved over in the beginning of April, and thus rendered clean at the most critical season of the year for the larvæ that infest the soil. Besides, the plants grow with superior vigour, in consequence of the repeated hoeings, and are thus better able to resist injuries. Mr Macdonald, indeed, sometimes practises the dipping of the roots of seedlings in a puddle prepared with one part of soot and three parts of earth; but this may probably be dispensed with, as it seems likely that the exemption from the attacks of the worm, or the power of resisting them, depend rather on the other circumstances mentioned. It may be added, that all the varieties of onion seem to answer equally well for transplanting.

Various means have been suggested of guarding against the attack of the maggot alluded to. One of the most simple and most important consists in selecting a fresh soil and an airy situation, never sowing on recently manured land. It is proper to avoid having very tender plants at the season when the maggot is known commonly to make its appearance: by sowing a fortnight or three weeks later or earlier, crops might often be saved. It is frequently remarked, that while spring sown onions are cut off, the autumn sown crop escapes. Mr Machray at Errol has suggested the propriety of sowing onions only after crops known not to be subject to the attacks of the maggot, such as strawberries and artichokes. This plan, he informs us, (*Scottish Hort. Mem.* i. 274.) he has practised for a number of years, and has found effectual in preserving his onions; while it is attended with no inconveniency, as nothing can be more easy than to keep up a succession of strawberry and artichoke plants.

336. The procuring of fresh seed is a matter of importance; for if it be kept over a year, a great part will not germinate. Onion seed can be ripened in our climate; but some how or other it is very apt to degenerate. A good deal, however, is yearly saved in the neighbourhood of Deptford. Imported seed is always *proved* by attentive gardeners, and also by seedsmen: a small sample being sown in a flower-plot, and placed in a hot-house, the quality, as far as capability of germination is concerned, is soon determined. When it is intended to collect home seed, some of the firmest, largest, and best shaped bulbs are selected, and planted out in February or March, in good ground, near a south wall or hedge. When the heads are formed, they are supported by lines of small cord passed between stakes. In September, if the season be favourable, the seed ripens, turning to a brown colour, and beginning to burst the cells which contain it. The heads are then gathered; and, when dried, the seeds are beat out, and kept in paper bags.

337. A bulbiferous variety is cultivated in some gardens, under the name of *Tree onion.* Its culture has been recommended by Mr George Nicol of Edinburgh, in the Memoirs of the Caledonian Horticultural Society, (vol. i. p. 350.) under the title of *Allium Canadense*, a species for which it has very generally been mistaken. The stems from two-year old plants rise more than two feet high. Several bulbs of different sizes are produced at the top of the stem, and these, as well as the root-bulbs, may be used for kitchen purposes, like common onions. They are of good flavour, though rather stronger in taste than common onions. They are well adapted for keeping, and especially for pickling. Mr Nicol observes, that they are very seldom infested by maggots; and he recommends, therefore, that a few stock-bulbs should be preserved in gardens, to provide against the contingency of the crop of common onions failing.

This bulb-bearing or tree-onion is figured in the "Botanical Magazine," plate 1469, and described by Dr Sims as merely a variety of the *Allium cepa.* It is certainly not the *Allium Canadense* of Willdenow or Pursh, (for which, as already noticed, it has been generally mistaken.) the Canadian plant having flat linear leaves, and a slender uninflated stem, with top-bulbs resembling those of garlic. But, on the other hand, it differs from the common onion, not only in producing bulbs at top, but in having a stronger alliaceous flavour, and in being perennial. Possibly therefore it might constitute a distinct species.

338. The *Egyptian onion*, or *Ground onion*, has been considered as another variety of *Allium cepa*, but seems to be more nearly allied to *A. fistulosum.* Instead of producing bulbs at the top of the stem like the former, this plant produces clusters at the surface of the ground in the manner of potatoes. It was brought from Egypt, it is believed, during the occupation of that country by the British army, and was first cultivated in the neighbourhood of Edinburgh in 1811, by Lieutenant Burn of the Royal

* *Systema Horticulturæ*, by J. W. gent.—2d edit. 1683.

Navy. The bulbs are planted in April, at a foot or sixteen inches asunder, and covered with earth only about half an inch deep. In the course of the season, a number of bulbs form in clusters around the parent bulb, as already described; those nearest the surface grow largest; those toward the centre are soonest ripe, and may be removed, to give room to the others. If intended for keeping, they should be taken up before they attain maturity. If allowed to remain long in the ground, they sometimes become of a very large size. The bulb seems quite hardy, having been observed to brave the severity of frosty weather, at least equally well as the common onion. Flower stems rise sparingly, and only from strong bulbs. In quality the ground onion seems not inferior to the common onion. It more speedily reaches maturity, being planted in April, and reaped in August and September. Maggots have not been observed to infest it; but it has not been ascertained that they will not attack it. From our own experience, we suspect that it will speedily degenerate in this country.

339. The *scallion* seems to be a third variety of the Allium Cepa, distinguished by the circumstance of its never forming a bulb at the root. Miller states, that the scallion is propagated by parting the roots in autumn; that it grows in almost any soil or situation, and resists our severest winters. He adds, that, being green and fit for use very early in the spring, it is worthy of a place in all good kitchen gardens. It was, indeed, formerly much in use; but the true scallion is now very little known, and is said to exist only in a few gardens, where it is preserved by way of curiosity. Some derive the name *scallion*, or *escallion*, from *ascalonicum*, and without more ado identify it with the rocambole, (*A. ascalonicum*); others consider it as synonymous with the Welch onion, (*A. fistulosum*); but both these species were well known to Miller, and accurately distinguished by him, and yet he describes the scallion as something different. In popular language, scallion means sometimes a thick-necked seedling onion, drawn for use in the green state; and sometimes, as already mentioned, a winter kept onion which has sprouted, and is planted for some weeks in the spring till it acquire green leaves.

*Leek.*

340. The *Leek* (*Allium Porrum*, L; *Poireau* of the French) is a native of Switzerland, and a biennial plant. The stem rises three feet, and is leafy at bottom, the leaves an inch wide. The flowers appear in May, in close very large balls, on purplish peduncles. The whole plant is used for culinary purposes; but the blanched stem is most esteemed. It is in season in winter and spring, and is chiefly used in soups, and for stewing. It is mentioned by Tusser in 1562, but was no doubt known in this country long before that date. The Welch are proverbially fond of leeks.

"Leek to the Welch, to Dutchmen butter's dear!"

sings Gay; and the description of a plain prose writer justifies the remark: "I have seen the greater part of a garden there stored with leeks," says Worlidge, speaking of Wales, "and part of the remainder with onions and garlic." Leeks formerly constituted an ingredient in the dish called *porrage*,—a name, indeed, which may be supposed to be derived from *porrum*.

There are three varieties: the narrow-leaved or Flanders leek; the Scotch, or flag leek, sometimes called the Musselburgh leek; and the broad-leaved or tall London leek. The latter variety is often cultivated; but for exposed situations, the Scotch leek is by much the more hardy.

Leeks are raised from seeds sown in the spring, much in the same way as onions, and occasionally along with these. They are at first sown closely in beds; and in June or July, when early cabbage or an early crop is removed, the leeks are planted out in rows, about a foot apart, and six inches asunder in the rows. The tips of the leaves, and the points of the fibrous roots, are commonly trimmed off before planting. A good rule is, to make a deep hole with the dibble, and merely to lay in the leek-plant up to the leaves, without closing the earth about it. In this way the stem of the leek is encouraged to swell and lengthen, and is at the same time blanched. This plan, however, must either be adopted only in moist weather, or the plants must be well watered, so as to ensure their taking root. It is remarked, that if the leaves be topped two or three times during the summer, the leeks grow to a larger size; as new heart leaves are pushed forth, and the stalks, or useful part, are thus increased. They are ready for use in the autumn and winter. When there is a prospect of severe frost, part of the leek crop is sometimes lifted, and laid, with the roots in sand, in a cellar.

In good seasons, the seed ripens perfectly well in this country. For producing seed, the largest plants are selected, and in February are transplanted to the south side of a wall or hedge. As the flower-stems advance, they are supported by strings passed along and fixed to stakes, being apt to be kroken by the wind, especially when the heads get large and heavy. When ripe, which is generally in September, the heads become brown; they are cut off along with part of the stalk, and hung up for some weeks, and the seed is then rubbed out.

*Cibol.*

341. The *Cibol*, or Welch Onion, (*Allium fistulosum*, L.; *La Ciboule de St Jacques* of the French), is a perennial plant, a native of Siberia. It appears, from Parkinson, that it was cultivated in 1629, but it was known long previously. Although called Welch *onion*, it produces no bulb; but the fistular leaves, and the lower part of the stems, are much used in salads in the spring months. They have rather more of the garlic than of the onion flavour. Sometimes they are planted as scallions; indeed, some consider this plant as the true scallion, but without sufficient evidence.

Cibols are chiefly raised from seeds, which are sown in July. The seedling plants soon appear; but, in the course of October, the leaves go off, and the ground seems quite bare. As early as January, however, they again begin to shoot, and by March they are fit for use, being then very green and tender. As might be expected of a Siberian plant, it withstands our severest winters. The wide-swelling fistular leaves give it rather a curious appearance; a few plants may therefore be suffered to stand on a south border of the garden, where they will in general ripen their seed.

Dr Johnson (*Dict. in loco*) remarks, that the name *cibol* is frequently used in the Scotch dialect, but that the *l* is not pronounced. By the term *cibo* or *sybie*, however, the Scots mean a young seedling onion of the common kind, gathered for use before the swelling of the bulb: the true cibol is very little cultivated in Scotland, and is not distinguished by the common people.

*Chives.*

342. The *Chive* or Cive, (*Allium Schœnoprasum*, L.) is

a perennial plant, of more humble growth than any of its congeners in the garden. It is a native of Britain, but not common: it occurs, among other places, in the south of Scotland, on low hills near Hawick; it is figured in "English Botany," plate 2441. The bulbs are very small and flat, and grow connected together in clusters. When gathered for use, they are cut or shorn like cresses, and on this account are generally spoken of in the plural. The young leaves are employed principally as a salad ingredient in the spring, being accounted milder than scallions. Occasionally the leaves and small bulbs are used together, slipped to the bottom, and thus forming, as it were, separate little cibols. Sometimes they are added as a seasoning to omelets; and they are useful for other culinary purposes.

Chives are readily propagated by parting the roots either in autumn or spring, and they will grow in any soil or situation. They should be repeatedly cut during the summer season, the successive leaves produced in this way being more tender. A small bed or border thus managed, will afford a sufficient supply: it will continue productive for three or four years, when a new plantation should be made. Chives are sometimes planted as an edging; and if they be allowed to grow up, they make a pretty enough appearance with their pale purple flowers in June.

*Garlic.*

343. *Garlic* (*Allium sativum*, L.; *Ail* of the French) is a perennial plant, growing naturally in Sicily, and in the south of France. The leaves are linear, long, and narrow. It has a bulbous root, made up of a dozen or fifteen subordinate bulbs, called cloves. It was cultivated in England in 1548; but had probably been known long before that period. When an entire bulb is planted, it does not fail to throw up a flower-stem in the summer; but this is not wished. Garlic is therefore propagated by detaching the cloves, and planting them; and in this way the tendency to flower is less. It may be propagated also by the seed; but this mode is tedious, three years elapsing before a tolerable crop is produced. The soil should be light and dry, well delved, and broken fine. The sets are placed four inches distant from each other in every direction, and between two and three inches deep. The smaller the cloves, the more healthy and productive are the plants. They are put in in February or March. About the middle of June the leaves are tied in knots, to prevent the stronger plants from spindling or running to flower, and to promote the swelling of the bulbs. The crop is taken up in August, when the leaves begin to wither. The roots are tied in bunches, and hung in a dry room for use. Garlic is used in seasoning various kinds of dishes, being in general introduced only for a short time into the dish while cooking, and withdrawn when a sufficient degree of flavour has been communicated. It is much more employed in French cookery than in ours. An ordinary sized bed commonly furnishes a sufficient supply for the use of a large family in this country.

*Shallot.*

344. The *Shallot* (*Allium ascalonicum*, L.) is a perennial plant, a native of the Holy Land, where it was observed by Hasselquist. *Eschalot* (or *Eschalotte*, F.) is the more correct denomination, the name being derived from Ascalon, a town in Palestine. In some old books it is styled *barren onion*, from the circumstance of its seldom sending up a flower-stalk. In size and general growth the plant resembles the chive; but it produces bulbous roots, composed of cloves like garlic. These are used for culinary purposes in the manner of garlic; but they are milder, and do not communicate to the breath the offensive flavour which garlic or even raw onions impart.

The culture of shallots is greatly similar to that of garlic; only the offsets or cloves are planted more early, and the crop is somewhat sooner taken up. The smallest and longest cloves form the best sets, being least subject to grow mouldy. A good soil is desirable for them; but one that has been manured for a former crop is to be preferred; for in soil newly dunged the plants are much more apt to be infested with maggots. Mr Marshall very properly recommends planting in autumn where the soil is dry, and in spring where it is naturally damp. The severest frosts seem to have no effect in injuring the roots. The crop is taken up, in the end of summer, when the leaves become discoloured; and the bulbs are hung up in nets in a cool airy place, for use.

Mr Machray at Errol mentions (*Scottish Hort. Mem.* i. 275), that he has found soot mixed with the manure given to shallot beds effectual in preventing the appearance of maggots, while the shallots were improved in size. But Mr Henderson, gardener at Delvine in Scotland, has recommended the planting of shallots in autumn, as the surest way of enabling them to escape or withstand the attacks of these vermin, (*Scottish Hort. Mem.* i. 200.) He plants his shallots about the middle of October, the ground being previously manured with old well-rotted dung mixed with house ashes. He mentions, that he had, on one occasion, a parcel of spring planted shallots only seven feet distant from those planted in autumn; and that the former were totally destroyed by the maggot, while the latter proved productive and good.

*Rocambole.*

345. The *Rocambole* (*Allium Scorodoprasum*, L.; *Ail d'Espagne* of the French) is a perennial plant, indigenous to Sweden and Denmark. It has compound bulbs like garlic, but the cloves are smaller; it sends up a stem two feet high, which is bulbiferous. We know that the rocambole was cultivated by Gerarde in 1596, but it was probably introduced long before. The cloves are used in the manner of garlic or shallot, and nearly for the same purposes. At the top of the stem, along with the flower, in July and August, small bulbs (which have sometimes been called *seeds*) are produced; these may likewise be used, and indeed they are, strictly speaking, the proper rocamboles.

The plant may be propagated by means of either sort of bulbs; but those of the root are most speedily productive. They are commonly planted in the spring; but in dry ground they are put in in the autumn, the produce being in this way of a larger size. Those plants which do not push up a flower-stem naturally produce the strongest root-bulbs; and if it is not wished that the plants should fruit, the smaller the offsets planted the better. The culture is otherwise the same as that of garlic. A few rows of rocambole are sufficient.

## *Spinach Plants.*

*Spinach.*

346. *Spinach* (*Spinacia oleracea*, L.; *Diœcia Pentandria; Atriplices*, Juss. *Epinard*, F.) is an annual plant, with the leaves large, the stems hollow, branching, and, when allowed to produce flowers, rising two feet high. It is diœ-

cious, or the male and the female flowers are produced on different plants; the former come in long spikes; the latter appear in clusters, close to the stalk, at every joint. Spinach is the only diœcious plant cultivated for culinary use. Western Asia is the country of which our garden spinach is considered as originally a native. It has been cultivated in Britain, from the earliest times of which we possess any horticultural record, for the sake of the leaves, which are used in soups, or boiled and mashed, and served up with butter, and eggs hard done.

There are two principal varieties, the prickly-seeded, with triangular, oblong, or sagittate leaves; and the smooth-seeded, with round or blunt leaves. The former is the more hardy, and is employed for winter culture; the latter has more succulent leaves, and is preferred for summer crops.

For the winter crop, therefore, the seed of the prickly kind is sown in the beginning of August, when rains may soon be expected. A light dry but rich soil is preferred; and a sheltered situation is desirable. When the plants shew four leaves, the ground is hoed, and the spinach moderately thinned; and the hoeing is repeated, as the growth of weeds may require. In October and November, the outer leaves of the spinach are generally fit for use; and in mild weather, during the winter and early spring, successive gatherings may thus be procured. In February, some fine dry days generally occur, and at this time the surface of the ground around the winter spinach is stirred, the plants cleaned, and finally thinned out. With due attention, the prickly spinach thus proves productive till April or May.

The first sowing of smooth-seeded or round-leaved spinach is commonly made in the end of January, on a sheltered border. This early crop, if sown broad-cast, is at first thinned out to three inches apart, and, at subsequent hoeings, to eight or ten inches. Successive sowings are made in February, March, and April, in the ordinary garden compartments, and these are at once thinned out to six or eight inches apart. In some places these crops are placed between wide rows of cabbages, as they afford a crop before the cabbages advance much in growth. Sometimes radish seed is sown along with them, the radishes, on the other hand, being drawn off in time to give room to the spinach. If spinach be sown late in the season, it is done only on moist clayey grounds, the quality of which, while it promotes the production of leaves, rather retards the inclination to flower; and the sowings are repeated every fortnight. Spinach is often sown in shallow drills, about a foot asunder: this mode is more troublesome at first; but this is compensated by the facility with which the thinning, cleaning, and gathering, are afterwards accomplished: indeed, less thinning is necessary, as drilled spinach is generally cut straight over like cresses. When spinach is sown in drills, between rows of other vegetables, the prickly-seeded should be preferred, even in spring, as it does not grow so large, nor spread so wide.

When spinach seed is wanted, the plants are thinned out to at least a foot separate. A very few plants with staminiferous spikes are sufficient for fertilizing a considerable row of the female or seed-bearing plants. The seed ripens in August; it should be covered with a net, small birds being very fond of it.

*White Beet.*

347. The *White Beet* (*Beta Cicla*, L.; *Pentandria Digynia; Atriplices*, Juss.) is a biennial plant, a native of Portugal and Spain. This has been known and cultivated in gardens since the days of Gerarde and Parkinson; not for the sake of the roots, which are generally small, seldom larger than a person's thumb, but for the lower leaves and their footstalks: the leaves are thick and succulent, and are boiled as a spinach, or put into soups. There is a larger variety, called the great white or sweet beet, of which the stalks and midribs of the leaves are stewed and eaten as asparagus, under the name of *chard*.

White beet is sown in the beginning of March, on an open spot of ground. When the plants have put out four leaves, they are hoed and thinned out to at least four inches asunder. A month afterwards, a second hoeing is given, and the plants are left perhaps eight inches separate. The outer leaves being first picked for use, a succession is afforded for the whole season. The plants endure for two years, but it is best to make a small sowing annually. When beet-chards are wanted, the plants are frequently watered during summer; they are kept protected with litter over winter, and have earth heaped against them. In this way the chards may be had till the approach of the following summer.

348. A variety, by some considered a hybrid, between the red and the white beet, having very large roots, as well as large leaves, was introduced into this country about the year 1786, chiefly by the exertions of the late distinguished Dr John Coakley Lettsom. It was called, in Germany, Mangold-Wurzel, or Beet-Root; but Abbé Commerell, in recommending it in France, having mistaken Mangold, *beet*, for Mangel, *want*, converted the name into Racine de Disette; and in this country we have sanctioned the blunder, by adopting the name, Root of Scarcity. Of this variety most of the roots weigh 10lb. or 12lb.; in rich and deep soil, often 20lb. Some which grew in the island of St Helena weighed above 50lb. each. The seed is sown in March; and the seedlings, when their roots are the size of goose-quills, are transplanted into rows a foot and a half distant, and nearly as much apart in the rows. In transplanting, the leaves are cut over at top, but the roots are not touched; and the tap root is not fully sunk in the soil, but only so deep as that half an inch may project above ground. The root is rather coarse for table use, but excellent for cattle. The mid-rib of the leaf, dressed like asparagus, is pretty good.

*Orache.*

349. *Garden Orache*, or Mountain Spinach, (*Atriplex hortensis*, L.; *Polygamia Monœcia; Atriplices*, Juss.) is an annual plant, a native of Tartary. The stem rises three feet high; the leaves are various in shape, thick, pale green, and glaucous, and of a slightly acid flavour. There are two varieties, the White or pale green, and the Red or purple. Orache was formerly much cultivated as a spinach; but now it is less frequently sown. Some, however, prefer it to common spinach, and it is much used in France. It is sown in drills, in autumn, soon after the seed is ripe; and the plants are thinned out, next spring, to four inches asunder. The stalks are good only while the plant is young; but the larger leaves may be picked off in succession throughout the season, leaving the stalks untouched, and the smaller leaves to increase in size; and still the spinach thus procured will be found very tender.

*Wild Spinach.*

350. *Wild Spinach*, or Good Henry, (*Chenopodium bonus Henricus*, L.; *Pentandria Digynia; Atriplices*, Juss.) is a perennial plant, indigenous to Britain, growing by road-sides in many places. It is figured in Sowerby's "English Botany," pl. 1033. The stem rises rather more than a foot

high; it is round and smooth at the base, but upwards it becomes somewhat grooved and angular; it is covered with minute transparent powdery globules. The leaves are large, alternate, triangular arrow-shaped, and entire on the the edges. While young and tender, it makes no despicable substitute for spinach. Curtis mentions, that in some parts of Lincolnshire it is greatly esteemed, and cultivated in gardens in preference to common spinach. Withering observes, that the young shoots, peeled and boiled, may be eaten as asparagus, which they resemble in flavour. The leaves are often boiled in broth, of which they form a very palatable ingredient.

The seed is sown in March or April, in a small bed. In the course of the following September, in showery weather, the seedlings are transplanted into another bed, which has been deeply dug, or rather trenched to the depth of a foot and a half, the roots being long and striking deep, while at the same time they are branched; so that each plant should have a foot or fifteen inches of space. Next season the young shoots, with their leaves and tops, are cut for use as they spring up, leaving perhaps one head to each plant, to keep it in vigour. The bed continues productive in this way for many successive years. The first spring cutting may be got somewhat earlier, by taking the precaution of covering the bed with any sort of litter during the severity of winter.

### *Herb Patience.*

351. *Garden Patience*, or Patience Dock, (*Rumex Patientia*, L.; *Hexandria Trigynia; Polygoneæ*, Juss.) is a perennial plant, a native of Germany. The leaves are broad, long and acute pointed, on reddish foot-stalks; the stems, when allowed to spring up, rise to the height of four or five feet. In old times, garden patience was much cultivated as a spinach. It is now very much neglected, partly perhaps on account of the proper mode of using it not being generally known. The leaves rise early in the spring; they are to be cut while tender, and about *a fourth part of common sorrel* is to be mixed with them. In this way patience dock is much used in Sweden, as we have been informed by the late Sir Alexander Seton of Preston, who had an estate in Sweden, and frequently resided there. This mixture may be safely recommended as forming an excellent spinach dish. Garden patience is easily raised from seeds, which may be sown in lines in the manner of common spinach, or white beet. If the plants be regularly cut over two or three times in the season, they continue in a healthy productive state for a good many years.

## *Boiled Salads.*

Under this title (not perhaps strictly correct, as *salad* may be considered as implying rawness in the vegetable) we include a few plants which cannot well be ranked as pot-herbs, and yet are generally boiled before being presented at table. One of the chief of these is

### *Asparagus.*

352. (*Asparagus officinalis*, L.; *Hexandria Monogynia; Asparagi*, Juss.; the Asperge of the French, and Spargel of the Germans.) This is a perennial plant, which occurs native in some parts of England, as near Bristol, and in the Isle of Portland; and it has been observed sparingly in one place in Scotland, Seaton Links, East Lothian. It is figured in "English Botany," t. 339. In its native state it is so dwarfish in appearance, even when in flower, that none but a botanist, attending to the minute structure, would consider it as the same species with our cultivated plant. The roots consist of many succulent round bulbs, forming together a kind of transverse tuber; numerous stems arise, with alternate branches, subdivided into alternate twigs; the leaves are very small, linear and bristle-shaped; the flowers yellowish-green, the berries red. The whole plant, with its fruit, is very elegant in appearance, and is often placed in chimneys as an ornament in the autumn months. The early shoots, when about three or four inches high, are greatly esteemed for the table. For the sake of these, the plant has been cultivated in gardens for ages.

There are two varieties, the Red-topped and the Green-topped; the former commonly rising with a larger shoot, but not reckoned so delicate in flavour as the green sort.

353. Asparagus is propagated either by seeds, or by year-old plants purchased from nurserymen or market-gardeners. It is best to raise the plant from seed; and it is of considerable importance to procure the seed from an experienced and attentive gardener: for seed gathered from the strongest and most compact shoots, is found, as might naturally be expected, to yield by much the better plants. It is sown as broad-cast on a seed-bed in March, not very thickly, and the bed is slightly trodden, and raked smooth; or it is sometimes sown in shallow drills, six inches asunder, and earthed in, from half an inch to an inch deep. The young plants are kept as free of weeds as possible during the summer; and in the end of October following, some rotten dung or other litter is spread over the surface of the ground, to protect the buds during winter. In the following March or April, according to the dryness of the season, these year-old plants are transferred from the seed-bed into a quarter prepared for them.

Asparagus ground should be light, yet rich; a sandy loam, well mixed with rotten dung or sea-weed, is accounted preferable to any. The soil should not be less than two feet and a half deep; and before planting a bed, it is considered good practice to trench it over to that depth, burying plenty of dung in the bottom, as no more can be applied there for eight or ten years. It can scarcely therefore be too well dunged: besides, although the plant naturally grows in poor sandy soil, it is found that the sweetness and tenderness of the shoots depend very much on the rapidity of the growth, and this is promoted by the richness of the soil. Damp ground or a wet subsoil are not fit for asparagus: indeed the French consider wetness as so prejudicial to this plant, that they raise their asparagus beds about a foot above the alleys, in order to throw off the rain.

The plants are generally raised with a narrow-pronged fork, to avoid cutting the roots; and when they are taken up, the roots are kept in a little earth, or covered with a mat, till replanted, being very apt to sustain injury from drying, or being too much exposed to the air. A trench about six inches deep being prepared, the roots are carefully laid in, a foot distant from each other, the buds or crowns being kept upright, and about two inches below the surface. A foot between each ordinary trench is reckoned sufficient; but between every four rows a double distance is left for an alley. Some plant in single rows, at two feet and a half, or perhaps three feet apart; and this is by many experienced asparagus farmers considered as better than the bed form.

It is a general rule, that, in dry weather, the new planted beds or rows should be carefully watered. With attention to this rule, asparagus may be transplanted at a later period of the season than March or April. From the Scots Horticultural Memoirs, (Vol. i. p. 71.) we learn that this operation has been very successfully performed at midsummer. The plants were at that time fourteen months old, and from twelve to fifteen inches high. Being removed with care, and well watered, none of them failed; on the contrary, they gained considerably on those left in the seed-bed. Next spring the remainder of the seedlings were planted out, but many of them failed, while the midsummer plantation continued to grow vigorously, and far surpassed those that survived of the spring planting.

354. Another mode of propagating asparagus is followed by some cultivators. They sow the seeds in the spot where the roots are to remain, either by dibbling holes about half an inch deep, and at a foot distant, and dropping two seeds into each hole, for fear of one failing; or making drills an inch deep, and three feet asunder, and sowing rather thickly, so as to insure a crop, and afterwards thinning out, at first to five or six inches, and ultimately to nine or ten. In this way, it is thought, stronger plants are produced.

It is a common practice to take a crop of onions along with the drilled seedling asparagus; and likewise to plant rows of cauliflower, or sow drills of carrot or turnip, between the lines of transplanted asparagus the first year.

Several hoeings are given in the course of the summer, generally three. In the end of September, or beginning of October, the haulm decays, and is cut over; all the refuse is dug into the alleys, and the superfluous earth thus acquired is often spread over the beds to the depth of an inch or more, which is called *landing up*. Frequently small dung, or perhaps sea-weed, is spread on the beds, and this is accounted the better practice; the surface being previously stirred with a fork, so as to allow the juices of the manure washed down by the rains to be readily imbibed.

In the spring dressing of the beds, the intervals are slightly delved over. For this purpose, the narrow pronged fork, already mentioned, is generally employed, being much less apt to injure the roots. This dressing is given just before the buds begin to appear, and the raking requires some delicacy of hand.

The same practice, both for the autumn and spring, is observed for the second year; it being only in the third year after planting out, or the fourth from the seed, that cutting for use is begun. In April, a few shoots may generally be cut; in May and June they come rapidly and copiously. In the first productive season, only the large buds or shoots are taken, the smaller being left to spring up and draw strength to the plants. In subsequent years all the shoots are gathered as they advance, till the end of June or beginning of July. A common rule is, to cease to cut, or to let asparagus *spin*, (grow up,) when green peas come in. With due attention, an asparagus quarter may be kept in a productive state for ten years or more. In cutting the shoots for use, some of the earth is removed, in order to enable the gatherer to avoid the succeeding buds below. Some use a common gardener's knife, and others employ a narrow-pointed knife, with its blade notched like a saw. Shoots two inches under the ground, and three or four above, make the best dishes of asparagus. The crop, if judiciously cut, may last nearly three months; from the middle of April to the middle of July. An asparagus quarter should not contain less than a pole of ground, as it often needs this quantity to furnish a good dish at one time. For a large family about sixteen roods are kept in a productive state, which are calculated to furnish, on an average, between 200 and 300 shoots every day in the height of the season. Several of the market gardeners in the neighbourhood of London have many acres of asparagus ground, as mentioned in a former part of this article, § 38.

355. The *forcing* of asparagus was practised in England in the middle of the 17th century. Meager mentions, that the London market was, at that period, supplied with forced asparagus early in the year: "Some having old beds of asparagus which they are minded to destroy, and having convenience of new or warm dung, lay their old plants in order on the dung, and the heat doth force forward a farewell crop," (p. 188.) The forcing of this article is now carried to a considerable extent in the neighbourhood of London. It is likewise very generally practised in private gardens.

A common hot-bed, prepared with horse dung, is formed according to the size of the frame or frames. A layer of turfs is sometimes placed on the dung, to prevent the access of the vapour from it, which is apt to hurt the flavour of the crop. About four inches of good light soil or old tan-bark are placed on the turf. In this plants six or eight years old are closely deposited. These plants are sometimes got from nurserymen, to whom such stock is no longer useful; or one of the oldest beds in the garden is for this purpose sacrificed, care being taken to have succession beds coming forward. But where the demand for the market, or for a private family, is regular, the best way is to have several successive beds in progress. Those plants intended for forcing may be transplanted as usual when one year old, but in much closer order, and so kept till the fourth year. A three-light garden frame will hold from 600 to 800 three-year-old plants. The roots are placed as close together as possible (as already hinted,) with the buds standing upright, and covered with three or four inches of soil. The temperature of the dung is generally regulated merely by guessing the heat imparted to sticks plunged into it: if it becomes too weak, a *lining* of weeds or dung is heaped around the sides: if it prove too strong, some air holes are formed, by pushing large sticks into the sides and withdrawing them, leaving empty spaces, or by removing the glass covers for some time. The proper temperature is about 55° Fahrenheit. Air is occasionally admitted, by raising the glasses a little; and sometimes a slight watering is necessary. At other times, in severe weather, mats are laid over the frames. A little fine light earth is sometimes added, once or twice, as the buds rise. In five or six weeks some of the shoots are generally fit for gathering. In France they often cut in a fortnight; but shoots produced in this rapid way are in a great measure colourless and tasteless, having been forced nearly without access of light and air. In gathering the shoots from a hot-bed, it is thought better to avoid cutting with a knife, and to employ only the finger and thumb; by a gentle twist the shoot is detached, and with less risk of injuring the tender buds below. Each light or frame yields on an average 300 shoots, which come in succession during about three weeks. Where a regular winter supply of this article is desired, beds are made up in succession accordingly, from November to March. After being forced, the plants are cast on the dunghill as useless.

M. Nicol describes a mode of forcing asparagus in flued pits, such as are used for young pine-apple plants. A layer of old half rotten bark, placed over well fermented dung, forms the bed, the plants being placed in light dry earth. Very little fire-heat is found to be necessary; generally a slight fire at night is sufficient. Watering, and the regular admission of air, are to be attended to. He remarks, that by means of very simple expedients, one half of a flued pit may be forced, and the other kept back, and thus a succession of shoots secured.

356. Asparagus, it may be remarked, was a favourite of the Romans; and they seem to have possessed a very strong growing variety, as Pliny mentions that, about Ra-

venna, three shoots would weigh a pound; with us, six of the largest would be required. It is much praised by Cato; and as he enlarges on the mode of culture, it seems probable that the plant had but newly come into use. In this country, Dutch asparagus was preferred in the end of the 17th century; and this variety is still distinguished for affording the thickest shoots. In a garden formed at Dunbar in the very beginning of the 18th century, by Provost Fall, (a name well known in the mercantile world,) asparagus was for many years cultivated with uncommon success. The variety used was the red topped, and it was brought from Holland. The soil of the garden is little better than sea sand. This was trenched two feet deep, and a thick layer of sea-weed was put in the bottom of the trench, and well pressed together and beat down. This was the only manure used either at the first planting, or at subsequent dressings. There was an inexhaustible supply of the article generally at hand, as the back-door of the garden opens to the sea-shore.

*Sea-Cale.*

357. *Sea-Cale*, (*Crambe maritima*, L.; *Tetradynamia-Siliquosa*; nat. ord. *Cruciferæ*), is a perennial plant, growing naturally on many of the sandy and gravelly beaches of the west of England, and also among cliffs on the sea coast of Essex and Sussex. It is not mentioned by Lightfoot in his Flora of Scotland; but it grows on the shore of the Frith of Forth at Caroline Park, near Edinburgh. It is figured in English Botany, t. 924. The roots are spreading (rather than creeping, as they are commonly described); the whole plant is smooth, glaucous, or covered with a fine bloom; the lower leaves large and waved; the stalks rise near two feet high, producing white flowers, followed by spherical seed-pods, resembling peas, each containing only a single seed.

358. The common people, particularly on the western shores of England, have for time immemorial been in the practice of watching when the shoots begin to push up the sand or gravel, in March and April, and cutting off the young shoots, which are thus blanched and tender, and using them as a pot-herb. It was toward the middle of the 18th century, however, before sea-cale was introduced into the kitchen-garden. About the year 1767, it was first brought into general notice in the neighbourhood of London by the late distinguished Dr Lettsom, who cultivated it in his garden at Grove Hill. In the "*Gardener's Dictionary*," published in 1774, by James Gordon at Fountainbridge, are contained directions for the cultivation of this vegetable, and for blanching it by covering the beds four inches deep with sand or gravel. A good many years afterwards, a detailed account of its culture was given by the Rev. Mr Laurent, in the third volume of Young's *Annals of Agriculture*. The late Mr Curtis, well known for his botanical writings, next published a tract recommending it; and in the first volume of the *Transactions of the Horticultural Society of London*, there is a very good paper on its cultivation, by Mr John Maher, gardener at Edmonton. It is now become a pretty common vegetable in Covent Garden market, and has even begun to appear on the green stalls of the Scottish metropolis.

359. The bed or quarter intended for sea-cale is trenched deep, at least two feet. The soil should be sandy and light, but at the same time mixed with fine rich mould; and it may here be noticed, that of all manures for this crop, *drift ware* or sea-weed is the best. The plant may be propagated either by offsets or pieces of the roots having two or three eyes or buds attached to them, or by seeds. The latter mode is generally preferred. The seeds are sown in March, perhaps about two inches deep. Three seeds are sometimes set in a triangular form, six inches apart, leaving a space of two feet between the triangles. If the quality of the seed is any wise doubtful, two or more are commonly put in each hole, to make sure of a crop, any superfluous plants being afterwards thinned out. During the first summer, the only culture necessary is hoeing, to keep the plants clear of weeds. In November, some gardeners cover the whole bed with rotten dung, in the way that is often practised with asparagus. This is raked off in the spring, and the surface of the earth stirred with the asparagus fork. During the second year, the same plan is followed. In the third year, most of the plants will be strong enough to be blanched for use.

360. The blanching is accomplished in different ways. For a long time the only provision for this purpose was, to make the shoots pass through several inches of soil before reaching the surface, and afterwards drawing up the earth to them as they advanced. It was an improvement to use sifted coal-ashes for the earthing up, and a farther improvement to use old tree-leaves for that purpose. Some cultivators placed hoops over the beds, and covered them close with mats. Large flower pots, such as are denominated No. 1, inverted over the plants, were found very useful in forwarding the etiolation, and in keeping the plant crisp and clean. Blanching pots with handles were afterwards used; and a figure of one of these is given in the *London Horticultural Transactions*, vol. i. plate 1. A very great improvement in the constructing of blanching pots was suggested by Mr R. A. Salisbury, Secretary to the London Horticultural Society,—the making them in two pieces, or with moveable tops or lids. Such are now used in the neighbourhood of Edinburgh, and are found exceedingly convenient; a figure of one of them may be seen Plate CCCXII. Fig. 5. These pots should be nearly as wide at top as below, in order to give room for the cutting of such shoots as are ready, without breaking the others; and the covers should fit very nicely, so as to exclude light and air as completely as possible; the pot in this way serving not only for blanching, but to a certain extent for forcing. It is necessary to have from thirty to fifty such covers; each affording only as much as will form a dish, during the season. Sir George Mackenzie, Bart. whose name has more than once been mentioned as a horticultural improver, has described (*Scottish Hort. Mem.* i. 313) a simple and easy mode of blanching practised in his garden at Coul. This consists in covering the beds with clean dry straw, which is changed when it becomes wet or heavy. Oat straw, when it is broken in the thrashing-mill, is found to be well suited for this purpose.

361. It is justly remarked by Nicol, that vegetables are seldom improved by forcing; but that sea-cale is perhaps an exception; the forced shoots produced at midsummer being more crisp and delicate in flavour than those procured in the natural way, in April or May. Certainly no vegetable is more easily or more cheaply forced. It is done in two ways; either in the beds in the open air, or in hot-bed frames or flued pits. In the open air beds, the operation consists merely in placing blanching covers over the plants as soon as the leaves are decayed in the end of autumn; and then covering up the whole bed with stable-dung, packing it closely between the pots, and heaping it over the tops of them to the depth of six inches or more. In the course of December the sea-cale vegetates, and advances in proportion to the heat generated by the fermentation of the covering of dung. In general, it is fit for cutting in January and February. If the heat of the litter at any time decline, a portion of new stable dung is mixed with it. The advantages of having blanching pots with

moveable lids, are, in this kind of forcing, very great: the temperature may more easily be ascertained, by lifting a lid in one or two parts of the bed, and introducing a thermometer: in the same way, it is easy to examine whether the shoots be ready for cutting, and to select the most forward from several stools, without materially disturbing the dung and dissipating the heat. The method of forcing sea-cale on the open ground was described by Mr Maher, in 1805, in the paper above alluded to; but he was not acquainted with blanching-pots having moveable tops. It is also described by Nicol, in his "Kalendar," 1810, with the improved blanching-pots. It is curious, therefore, that Abercrombie, in his "Practical Gardener," 1813, should take no notice of it, while he recommends planting sea-cale in hot-beds under frames and glasses.

362. Mr Barton, gardener at Bothwell Castle in Scotland, covers the sea-cale beds to the depth of a foot and a half, with leaves, as they fall from the trees, and are raked from the shrubberies and walks in the end of autumn, adding over all a very slight layer of long dung, sufficient only to keep the leaves from being blown about. The shoots rise sweet and tender among the leaves, early in the spring, being in some measure forced, and very perfect etiolation is at the same time accomplished.

In a hot-bed frame, or in flued pits, sea-cale is forced nearly in the same manner as asparagus. The plants should be strong and healthy, and at least three years old: they are by this mode of forcing exhausted, and not worth preserving. The best way therefore is, to sow a bed of sea-cale annually: in this way a regular succession of plants will always be ready, either for forcing in the open ground or in hot-bed frames.

By the various improvements, therefore, of late years made in the culture of sea-cale, this desirable vegetable may be commanded for table, with very little trouble or expence, at any time from November till May; a period including all the dead months of the year. It may be affirmed that sea-cale shoots, when duly blanched, are not inferior to asparagus when prepared like it; and farther, that they form an excellent ingredient for soups. Not only the head or shoot (sometimes also called the crown) is fit for use, but the blanched stalks of the unfolding leaves, four or five of which are attached to each head. Before boiling, these are detached, and tied in small bundles like asparagus. It is a vegetable which (as remarked by Sir George Mackenzie, in the paper already mentioned) cannot easily be overdone in cooking; it should be thoroughly drained, and then suffered to remain a few minutes before the fire, that a farther portion of moisture may be exhaled. From four to six heads, according to the size, make a tolerable dish.

363. It is somewhat strange, that in France the use of sea-cale as a delicate culinary vegetable should be nearly unknown. Bastien, in an edition of his popular *Manuel du Jardinier*, published in 1807, describes the *chou marin d'Angleterre* correctly enough; but he appears to have tried to make use of the full grown leaves, instead of the blanched shoots, in early spring: a coarser mess can hardly be imagined; and it is no wonder therefore that he should deny the merits of sea-cale, and resign the plant, as he does, with a sneer, to colder climates!—*mais elle convient mieux que d'autres dans des climats froids.* When the French gardeners learn how to cultivate it, and particularly when they are able to force and to blanch it at mid-winter, by the simple means above described, there can be no doubt that sea-cale will become a favourite with the Parisians.

When seed is wanted, if two or three strong plants be left to flower, they will not fail to produce it in plenty. The flower is of a rich white colour, and gives the plant an ornamental appearance; when fully expanded, the flowers smell strongly of honey.

### *Artichoke.*

364. The *Artichoke* (*Cynara Scolymus*, L.; *Syngenesia Polygamia Æqualis; Cinarocephalæ*, Juss.) is a perennial plant. It is a native of Italy, according to Linnæus, and of the south of France, according to Garidel: but Beckmann, (*History of Inventions and Discoveries*, translated by Johnston, vol. i. p. 339, et seq.) has given reasons for thinking, that its native country is uncertain, the Italian and French specimens being probably only the outcasts of gardens, and that the plant mentioned by ancient Greek and Roman writers, is not to be considered as our artichoke, but as a similar plant, the true artichoke having been brought to Italy from the Levant only in the 15th century. It is not known to have been cultivated in English gardens till near the middle of the 16th century.

It is a remarkable and a well known plant in gardens. From the root spring many large pinnatifid leaves, three or four feet long, covered with an ash-coloured down; the midrib deeply channelled and furrowed. The appearance of the flower-heads is familiar. These, in an immature state, contain the part used, which is the fleshy receptacle, commonly called the *bottom*, freed from the bristles and seed-down, vulgarly called the *choke*. In the usual way of cooking, the entire heads are boiled. In eating, the portions of the receptacle adhering to the base of the calyx-leaves or scales are also used. The bottoms are sometimes fried in paste, and they form a desirable ingredient in ragouts. They are occasionally used for pickling; and sometimes they are slowly dried, and kept in paper bags for winter use. In France the bottoms of young artichokes are frequently used in the raw state as a salad; thin slices are cut from the bottom, with a scale or calyx-leaf attached, by which the slice is lifted, and dipped in oil and vinegar before eating.

365. There are two varieties cultivated; the French conical, or green artichoke; and the Globe or red artichoke. The head of the former is rather of an oval shape; the scales are open, and not turned in at top, as in the globe artichoke. The latter is distinguished not only by the shape, and by the position of the scales, but by being chiefly of a dusky purple colour. The receptable of the globe artichoke is more succulent than that of the French, but the latter is generally considered as possessing more flavour.

Artichokes are increased by rooted slips or suckers taken off at the time of the spring dressing, in the beginning of April. They delight in a light loam, cool but dry, and which is at the same time rich and deep. In preparing for this crop, the soil should be trenched to the depth of three feet, or at least two feet and a half, and manure should be liberally placed in the bottom of the trench. In dry weather, the young plants require regular watering for some time. Artichokes will grow pretty well in a situation somewhat shaded, but they should not be under the drip of trees. In a free and airy situation, however, the heads are of better quality.

Nicol mentions, that the strongest crops he ever saw, grew in rather a mossy earth that had been trenched fully a yard in depth, and had been well enriched with dung, and limed; and that the plants were generally covered before winter with a mixture of stable litter and sea-weed. This last article, we believe, is one of the very best manures for artichokes. In no place is the plant to be seen in greater perfection than in gardens in the Orkney

Islands; and we know that the luxuriance of the plants in these is to be ascribed to the liberal supply of sea-weed dug into the ground every autumn. It was long ago remarked by a horticultural writer, that "water drawn from ashes, or improved by any fixed salt, is very good for artichokes." *Systema Agriculturæ*, 1682.

366. The plants are often placed four feet apart every way: sometimes they are planted three feet apart in rows, and the rows are kept six feet asunder. In many of the market-gardens near London, the rows are eight or ten feet from each other; intermediate low growing crops are sown or planted, the artichokes being always allowed five feet free. Some gardeners plant two offsets together; and if both survive and prove strong, they afterwards remove one. Others plant three offsets in a triangular patch or stock, each offset being ten or twelve inches from the other; and these stocks are afterwards treated as if they were single plants. A crop of spinach or turnip is generally taken, for the first year, even between the closest rows. At the end of the first season after planting, a small and late crop of artichoke-heads is procured, generally in October. In the second year, the leaves of the plants will almost meet in the rows.

To encourage the production of large main heads, some detach all the lateral heads in a young state. These are commonly in a fit state for eating raw, having attained about one third of their proper size; and they are for this purpose frequently sold in Covent Garden market, chiefly to foreigners. Another thing, practised with the same view, is the shortening the ends of the large leaves. When all the heads are gathered, the whole stalks are broken down close to the ground, in order to save the useless expenditure of sap, and to promote the setting out of young shoots at the root.

In November the plants are earthed up, or, in other words, a portion of earth is drawn around each plant. It was formerly a custom to make a trench between the rows, and to fill this trench "with dung which would not freeze;" the earth thrown out, forming a ridge around the plants. Some modern writers recommended the making of the trench, but omitted to speak of filling it with dung; so that the roots of the plants were thus more exposed than if the ground had been left untouched. In this way the forming of any trench came into disrepute; and, as already noticed, the best practical gardeners now only draw the earth from the surrounding surface towards the plants. Long dung, peas haulm, old tanners' bark, or such stuff, are then laid around, but kept at some distance from the stems and leaves of the plants.

367. The spring dressing is equally important. The litter and earth being removed, in March or April, according to the kind of season, the stocks are examined; and two or three of the strongest or best shoots being selected for growing up, the rest are removed: this is often done merely by pressure with the thumb, but sometimes a knife or chisel is employed. It was formerly mentioned that this is the proper time for procuring young plants. It is remarked by gardeners, that the shoots from the under part of the stock, which are soft and crisp, are preferable to those from the crown of the roots, which have hard and rather woody stems. If the shoot be six or eight inches long, it is enough; and if it be furnished with two or three small fibres, they are sufficient to ensure its growth.

Artichoke plants continue productive for several years; but, every season, some well-rotted dung, or fresh sea-weed, should be delved into the ground at the winter dressing. It is certain, however, that after a few years, the plants begin to degenerate, the heads becoming smaller and less succulent. It is therefore a general rule, not to keep an artichoke plantation beyond four or at most six years. Scarcely any kind of grub or wire-worm ever touches the roots of artichokes: they form, therefore, an excellent preparative for a crop of onions, shallot, or garlic. In many gardens a small new plantation is formed every year; and in this way the artichoke season, which begins in June, is prolonged till November; those from the old stocks continuing till August, when those from the new stocks come in. If the last gathered be cut with the stems at full length, and if these be stuck among moist sand, the heads may be preserved a month longer.

If some of the large heads on the old stocks be suffered to remain, the calyx-leaves expand, and the centre of the head becomes covered with jagged purple florets, producing a fine appearance. The flowers possess the quality of coagulating milk, and have sometimes been used in place of runnet. In general the seed is not perfected in our climate. When ripe seed is wanted, it is found useful to bend down the heads after flowering, in such a way that the autumnal rains may be cast off by the calyx-scales; and the heads are retained in this posture by being tied to stakes.

368. The *chard* of artichokes, or the tender central leaf-stalk blanched, is by some thought preferable to that of the cardoon. When the artichoke quarter is to be shifted, and the old stocks are at any rate to be destroyed, the plants may be prepared, after midsummer, when the best crop of heads is over, for yielding chards against winter. The leaves are to be cut over within half a foot of the ground; the stems as low as possible. In September or October, when the new shoots or leaves are about two feet high, they are bound close with a wreath of hay or straw, and earth or litter is drawn round the stems of the plants. The blanching is perfected in a month or six weeks. If the chards are wished late in winter, the whole plants may be dug up, before frost sets in, and laid in sand in their blanched state; in this way they may be kept for several weeks.

*Cardoon.*

369. The *Cardoon*, (*Cynara Cardunculus*, L.) or, as it is sometimes written, *Chardon*, is known by nearly the same name in all the European languages. It is a perennial plant, and is considered as indigenous to the south of France and to Spain. It so greatly resembles the artichoke as to require no other description. It rises to a greater height than that plant, and becomes sometimes really a gigantic vegetable. It was cultivated in 1683, by Sutherland, in the Botanic Garden at Holyroodhouse, Edinburgh; but its use as a culinary plant was known in England previous to that period. The leaf-stalks of the inner leaves, which are fleshy and crisp, afford the eatable part, or chard. They are rendered white and tender by blanching, to the extent of two or even three feet. Cardoons are in season in winter; they are employed in soups and stews, and sometimes as a salad, eaten either raw or boiled. In this country they are not much in demand, and the crop is to be seen only in some private gardens, and in a few of the principal market grounds near London.

The best soil for cardoons is one that is light, and not over rich; but it ought to be deep. Although the cardoon is a perennial plant, it is sown for use every year. Formerly the plants were raised on hot-beds, and transplanted in May or June; but now the seed is generally sown where the plants are to remain. This is not done sooner than the middle or the end of May, lest the plants should be inclined to throw up flower-stems. Some gardeners sow in small hollows, perhaps three inches deep, and four feet distant from each other every way. Two or three seeds are placed in each hollow, for security; but only the strongest plant is ultimately retained. Others sow in trenches, prepared as for celery, and keep the plants much closer in line, not allowing more than nine or ten inches to each plant; it is better, however, that they should have more space. The cardoon requires a good deal of water; and in very dry weather this should be copiously afforded, as it tends both to make the leaves succulent, and to prevent the inclination to flowering. The young plants that are rejected in either way, may be transplanted, if wished; but in this case it is useful to preserve a small ball of earth with each plant, and liberal watering is proper.

370. In September, when the leaves are large, they are tied up for blanching, leaving only the top free. This is generally done with hay or straw bands, and a dry day must be selected for the purpose. At the same time a hillock of earth is formed around each plant, to the height perhaps of a foot or eighteen inches; and this is smoothed on the surface, that the rain may run off, and not fall into the centre of the plants. In proportion as they advance in growth, additional bands are added, and the earth is raised higher. When the plants are in trenches, they are gradually earthed up like celery, without using bands: the earthing is of course begun in July. In either way, the blanching is completed in about two months. If severe frost come on, the tops are covered with haulm or long litter. If cardoons be wanted more early, the tying and earthing may be begun sooner; but the leaf-stalk will not probably be found so broad and thick as it ought to be.

A few of the strongest plants are sometimes left, to produce their flowers and seeds the following year; but ripe seed is to be procured only in very favourable seasons in this country. It is therefore generally imported from Holland or France; and it keeps for several years.

In France, the native prickly plant is sometimes cultivated, under the name of Cardoon of Tours, and is accounted preferable to the common garden variety. So formidable are its spines, that great care is necessary in working about it, to avoid personal injury; a strong leather dress, and thick gloves, are therefore worn. This prickly sort has not yet been introduced into Britain.

*Rampion.*

370. The *Rampion* (*Campanula Rapunculus*, L.; *Pentandria Monogynia; Campanulaceæ*, Juss.) is a biennial plant; a native of England, but rare; figured in English Botany, t. 283. The lower leaves are oval-lanceolate, and waved. The whole plant abounds with a milky juice. The part used is the root, which is of the size and shape of a small radish, but of a white colour, and mild taste, or with only a slight degree of pungency and bitterness. It is eaten either raw, in fresh salads, or more commonly boiled like asparagus. It is much more esteemed in France, under the name of *raiponce*, than in this country. There the roots and the young leaves are used together in the spring months. So little is it cultivated here, that Nicol does not speak of it in his "Gardener's Kalendar."

The seed is sown in the end of May, in a quarter somewhat shady. If sown earlier, or in a warm sunny situation, the flower-stems would be apt to spring up the first year, when, as repeatedly mentioned in similar cases, the roots would become hard and unfit for use. The seed is very minute, insomuch that, to enable the gardener to sow it equally and thin enough, it should be mixed with sawings of timber. A thimble-full of the seed is sufficient to sow a large bed. When the plants are about an inch high, they are hoed, and thinned out to the distance of three or four inches from each other. They are afterwards to be kept free of weeds, and the surface is occasionally stirred. The roots are ready for use at the approach of winter, and continue good till the spring growth commences. If a few plants be left, a flower-stalk rises, and the pale purple bell-flowers appear in the end of July, followed by plenty of seed in the autumn.

## *Fresh Salad and Soup Herbs; Garnishes, &c.*

Several of the principal plants which are used raw in salads, are likewise employed in making soups; such are lettuce, endive, and parsley. Others are merely salad plants; such are cresses and radishes.

*Lettuce.*

371. *Lettuce* (*Lactuca sativa*, L.; *Syngenesia Polygamia Æqualis; Chicoraceæ*, Juss.; *Laitue*, F.; *Gartensalat*, G.) is an annual plant, the original country of which is unknown. Some authors indeed seem inclined to consider it as merely an accidental variety, sprung from some of the other species of Lactuca. It was cultivated in England in the middle of the 16th century, and probably much earlier. The leaves are large, milky, frequently wrinkled, usually pale green, but varying much in form and colour in the different varieties. The use of lettuce as a cooling and agreeable salad is well known; it is also a useful ingredient in soups. It contains, like the other species of this genus, a quantity of milky juice of an opiate nature, from which of late years a medicine has been prepared by Dr Duncan, senior, of Edinburgh, under the title of *lactucarium*, and which he finds can be administered with effect in cases where opium is inadmissible.

372 Many varieties are cultivated; but these are generally considered as belonging to one or other of two kinds, the Coss (also called Roman and ice) and the Cabbage lettuce; the former with long upright leaves, the latter with the leaves round, rather flaccid, and growing squat upon the ground. The sorts at present most approved are, of the coss lettuces, the Egyptian green, and the white coss or Versailles; of the cabbage lettuces, the imperial, and the grand admiral, or admirable. The large Roman and the Cilicia lettuce, brown and green, are the kinds chiefly used in soups, or for stewing.

By means of successive sowings, and by care during winter, fresh lettuce is now produced almost the whole year round. The plants are used either when quite young and open, or when at full growth and cabbaged. A small sowing is often made in January, the seedlings being transplanted in March. A considerable crop is sown in the end of February; the main sowing is in March and April; and sometimes a portion of lettuce seed is sprinkled in along with onions or carrots, the lettuces being drawn before they can hurt the other crop. Lettuce seed is sown at broadcast, and is merely raked into the ground. The plants bear transplanting very well, particularly in showery weather; and a part of each crop should be regularly transplanted, to come in season immediately after those left in the seed-beds. They may be transplanted very young; when they have four or six leaves, they are fittest for this purpose. They are placed from ten to fifteen inches apart, according to the size they are likely to attain. When it is wished to forward the cabbaging of coss lettuce, the leaves are sometimes tied together, in the manner practised with endive. If the winter do not prove very severe, lettuces will stand without much injury close by the foot of a south wall, and be fit for use in January, February, and March. In some places they are protected by hoops and mats; in others, by means of glass-frames; and sometimes a few cabbage lettuces are kept on a slight hot-bed.

When it is wished to save seed, the best plants of the approved kinds are selected, and planted at a distance from all others, so as to avoid any intermixture of pollen. If the plants have stood over winter, they produce their flowers more abundantly, the stem becoming thick, and rising between two and three feet high; and such plants also ripen their seed more certainly and early.

*Endive.*

373. *Endive* (*Cichorium Endivia*, L.; *Syngenesia Polygamia Æqualis; Cinarocephalæ*, Juss.) is an annual, or at most a biennial plant, a native of China and Japan. The root-leaves are numerous, large, sinuate, toothed, smooth; the stem rises about two feet high, is branched, and produces pale blue flowers. It was introduced into this country about the middle of the 16th century.

There are three varieties; Broad-leaved Batavian, Green curled leaved, and White curled leaved. The curled varieties, having less of the bitter quality, are now generally preferred; and the green curled, being the hardiest sort, is adopted for the late or winter crops. Endive is one of the principal ingredients in autumn and winter salads, and is frequently used for stewing, and for putting in soups.

The seed is not sown till after the middle of May, often not till near the middle of June; because, if sown earlier, the plants would be apt to run to flower. Another sowing is made in July. The seeds are scattered thinly, so that the plants may not rise in clusters, and become weak. When they are about three or four inches high, they are transplanted into a well prepared bed of rich soil, in rows a foot asunder, and at the distance of ten inches from each other in the row; or in large drills, at the same distances, the blanching being in this way facilitated. In dry weather, watering is necessary.

374. The blanching is the next operation; and on this being well done, the tenderness, crispness, and mild flavour of the endive depend. It is accomplished by tying up the heads with strands of bass-mat or small willow twigs: this must be done when the plant is dry, that is, when neither rain nor dew rests on it; and some nicety is requisite in gathering the leaves together in regular order, so as not to cross each other, and in rejecting such leaves as are unhealthy. The plants are at first tied two inches below the top; afterwards about the middle of the plant. In three weeks or a month they are found to be blanched; and they continue fit for use in this state for about a fortnight. A few plants are therefore tied up every week, when the weather permits, in order to their being ready for use in succession.

The plants from later sowing are placed in sheltered borders near a wall or hedge; and when very severe weather comes on, the rows are protected with dry fern or any other light covering. After October, indeed, the mode adopted is, to make some trenches or small oblong mounds of earth, and to sink the plants nearly to the head in these: here they become sufficiently blanched in four or five weeks; and if additional plants be sunk in the trenches every fortnight, when the weather happens to be so mild and dry as to permit it, the endive season may be continued for a long time. Endive thus blanched in the earth must be dug out with the spade, and it requires to be very thoroughly washed.

A few of the strongest and most early plants are selected for producing seed. These are planted in the beginning of March, in a sheltered situation, if possible, near a paling, to which the flower-stems may be tied, so as to prevent accidents from the wind. The flowers come out in June, and are succeeded by ripe seeds about the middle of July. The seeds are gathered at different times, as they are observed to become ripe.

*Parsley.*

375. *Parsley* (*Apium Petroselinum*, L.; *Pentandria Digynia; Umbelliferæ*) is a biennial plant, considered as a native of Sardinia, but naturalized in several places of England and Scotland.

Three varieties are cultivated; Common parsley, and Curled parsley, for the leaves; and Large-rooted or Hamburgh parsley, for the roots.

The common and the curled parsley are raised in drills, generally on the edges of a border in the kitchen-garden. They are sown in February, or early in March, as the seeds lie from a month to six weeks in the ground before springing. Parsley bears transplanting, so that blanks in the edging may easily be filled up in rainy weather.

In order to have fresh parsley leaves through the winter, it is worth while to lay some larch or beech branches, or long broom, over the parsley border, and above these, in hard weather, a little dry bean haulm, *braken* fronds, bents or reeds, preferring the two latter articles on account of their durability. Mr Nicol remarks, that in this way fine young parsley may be had all winter, and may be gathered even from under the snow.

If a few strong plants be allowed to run to flower in May or June, plenty of seed will be produced in August.

It may be right to notice, that the poisonous plant called fool's parsley, (*Æthusa Cynapium*,) a common weed in rich garden soils, has sometimes been mistaken for common parsley. They are very easily distinguished: the leaves of fool's-parsley are of a darker green, of a different shape, and, instead of the peculiar parsley smell, have, when bruised, a disagreeable odour. When the flower-stem of the fool's-parsley appears, the plant is at once distinguished by what is vulgarly called its *beard*, three long pendent leaflets of the involucrum. The timid may shun all risk of mistake, by cultivating only the curled variety. This last, it may be remarked, makes the prettiest garnish.

*Hamburgh Parsley.*

376. *Hamburgh parsley*, although considered only as a large-rooted variety of the common kind, is somewhat different in its whole appearance. The leaves have longer foot-stalks, and their subdivisions are not so numerous; the leaflets at the same time, are much broader, and of a darker green. The roots are at least six times larger than those of common parsley. For the sake of these it is cultivated; and this variety might therefore without impropriety be ranked among the esculent roots.

It was introduced by Philip Miller, from Holland, in 1727. He could not for some years persuade the market-gardeners of London to cultivate it: Now, however, it is regularly brought to Covent Garden; but in many parts of the country it still remains nearly unknown. The roots, which are the size of ordinary carrots or parsnips, are of a white colour, sweet and tender: they are frequently boiled and eaten like carrots, and are excellent in soups and stews.

The culture of this variety of parsley necessarily differs from that of the other two, the object being here to produce large roots. In March or April it is sown in beds, the soil of which has been deeply delved, or perhaps trenched, and at the same time made fine. The plants are afterwards thinned out with the hoe to six or eight inches asunder; and this is all the culture they require. They are ready for drawing in the end of August. In October the roots are commonly raised, and placed in sand till wanted. They have more flavour, however, when newly taken from the ground; and if a bed be sown about midsummer, the roots continue young and good through the winter, being raised when the weather permits.

*Celery.*

377. *Celery* (var. of *Apium graveolens*, L. or smallage) is a biennial plant. Smallage grows in many places in England and Scotland, frequently by the sides of ditches near the sea. It is figured in *English Botany*, t. 1210. The effects of cultivation in producing upright, mild, and sweetish stems of celery from an original stock, of a rank coarse taste and abounding with suckers, are very remarkable. The blanched leaf-stalks are used raw as a salad, from August till March; and also in soups or for stewing.

378. Two very distinct kinds of celery are cultivated; the Upright or Italian, and the Celeriac or turnip-rooted celery. Of the former there are two subvarieties, with hollow and with solid stalks. The hollow is much cultivated for eating as salad; the solid is considered as preferable for soups and stews, and indeed is by many accounted the best for all purposes; but it is less able to endure the severity of winter, and is very brittle, and therefore troublesome to the market-gardener. There is a large upright variety with red stalks, much used for kitchen purposes. Celeriac differs chiefly in the roots swelling out like turnips: these are cut into slices, and either eaten raw in salads, or used as an ingredient in stewed dishes and soups. The leaves, at the same time, are shorter than in the other varieties, and spread open horizontally. Celeriac is not often brought to market.

Celery is sown at several different times, in order to ensure a succession of plants fit for transplanting at various seasons. The first sowing is commonly about the beginning of March, on a gentle hot-bed; the second, perhaps three weeks afterwards on a sheltered border; the third, about the beginning of May, on a moist shady border. The strongest plants of the first sowing are generally ready, from the middle to the end of April, for pricking into nursery beds of rich earth, in which they may stand separate three or four inches every way, in order to gather strength. Water is given, and the plants are shaded from the sun for a few days. A quantity of every successive sowing should thus be pricked out. Some gardeners, however, content themselves with sowing very thin, and take the plants directly from the seed-bed to be placed in the trenches; but it is not a good plan. If any plants be inclined to run to flower, it is better they should shew this tendency in the nursery-bed.

379. An improvement on the formation of the seedling-bed has been adopted at Mr Walker's of Longford, near Manchester. It is made entirely of very old hot-bed dung, laid thinly on a piece of well trodden soil, or ground beat hard with the back of the spade, so as to be impervious to the roots. The young celery plants, therefore, form bushy fibrous roots, as they cannot send down tap-roots: and in consequence of this, they shew no inclination to throw up a flower-stem till the following spring.

Towards the end of May, the most forward plants may be transplanted into the trenches for blanching. In dry weather, at this season, water is given freely, both to the transplanted plants, and to those left in the seed-bed. The usual modes of transplanting and blanching are the following: Trenches are formed, at the distance of three or four feet from each other, a foot and a half wide, and about a foot in depth. The soil in the bottom of this trench is delved and worked fine; and, if thought necessary, a little rotten dung or rich compost is mixed with it. The soil for celery should be deep and rich, somewhat moist, yet of a light nature: in mossy earth, if moderately dry, it succeeds remarkably well; the natural plant, smallage, as has been remarked, delights in growing by the sides of ditches. The earth taken from the trench is laid in ridges on each side, ready to be drawn in as wanted. The plants being trimmed, or having the tops of the long leaves cut off, and any side shoots removed, are placed in the bottom of the trenches, at the distance of four or five inches from each other. As they advance in growth, the earth is drawn in towards them, perhaps once in ten days, taking care to perform this operation only in dry weather, and not to cover the heart or centre of the plants with soil. When the plants rise considerably above the surface of the ground, all the earth laid in ridges will be exhausted; a new trench, therefore, is now opened between each row, for a supply of soil to continue the earthing up till the celery be fit for use, or till the leaf-stalks be blanched from eight to fourteen inches in length. The management of all the sowings is similar. The last is destined to stand over winter; and although the seedlings were directed to be raised on a moist shady border, the soil into which they are finally transplanted, should be as dry as possible. In severe weather, peas-haulm or other loose litter is thrown over the beds. It is a common complaint, that very fine looking celery is often found to be rotten at the base of the leaf-stalks: the fact is, that after the blanching is completed, celery will not keep good in the ground for more than a month at most. The necessity of successive crops is therefore evident. In lifting the plants for use, it is proper to dig deep, and to loosen the roots with the spade, so that the entire celery plant may be drawn, without risk of breaking the leaf-stalks or injuring the main roots, the fleshy tender part of which is relished by many.

380. Celeriac, after being raised in a seed-bed, is planted out on level ground, or in very shallow drills, as it requires but one earthing up, and that a slight one.

Attentive gardeners generally save celery seed for their own use. All that is necessary is, to select several strong healthy plants of the winter stock, and plant them out in rich soil early in the spring. When the stems run up to flower, they are apt to be broken by high winds, and should therefore be secured by stakes. The seed is ready in the end of August, and is dried in the usual way. It may be mentioned, that the seed, when bruised, communicates the celery flavour to soups, and may be thus employed when stalks or roots cannot be procured.

*Garden-Cress.*

381. The *Garden-Cress* (*Lepidium sativum*, L.; *Tetradynamia Siliculosa; Cruciferæ*, Juss.) is an annual plant, the native country of which is not known. Besides the common or plain sort, which is the kind principally used for salads, there are two varieties, with curled leaves and with broad leaves. The plant partakes strongly of the smell and taste which distinguish the Cruciferæ. Like mustard, it is very easily raised during winter on a slight hot bed; and in the spring months, in close patches, under hand glasses, in the open border, or in drills near a south wall, or in front of a hot-house. It is therefore a favourite article in winter and early spring salads. Where it is wanted through the summer, it must be sown once a fortnight,

as it is only fit for use when young and tender. The plain cress is sown thick, and remains so; but the curled and the broad-leaved require to be thinned out to half an inch asunder. The curled variety makes a pretty garnish; it is rather the hardiest of the kinds, and may therefore be sown late in the season. If a row of cress plants of each of the different sorts be allowed to spring up, plenty of seed will be produced in the autumn. During winter, cresses are often raised on porous earthen-ware vessels, of a pyramidal shape, having small gutters on the sides, for retaining the seeds. These are called pyramids; they are somewhat ornamental, and they afford repeated cuttings.

### *American Cress.*

382. The *American Cress*, (*Erysimum præcox*, Smith; *Tetradynamia Siliquosa; Cruciferæ*, Juss.), although its name might lead us to expect a transatlantic origin, is a native plant of this country. It was formerly considered as a variety of the common winter-cress, (*E. barbarea*); it was described as such by Ray and Petiver: Miller made it a distinct species, by the name of *E. vernum;* and Sir J. E. Smith has figured and described it, under the name of *E. præcox*, *Eng. Bot.* t. 1129. It is only biennial; while the common winter-cress is perennial. It has smaller leaves, more frequently sinuated; the pods thicker, and the seeds larger. It is often called Black American cress, and sometimes French cress.

It is either sown at broad-cast, on a small bed of light earth, or thinly in drills a foot asunder. Three or four sowings are usually made, at intervals of about five weeks, from March to July; and in this way young leaves are always to be had. A late sowing is made in August or September on some sheltered border; the plants stand the winter without injury, and are fit for use in February and March. The plants being cut over, or the outside leaves gathered, new leaves are produced, fit for use in succession.

### *White and Black Mustard.*

*Mustard*, (*Sinapis*, L.; *Tetradynamia Siliquosa; Cruciferæ*, Juss), is of two kinds, white and black. Both are annual plants, and both natives of this country.

383. *White Mustard* (*S. alba*), grows naturally in our fields, though not so common as some of its congeners. It is figured in *English Botany*, t. 1677. It is cultivated only as a small salad, and is used while in the seed-leaf, along with cresses. It may be raised at all seasons; during winter, in boxes in a hot-house or on a hot-bed. When it is wished to save the seeds, a spot of ground somewhat remote from other similar plants should be chosen.

384. The *Common* or *Black mustard*, (*S. nigra*) is a more common native than the white. It is figured in *English Botany*, t. 969. The French call the plant *senevé*, and confine the term *moutarde* to prepared table mustard. The tender leaves are sometimes used as greens in the spring, and the seed-leaves occasionally as a salad ingredient; but the plant is chiefly cultivated for the seed, which, when ground, affords the well known condiment. If the seeds taken fresh from the plant be ground, the powder has little pungency, but is very bitter; by steeping in vinegar, however, the essential oil is evolved, and the powder becomes extremely pungent. In moistening mustard powder for the table, it may be remarked, that it makes the best appearance when rich milk is used; but this mixture does not keep good for more than two days. The seeds in an entire state, are often used medicinally.

The black and the white mustard plants may be distinguished by observing, that the black is a larger plant than the white; that it has much darker leaves than the white, and the divisions of the leaves blunter; the whole upper part of the plant smooth, and the upper narrow leaves hanging downwards; the flowers small, the pods generally quite smooth, and lying close to the stem; while in the white, the flowers are large, the pods rough or hairy, and standing out from the stalk. The names white and black are given in consequence of the colour of the respective seeds.

Black mustard is principally cultivated in fields; but a small bed of it in the garden is often found convenient. The plants require considerable space, and repeated hoeings. The seed ripens in August.

### *Chervil.*

385. *Chervil*, (*Scandix Cerefolium*, L.; *Pentandria Digynia; Umbelliferæ*), is an annual plant, a native of various parts of the continent of Europe, and sometimes observed naturalized near gardens in England, but not admitted into our Flora by Sir J. E. Smith. The leaves are of a very delicate texture, three times divided. The plant rises from a foot to near two feet high, when in flower; but it is the foliage only when in a young state that is used. It was formerly much more cultivated in gardens than it is at present. The young leaves, however, are still sometimes put in soups, and frequently form an ingredient in salad.

It may be right to mention, that care should be taken to distinguish between this and the rough chervil, (*Scandix Anthriscus*,) which is a common denizen of our way sides, and not a wholesome plant. The seeds of the wild species are rough or prickly, while those of garden chervil are smooth. While the plants are only in leaf, they may be distinguished by those who are no botanists by the smell; the leaves of garden chervil, when rubbed, emitting a pleasant scent; while the smell of the wild kind is disagreeable. Chervil is much relished in Holland; and it is said, that some of the Dutch soldiers brought into this country to repress the rising in favour of the Stuarts, perished by using our wild species.

The seeds of garden chervil are sown in autumn, soon after they have ripened, commonly in shallow drills, about eight inches apart. They quickly come up, remain during winter, and are fit for use very early in the spring. Chervil may be repeatedly cut like parsley. It may also be sown in spring or summer; but at these seasons it almost immediately runs to flower. If a few plants be left uncut, they will afford plenty of seed in the end of July. There is a very beautiful variety cultivated in the Paris gardens, with finely frizzled leaves.

### *Purslane.*

386. *Purslane* (*Portulaca oleracea; Dodecandria Monogynia; Portulaceæ*, Juss.; *Pourpier* of the French) is an annual plant, a native of the East. It has a round smooth rather procumbent stem, and diffused branches; the leaves somewhat wedge-shaped and fleshy; the flowers yellow, and sessile. Purslane was well known in England at least as early as the middle of the 16th century. The young shoots and succulent leaves are the parts used. They were formerly much more in request for salads and pickles, and as pot-herbs, than they are at present.

There are two varieties, the Green and the Golden, the principal difference consisting in the colour, but the former being rather the more hardy. Purslane requires a warm situation, and a rich light soil. It is sown any time from May to July. Nicol, in his "Kalendar," speaks of sowing it in the open border in the end of March; but this may be considered as an oversight, the time being much too early. The seed is very small, and attention is necessary to the sowing of it thinly. In dry weather, it is proper to water the young plants at night, two or three times a week. With this care they will be three or four inches high, and ready for cutting, in the space of six weeks. Purslane, when cut over, springs again, and it may be repeatedly cut. When thus taken young, it is of a cold and tender nature, and forms a pleasant salad. If it be wanted earlier than June, it must be raised on a hot-bed, and planted out toward the end of April. If a few of the earliest and strongest plants be left, they soon run to flower, and in warm seasons they ripen their seeds; but imported seed is always to be had in the shops, and it keeps good for several years.

*Fennel.*

387. *Fennel* (*Anethum Fœniculum*, L.; *Pentandria Digynia*; nat. ord. *Umbelliferæ*) is a perennial plant, which, though not an original native, is now so completely naturalized in several parts of England, that it has been admitted into the British Flora by Sir J. E. Smith, and figured in "English Botany," t. 1208. Fennel, or finckle, has long been an inmate of our gardens. Its finely cut leaves and capillary leaflets make it an ornamental plant, especially when strong, rising perhaps to the height of five or six feet. Three varieties are cultivated; the dark-green leaved, the sweet fennel, and finochio, or Azorian fennel. The tender stalks of common fennel are used in salads; and the leaves boiled enter into many fish sauces. The blanched stalks of finochio are eaten with oil, vinegar, and pepper, as a cold salad; and they are likewise sometimes put into soups.

Common fennel will grow in any soil or situation. It may be propagated either by parting the roots, or by seeds. The seeds should be sown in autumn, soon after they are ripe. A few plants are sufficient for a family, and they endure for many successive years.

Finochio is a dwarfish variety, characterized by a tendency in the stalk to swell to a considerable thickness. This thickened part is blanched by heaping earth against it, and is then very tender. As the plant grows rapidly, and the swoln stem is best when young and tender, several successive sowings are requisite, at least where the article is much in request. Owing to the peculiar nature of this variety, it is more tender than the common fennel, and often perishes in the course of the winter. Misled by this circumstance, several horticultural writers describe it as an annual species.

*Dill.*

388. *Dill* (*Anethum graveolens*, L.) is a biennial plant, a native of the corn fields in Spain and Portugal. It has long been cultivated in our gardens as an aromatic and carminative, and the leaves were formerly used in soups and sauces; but the plant is now scarcely employed, unless that the seeds are sometimes added to cucumber pickles. In order to ensure a crop, the seeds should be sown when they ripen in autumn. If some plants be allowed to scatter their seeds, plenty of seedlings will rise in the spring.

*French and Common Sorrel.*

*Sorrel* (*Rumex; Hexandria Trigynia; Polygoneæ*, Juss.; *Oseille* of the French) is of different kinds.

389. *French sorrel* (*R. scutatus*, L.) is a perennial plant, a native of France and Italy; it was cultivated in England before the middle of the 17th century, and it is now common. The leaves are somewhat cordate or hastate, but blunt or rounded, and entire; glaucous, smooth, soft, and fleshy; the stems rise from a foot to a foot and a half high. It is sometimes called Roman sorrel; and, from the breadth and bluntness of the leaves, gardeners often distinguish it by the name of Round-leaved sorrel; our native species being their Long-leaved sorrel. The acid is considered as more grateful than that of common sorrel, and the leaves are more succulent; it is therefore preferred for kitchen use. The plant runs at the root, and is in this way easily propagated. It grows best in a light sandy soil; and the plants are placed about a foot apart. The only attention it requires is the cutting off of the flower-stems and branches in July, so that new leaves may push out for autumn use. In three or four years, however, the plants generally give indications of decay; and new ones must be raised from seed, or offsets procured from young and vigorous plants. If a few stems be allowed to remain in the summer, plenty of seeds may be procured in autumn.

390. *Common Sorrel* (*R. Acetosa*, L.) is a well-known perennial native, growing in meadows and by the sides of rivers, and is figured in "English Botany," t. 1270. The lower leaves have long foot-stalks; they are arrow-shaped, blunt, and marked with two or three large teeth at the base: the upper leaves are sessile, and acute. It is easily raised from seeds sown early in the spring. It thrives best in a shady border. The leaves are used, like those of French sorrel, in various soups, sauces, and especially in salads. As formerly mentioned, they give an excellent flavour to herb patience, used as a substitute for spinach. This species, it may be remarked, is used in France nearly as much as the other, which we generally call French sorrel.

There is a third species of sorrel, reckoned by the Parisians more delicate than either of the others. It is the *Rumex arifolius* of the *Flore Française*. Its leaves are larger and less acid; and it very rarely throws up a flower-stem.

391. *Wood-sorrel* is an entirely different kind of plant, (*Oxalis Acetosella*, L.; *Decandria Pentagynia*; belonging to the *Gerania* of Jussieu.) Having a very grateful acid taste, the leaves form a desirable addition to salads, particularly when young, in the months of March and April. It is to be found in almost every wood; but if the roots be transplanted, in tufts, into the more shady parts of the shrubbery, they will there establish themselves, and be at hand when wanted.

*Corn-Salad.*

392. *Corn-salad*, or *Lamb's Lettuce* (*Valeriana olitoria*, Willd.; *V. Locusta*, Lin.; *Tetrandria Monogynia; Dipsaceæ*, Juss.) is a small annual plant, growing on the margins of our fields, (*Eng. Bot.* t. 811.) and only 2 or 3 inches high. Cultivated in gardens, it rises, when in flower, a foot or more in height. The leaves have a pale glaucous hue; they are long and narrow, the lower ones rather succulent. The flowers are very small, pale bluish, and collected into a close little corymb. In the fields, lamb's-lettuce may be gathered in March, and it flowers in April. In gardens it may be had still more early in the spring: indeed during the greater part of a mild winter. The tender leaves are little inferior to those of young lettuce, having a slight agreeable flavour; they form an excellent ingredient in winter and early spring salads. It has very long been a favourite spring salad-plant in France, under the various denominations of *mâche*, *doucette*, *salade de chanoine*, and *poule-grasse*. Gerarde tells us, that

foreigners using it when in England led to its being cultivated in our gardens. The seeds are sown in autumn, generally about the end of August. They are either sown at broad-cast or in drills, on a small bed or border. The plants soon rise, with a low tuft of oblong narrow leaves; they are then thinned out to two or three inches asunder; and in February they are fit for use. The entire plant is drawn, in the manner of lettuce. The younger the plants are when used, the better: in warm dry weather, the leaves soon acquire rather a strong taste, disagreeable to many persons. Sometimes a small sowing is made in February, which affords plants with fine tender leaves in April and May. A few plants may be allowed to spring up to flower, and they perfect their seeds in July and August. The culture of lamb's lettuce, as a salad plant, has for some time past been declining, but without any good reason.

*Milk-Thistle.*

393. The *Milk-Thistle*, or *Our Lady's Thistle* (*Carduus Marianus*, L.; *Syngenesia Polygamia æqualis; Cinarocephalæ*, Juss.) is a biennial plant, a native of Britain, (*Eng. Bot.* t. 976.) It is at once distinguished by the beautiful milky veins which form an irregular network on the leaves. Some readers may be surprized to find a native thistle ranked among our esculent plants; but it is certainly not more unpromising at first aspect than the artichoke or the cardoon. When very young, it is eaten as a salad; the tender leaves, stripped of their spines, are sometimes boiled and used as greens; the young stalks peeled, and soaked in water to extract a part of the bitterness, are said to be excellent; early in the spring of the second year, the root is pretty good, prepared like salsify or skirret; the receptacle is pulpy, and eats like that of the artichoke. The young plants are sometimes blanched like endive, and used in winter salads: for this purpose the seeds are sown in spring, and the plants are allowed to remain about a foot and a half distant from each other; in autumn, the leaves are tied together, and the earth drawn up close to them, till they be whitened. The plant, however, is but rarely cultivated for any culinary purpose.

It grows naturally, or has been naturalized, near all the old castles or strongholds of Scotland, such as the castles of Edinburgh, Stirling, and Dunbarton. From this circumstance, and the formidable spines of the calyx, many consider it as the "true Scots thistle," the national badge. But the way-thistle (*Carduus lanceolatus*) is incomparably more common in that country. The Gardeners' Lodge of Edinburgh, it may be remarked, generally adopts the cotton-thistle (*Onopordum acanthium*) as its emblem; but apparently without any good reason, that plant existing only in one or two parts of the country. It may be added, that the representations of the Scots thistle, whether carved on ancient buildings, impressed on the coins of the realm, or emblazoned on armorial bearings, as seen in seals or in old engravings, bear equal resemblance to all of these, or, to speak more correctly, are equally unlike any thistle described by Linnæus, as they are dissimilar to each other.

*Burnet.*

394. Burnet (*Poterium Sanguisorba*, L.; *Monœcia Polyandria; Rosaceæ*, Juss.; *petite pimprenelle* of the French,) is a perennial plant, growing naturally in some parts of England, in dry upland pastures. It is figured in "English Botany," t. 860. The leaves are pinnated; they form a tuft next to the root, but are alternate on the stem; the leaflets are partly round-shaped, partly pointed, and much serrated on the edges. The stem rises fifteen inches high, and the flowers form small greenish or purplish heads.

Burnet leaves are sometimes put into salads, and occasionally into soups; and they form a favourite ingredient for cool tankards. When slightly bruised, they smell like cucumber, and they have a somewhat warm taste. They continue green through the winter, when many other salad plants are cut off, or in a state unfit for use. The plant is easily raised by sowing the seeds in autumn, soon after they are ripe; or it may be increased by parting the roots. A few plants are sufficient, as it is not much in use. To promote the production of young leaves and shoots, the stems are two or three times cut over during the summer.

*Rape.*

395. *Rape*, or *Coleseed*, (*Brassica Napus*,) is sown thick as a salad herb, to be cut while in the seed-leaf, in the same way as mustard. A variety of this plant affords the small French turnip or navew, already treated of, § 318. Some consider rape leaves as a good stomachic, and take them boiled.

In the same way, radish seed (*Raphanus sativus*, § 329.) is sometimes sown thick, and cut in the seed-leaf for use.

*Horse radish.*

396. *Horse-radish* (*Cochlearia Armoracia*, L.; *Tetradynamia Siliculosa; Cruciferæ*, Juss.) is a perennial plant, growing naturally in marshy places and by the sides of ditches, in some parts of England, and figured in "English Botany," t. 2223. The leaves are very large, and vary considerably in appearance, being sometimes entire, or only crenated, sometimes deeply pinnatifid; the flowers are white, and come in loose panicles. It has long been cultivated in gardens; the root scraped into shreds being a well known accompaniment of the roast beef of old England, and also used to give a zest to winter salads. The soil should be rich and deep, in order to induce the plants to strike their roots freely. Crowns, having about two or three inches only of root attached to them, make very good plants; but cuttings of the knotty parts of the roots, provided always they be furnished with one or two buds or eyes, are often preferred, as they are to be planted entirely under the soil. They are generally planted, in February or March, in lines, leaving a foot and a half between each line; and for the first season, therefore, a slight crop of spinach or lettuce may be taken between the lines. The sets are placed at the depth of at least a foot; if the soil be light, fifteen inches is not too deep. The roots are not dug for use till the second year; and they are raised only when wanted, the pungent quality escaping rapidly as the root dries. The bed lasts for four or five years; care being taken, in digging the roots, to leave the stock plant, or original set, untouched, removing for use only the upright straight root of twelve or fifteen inches in length, produced by planting at that depth.

*Indian Cress.*

397. *Indian Cress*, or *Nasturtium*, (*Tropæolum majus*, L.; *Octandria Monogynia; Gerania*, Juss.) is a native of Peru: it was introduced into England near the close of the 17th century. It is the *capucine* of the French. The stalks, if supported, will rise six or eight feet high; the leaves are peltate, or have their petiole fixed to the centre of the leaf; the flowers are very showy, of a brilliant

orange colour, and continue in succession from July till destroyed by frost. In its native country it endures several seasons; but here, being unable to sustain our winter, it is treated as an annual plant, and sown every year. The flowers and young leaves are frequently eaten in salads; they have a warm taste like cresses, and from this circumstance the name of *nasturtium* has been bestowed. The flowers are also used as a garnish to dishes, and form a beautiful contrast with the flowers of borage. The seeds, when green, form a favourite pickle; they are often called capers, and substituted for them.

If the seeds be sown in April, in drills about two inches deep, in places where the stalks can have support, no other care is necessary. A fresh but poor soil is better than a rich one, which last makes them too rampant and less fruitful. The plant is often employed as a temporary hedge or screen, to hide any disagreeable object, stakes being fixed, which it soon completely covers. Although destitute of proper tendrils, the petioles or leaf-stalks make a peculiar bend, by which they attach themselves to any small body coming in the way, and support the plant. The seeds ripen freely in September, and may then be gathered for pickling, keeping some of the largest and ripest for next year's sowing.

There is a variety with double flowers, which is continued by cuttings, and sheltered in a hot-house, or the warmer part of a green-house, all winter. It is both highly ornamental as a flower, and forms a still more beautiful garnish than the single.

398. *Dwarf Indian Cress* (*Tropæolum minus*, L.) is also a Peruvian plant, and an annual; it is cultivated in the same way, and for the same purposes, as the other. It is generally sown on borders, and allowed to spread on the ground. There is likewise a double variety of this, which forms a very pretty green-house ornament.

*Marigold.*

399. *Marigold*, or *pot marigold*, (*Calendula officinalis*, L.; *Syngenesia Polygamia necessaria; Corymbiferæ*, Juss.) is an annual plant, a native of France and Spain; but one of the oldest and best known inhabitants of our gardens, its flowers having formerly been much in repute, as "comforters of the heart." Though little faith is now placed in its virtues, it still keeps its place; it is to be found in most cottage gardens both in England and Scotland; and Mr Marshall observes, that "the flower is a valuable ingredient in broths and soups, however it may have got into disuse." The flowers are dried in autumn, and kept in paper bags for use. The single-flowered orange marigold is most aromatic, and the most proper for keeping. There is a pale flowered variety, called the Lemon-coloured marigold; and there are double-flowered varieties both of the orange and lemon colour. The most curious variety is the childing or proliferous, which sends out small flowers from the margins of the calyx of the large central flowers; but this sort is very apt to degenerate; to give a fair chance of preserving it, seed should be saved only from the large central flowers. The common marigold sows itself abundantly, and the seedlings may be transplanted in May; so that, when the plant has once established itself, there is seldom any need for sowing.

*Borage.*

400. *Borage* (*Borago officinalis*, L.; *Pentandria Monogynia*; nat. ord. *Asperifoliæ*) is an annual plant, either a native, or completely naturalized in many parts of Britain; (*Eng. Bot.* t. 36) The lower leaves are oblong and spread on the ground; the flower-stems rise near two feet high; both they and the leaves are rough with white bristly hairs; the bright blue flowers make a beautiful appearance, and are produced for several months in succession. Borage was formerly high in estimation as a cordial plant, for driving away sorrow; but "very light, surely, (says Sir J. E. Smith,) were those sorrows that could be so driven away." It is still sometimes used when young as a pot-herb, and in salads; the spikes of flowers form an ingredient in cool tankards, and the blossoms are occasionally employed as a garnish. The juice of the plant affords nitre, and the withered stalks have been observed to burn like match-paper. Borage will sow itself, and come every year. There is a variety with white flowers, and another with flowers of a pale red or flesh colour; but neither is common.

*Angelica.*

401. This is the *Angelica Archangelica* of Linnæus, (*Pentandria Digynia; Umbelliferæ*): it is a biennial plant, with very large pinnate leaves, the extreme leaflet three-lobed. The roots are long and thick; and they, as well as the whole plant, are powerfully aromatic. It is truly a northern plant, being common in Lapland and Iceland. It was cultivated in Britain in 1568, and probably more early. The stalks of it were formerly blanched, and eaten as celery. Now they are used only when candied; and the young and tender stalks are for this purpose collected in May. Though the plant is only a biennial, it may be made to continue for several years, by cutting over the flower-stem before it ripen seed; in which case it immediately sets out below. It is easily raised from seed, which should be sown soon after being gathered. It grows best in a moist soil, and thrives exceedingly by the side of a ditch.

*Love-apple.*

402. *Love-apple*, or *Tomato*, (*Solanum Lycopersicum*, L.) is an annual plant, a native of South America; it was cultivated by Gerarde in 1596. The stem, if supported, will rise to the height of six feet or more. The leaves are pinnate, and have a rank disagreeable smell. The flowers are yellow, appearing in bunches in July and August, and followed by the fruit in September and October. The fruit is smooth, compressed at both ends, and furrowed over the sides; it varies in size, but seldom exceeds that of an ordinary golden-pippin. The common colour is yellow; but there is a red-fruited variety, which is now the sort principally cultivated; and there is also a small variety called the cherry-shaped. When ripe, it is put into soups and sauces, to which it imparts an agreeable acid flavour. The green fruit is frequently pickled; and sometimes also the ripe. A preserve is likewise made of the fruit.

The seed is sown on a hot-bed in March; when the seedlings are two inches high, they are transplanted into a slight hot-bed till they acquire a little strength. They are then placed near a wall, paling, or reed hedge, to which they can be trained, in a sheltered place, with a full south exposure. The fruit, after all, ripens only in favourable seasons. In dry weather the plants require regular watering. Two or three of the ripest and best of the berries are selected for seed, the pulp being taken out, and the seeds separated by washing.

Love-apples have by many been considered as the *Aurea mala* spoken of by Virgil: but the plant scarcely deserves the title of "arbor silvestris," and would hardly receive it from a poet who was a naturalist; and on this account, probably, Dr Duncan, sen. has suggested, that Virgil's plant might really be an apple-tree, such as the oslin or original pippin, the fruit of which is of a fine yellow colour. In this view, the Doctor is supported by the authority of Sir William Temple. (*Miscell.* vol. ii.)

403. Allied to the love-apple is the *Egg-plant*, (*Solanum melongena*, L.) It is a tender annual, rising about two feet high, with reclining branches. The flowers are of a pale violet colour; they are followed by a very large berry, generally of an oval shape, and white colour, much resembling a hen's egg, or, in large specimens, a swan's egg. There is likewise, however, a variety with globular berries; and the fruit is sometimes of a violet colour. In southern countries the fruit is eaten; here the plant is often cultivated as an ornament for the hot-house and the green-house; but the fruit is seldom made use of. It is sometimes transplanted to successive hot-beds, and planted out in June in a warm border; where, if the autumn prove fine, the fruit makes a beautiful appearance.

*Capsicum.*

404. *Capsicum*, or Guinea pepper, (*Capsicum annuum*, L.; *Pentandria Monogynia; Solanaceæ*, Juss.) is an annual plant, rising about two feet high; a native of both the Indies. It has been long known, being mentioned by Gerarde. It is raised principally for the sake of the young pods, or, to speak more correctly, inflated berries, which make a favourite pickle. They are sometimes also used in the ripe state, when they form a spice of the hottest quality. The seed is sown in the spring, on a gentle hotbed; and the seedlings are transplanted into another bed, where they are nursed till June, when they are planted out in a sheltered border. The berries vary much in shape, producing many subvarieties of the plant. They are long or short, heart-shaped or bell-shaped, and angular. They vary likewise in colour; being generally red, but sometimes yellow. In Scotland, capsicum plants are often potted and kept under glass, the climate being seldom sufficient to ripen the berries in the open border.

A small-fruited annual species, called Cherry-pepper, (*Capsicum cerasiforme*, Hort. Kew.) is sometimes raised; and occasionally the true Bell-pepper (*C. grossum*, L.) is cultivated. This last is a biennial species, of humble growth, but producing large berries. These are better for pickling than the others, the skin being pulpy and tender; while in the others it is thin and tough. This biennial species must of course have a place in the stove.

*Caper.*

405. The *Caper-bush* (*Capparis spinosa*, L.; *Polyandria Monogynia; Capparides*, Juss.), though common in the south of France, and growing in the open air even at Paris, seldom withstands our winters, even though placed in the most sheltered situation. Trained, however, against any spare piece of wall in a stove, it grows luxuriantly, and produces its flower-buds freely. Sometimes it effectually establishes itself in crevices of old hot-house walls, this sort of situation resembling its native one. The use of the flower-buds for pickling is familiar. Perhaps a hardier variety might be obtained by repeatedly raising it from the seed, at first in Guernsey or Jersey, and thus gradually inuring the progeny to cold. It may be mentioned, that in the garden at Campden House, Kensington, a caper-tree stood alive in the open air for near a century. It had a south-east aspect, and was well sheltered from the north. It had no covering, and was generally much injured by the frost during winter; but it made strong shoots, and produced flower-buds every year.

A species of spurge common in our gardens (*Euphorbia Lathyris*, L.) is vulgarly called Caper-bush, from the resemblance of its fruit to capers; but it is acrid, like the other spurges. The flower-buds of marsh-marigold (*Caltha Palustris*, L.) form a safe substitute for capers; and likewise the young seed-pods of the common radish.

*Rhubarb.*

406. Of *Rhubarb* (*Rheum*, L.; *Enneandria Trigynia; Polygoneæ*, Juss.) two species are commonly cultivated.

*Rheum rhaponticum*, L. with the leaves blunt and smooth, veins somewhat hairy underneath, petioles grooved above, and rounded at the edge. This is the species most commonly cultivated in the kitchen garden for the footstalks of the leaves, which are peeled, cut down, and formed into tarts, in the manner of apples. They are best when young and succulent, in April and the early part of May.

*Rheum palmatum*, L. with leaves palmate, acuminate, somewhat rugged, petioles obscurely grooved above, and rounded at the edge. This has by many been considered as the officinal species, and its cultivation has been greatly promoted by the Society for the Encouragement of Arts. In the Transactions of that Society may be found accounts of the different modes which have been followed in this country in cultivating the plant and drying its root for use; or a very distinct abstract of these accounts may be seen in the last edition of Miller's Dictionary, art. *Rheum.* There is still, however, a degree of uncertainty concerning the species which yields the true Turkey or Russian Rhubarb; and the Edinburgh Faculty, in their Pharmacopœia, therefore adopt the popular name of Rheum Russicum. The probability is, that the roots of several species are used. In many places the leaf-stalks of this species are employed in making tarts, and when young are scarcely inferior to the other. A few plants are commonly kept in gardens for curiosity. They are highly ornamental, and particularly remarkable for the rapidity of their growth, rising to the height of perhaps nine or ten feet in seven weeks, and sometimes growing five or six inches within twenty-four hours.

## *Sweet Herbs, and Medicinal Plants.*

*Thyme.*

407. *Thyme* (*Thymus vulgaris*, L.; *Didynamia Gymnospermia; Labiatæ* or *Verticillatæ*) is a perennial plant, indigenous to Spain. It has been cultivated in our gardens, from the earliest times. It is a larger and more woody plant than our native species, *T. Serpyllus*, but the flowers are smaller. Sprigs of thyme are used for giving flavour to soups. There are several varieties, particularly the broad-leaved or green thyme, and the narrow-leaved thyme. The plant is propagated either by parting the roots or planting slips in the spring, or by sowing the seed at the same season. It grows best on light dry soil, which has not been recently manured. A very small bed of the green thyme is enough for kitchen use. Sometimes it is planted as an edging to a border, in which case it must be cut close. It is often admitted to the flower-garden, and varieties with variegated leaves are to be met with. If the plants be allowed to ripen their seeds, numbers of seedlings will appear the following year, when they may be transplanted. In autumn, some of the bushes of thyme

are cut over, and hung up surrounded with paper, to dry for winter use.

The Lemon-scented thyme is a variety of our native species above mentioned. It is sometimes also cultivated, being in request for flavouring particular dishes.

*Sage.*

408. *Sage* (*Salvia officinalis*, L.; *Diandria Monogynia*; *Labiatæ*, Juss.) is a native of the south of Europe, which has very long been an inhabitant of our gardens. It is a branched shrub, about two feet high; the leaves are wrinkled, green, cinereous, white, or tinged with dusky purple; flowers terminal, in long spikes; of a blue colour. Several varieties are cultivated: Red or purple sage, and Green sage; and each of these with variegated leaves, forming ornamental plants in the flower-border. There is a small-leaved green variety, called Sage of Virtue; and there is a Broad-leaved balsamic sage. The red is the sort preferred for culinary purposes, but the green is also employed. The leaves are used in stuffings and sauces for many kinds of luscious and strong meats. Of sage of virtue the decoction called Sage-tea is usually made; but it is equally good from the broad-leaved or the common green. The plants do not endure in good condition for more than three or four years; but they are easily propagated by slips in the spring, or by cuttings when the summer is advanced. The cuttings should be five or six inches long, stripped of all the lower leaves, and plunged nearly to the top in the earth, being at the same time well watered. The lighter and poorer the soil, the better is the sage, and the more surely do the plants stand the winter. In July or August some parcels of sage twigs are commonly collected, and hung up in papers for winter use; but the leaves on the plants remain green through the winter, and a few may occasionally be gathered without doing injury.

*Clary.*

409. *Clary* (*Salvia sclarea*, L.) being of the same genus with sage, may here be noticed. It is a biennial plant, a native of Italy. The lower leaves are very large, the stem is about two feet high, clammy to the feel; the flowers are in loose terminating spikes, composing whorls, and of a pale blue colour. Clary was very early cultivated in English gardens, having been accounted medicinal. It is sometimes used in soups, but its very strong scent is not agreeable to many. A considerable bed of clary is seldom to be seen in gardens, excepting when it is intended to make clary wine. For this purpose, in dry weather, the flowers are gathered; some employ the whole spikes, and others carefully separate the blossom from the calyx. Most generally, clary flowers are used only for giving flavour to home-made wines, being thought to impart something of the frontignac zest. The plant is propagated by seeds sown in the spring, and transplanted in the summer months at fifteen inches apart. Next year they yield their flowers; and if a few plants be left, plenty of seed may be procured.

*Mints.*

Several species of *mint* (*Mentha*, L.; *Didynamia Gymnospermia*; nat. ord. *Labiatæ*) are cultivated in gardens; all of them indigenous to Britain, and hardy perennials. The principal kind is,

410. *Spearmint*, (*M. viridis*, L.) This is not a common native plant; it is figured in "English Botany," t. 2424. The young leaves and tops are a good deal used in spring salads in England; they also form an ingredient in soups, or, more frequently, are employed to give flavour, being boiled for a time and withdrawn. They are also shredded down, and mixed with sugar and vinegar as a sauce to roasted meat, particularly lamb. A narrow-leaved and a broad-leaved sort are cultivated in gardens; and some variegated kinds are considered as ornamental plants, particularly a reddish variety called Orange-mint.

411. *Peppermint*, (*M. piperita*, L.) is likewise a rare native, figured in *English Botany*, t. 687. A few plants are sufficient in a garden, it being scarcely used but for distilling.

412. *Pennyroyal*, (*M. pulegium*, L.) figured in *English Botany*, t. 1026, is sometimes cultivated; but a few plants are sufficient.

All of these mints delight in a moist soil. Spearmint and peppermint are readily propagated, by parting the roots in autumn, by making slips in spring, or by means of cuttings during summer. Pennyroyal is easily increased by its creeping and rooting stems. Stalks of spearmint are often dried in the latter end of summer, when the plant is coming in flower, and kept for winter use; but unless the drying be gradually accomplished, and in the shade, much of the flavour escapes. Young mint leaves, however, may be had at any time of the winter or early spring, by setting a few roots in flower-pots in the autumn, and removing some of these into the corner of a hot-bed, or of the stove, some short time before the leaves be wanted.

*Balm.*

413. *Balm* (*Melissa officinalis*, L.; *Didynamia Gymnospermia*; *Labiatæ*, Juss.) is a hardy perennial, with square stems, which rise two feet high or more; leaves large, growing by pairs at each joint; a native of Switzerland and the south of France, and very early cultivated in our gardens. It is readily propagated by parting the roots, preserving two or three buds to each piece, or by slips, either in autumn or spring. The roots or slips being placed about a foot and a half asunder, and watered, soon establish themselves; and the balm plantation does not require to be renewed oftener than every third or fourth year. In order to have young leaves and tops all the summer, it is proper to cut down some of the stalks every month, when new shoots immediately spring. As the remaining stalks approach the flowering state, they are cut over at full length for drying. They should be cut as soon as the dew is off in the morning; for in the afternoon, at least in bright sunshine, the odour of the plant is found to be much diminished. The stalks and leaves are carefully dried in the shade, and afterwards kept in small bundles, pressed down, and covered with paper. The *primum ens melissæ*, by which Paracelsus was to renovate man, is now quite forgotten, and the plant is used only for making a simple balm tea, which affords a grateful diluent drink in fevers, and for forming a light and agreeable beverage under the name of Balm Wine.

*Marjoram.*

*Marjoram*, (*Origanum*, L.; *Didynamia Gymnospermia*; *Labiatæ*, Juss.) Of this, three species are cultivated.

414 *Pot Marjoram* (*O. Onites*, L.) is a perennial plant, a native of Sicily. The stem is somewhat woody; it rises more than a foot high, and is covered with spreading hairs; the leaves are small and acute, almost sessile, and tomentose on both sides. Though it seldom ripens its seeds in this country, it is sufficiently hardy to withstand our win-

ters. It is easily propagated by cuttings or slips. It is now little used by the cook.

415. *Sweet Marjoram* (*O. Marjorana*, L.) is a native of Portugal. It resembles pot marjoram, but the leaves have distinct petioles, and the flowers are collected in small close heads; from which last circumstance it is often called Knotted Marjoram. Being only a biennial, a little of the seed should be sown every year. The seed seldom ripens in this country, and is therefore commonly imported from France. It flowers in July, and is then gathered and dried for winter use.

416. *Winter sweet marjoram* (*O. heracleoticum*, L.) is a perennial species, a native of Greece, and which requires a sheltered border and a dry soil. The leayes resemble those of common sweet marjoram, but the flowers come in spikes. The plant is propagated by parting the roots in autumn.

Both the kinds of sweet marjoram are a good deal employed to give relish to soups, broths, stuffings, &c. They are used fresh in summer; and, for winter use, are drawn by the roots, and dried slowly in the shade, being afterwards kept hung up in a dry place.

*Savory.*

*Savory* (*Satureja*, L.; *Didynamia Gymnospermia*; *Labiatæ*, Juss.) Two species are cultivated, the winter and the summer savory.

417. *Winter savory* (*S. montana*, L) is a native of the south of France and of Italy, which has been very long cultivated in gardens. It is a small shrubby evergreen perennial plant, with two narrow stiff leaves, an inch long, opposite at each joint, and from the base of these a few small leaves in clusters. It is propagated by slips, or by cuttings of the young roots, and also by seeds. It is hardy, and continues good for several years, especially on poor soils. Some plants having established themselves on an old wall, have been observed to continue for many years.

418. *Summer savory* (*S. hortensis*, L) is an annual plant, a native of the south of Europe, with slender erect branches about a foot high; leaves opposite about an inch in length. This is propagated only by seed, which is sown in the spring time, thinly, in shallow drills, eight or nine inches apart. When it is to be stored for winter use, it should be drawn up by the root, as in this way it retains its flavour better.

*Basil.*

*Basil* (*Ocimum*, L.; *Didynamia Gymnospermia; Labiatæ*, Juss.) Two species are cultivated, both natives of the East, and both annual plants.

419. *Sweet Basil* (*O. basilicum*, L.) is generally sown on a hot-bed in the end of March, and planted out in May, at eight or ten inches square. If raised from the hot-bed in small tufts, with a ball of earth attached, it is sure to succeed. In dry weather, liberal watering is proper. In a sheltered situation, sweet basil, thus treated, rises to about a foot in height. If sown at once in the open border, the plants are late and small. The leaves and small leafy tops are the parts used. On account of its strong flavour of cloves, basil is often in demand where highly seasoned dishes are in use: a few leaves are sometimes introduced into a salad, and not unfrequently into soups.

420. *Bush Basil*, (*O. minimum*, L) is little more than half the size of the common basil. It forms a round orbicular bushy head. It is raised on a hot-bed in the same way as the other, but should be planted out in a richer soil, and in a warmer situation. The same parts of the plant are used, and for the same purposes.

In very favourable seasons, and in the south of England, both species sometimes ripen their seed; but in general, Italian seed may be depended on.

*Tarragon.*

421. *Tarragon* (*Artemisia Dracunculus*, L.; *Syngenesia Polygamia æqualis; Corymbiferæ*, Juss.) is a perennial plant, a native of Siberia, which was cultivated in gardens in the time of Gerarde. It rises a foot and a half high, is branched, and has narrow leaves, green on both sides. The leaves and tender tips are used as an ingredient of pickles, for the sake of their fragrant smell and warm aromatic taste. A simple infusion of them in vinegar makes a pleasant fish-sauce. In France, tarragon is often added to salads, that its agreeable pungency may correct the coldness of other herbs; and it is frequently put in soups.

In a dry loamy soil, tarragon proves quite a hardy plant; but it is apt to perish in a wet situation. It is easily propagated by parting the roots, or by planting in the spring young shoots with only two or three fibres. During the summer months, even cuttings will grow; but both the shoots and cuttings must be plentifully watered till they strike root. The plant is therefore seldom raised from the seed. The stems containing the leaves and tops are sometimes dried for winter use; and if fresh young tops be wanted at that season, they can soon be procured by keeping some roots in pots, and placing these in a hot-bed or stove.

422. *Common Wormwood*, which is another species of Artemisia, (*A. absinthium*, L.) was formerly kept in gardens, being much used as a vermifuge. It is a native plant, figured in "English Botany," t. 1230, and wild specimens are more powerful than cultivated ones. It is easily propagated by slips or cuttings. The growth of this plant, it may be remarked, should be encouraged in poultry walks, it being found beneficial to them. The distillers of great still whisky in Scotland sometimes employ it in place of hops, and for their use small fields of it are occasionally sown.

*Rosemary.*

423. *Rosemary* (*Rosmarinus officinalis*, L; *Diandria Monogynia; Labiatæ*, Juss.) is a native of the south of Europe, but if planted on a dry soil, in a sheltered garden, it withstands our ordinary winters. When its roots enter the crevices at the base of an old wall, the plant is not injured by the severest frosts. It is an evergreen shrubby plant, rising sometimes six or eight feet high; the leaves are sessile, linear, dark green above, greyish or whitish underneath; the blossoms of a pale blue colour. As it is a highly aromatic and a medicinal plant, a few bushss should be in every garden. An infusion of the leaves is grateful to many people. The flowers and calyces form a principal ingredient employed by the makers of what is called Hungary water. A rosemary sprig is the emblem of remembrance. "There's rosemary; that's for remembrance," says the distracted Ophelia, in Shakspeare. In some parts of the west of England, the sprigs are still distributed to the company at funerals, and often thrown into the grave upon the coffin of the deceased. Abercrombie, in his *Practical Gardener*, alludes to this practice, but supposes the motive to be the "preventing of contagion." There are varieties, with white-striped and with yellow-striped leaves; the former rather tender.

The plant is easily propagated by slips or cuttings in the spring.

*Lavender.*

424. *Lavender*, or *Spike Lavender*, (*Lavandula Spica*, L.; *Didynamia Gymnospermia; Labiatæ*, Juss.) is a native of the south of Europe, and has been cultivated in our gardens since the middle of the 16th century. The plant is shrubby, rising from two to four feet high; the leaves linear, hoary, slightly rolled back at the edges; the flowers forming terminating spikes. There is a narrow-leaved and a broad-leaved variety. Lavender is rather a medicinal plant than one used by the cook. In every garden, however, a few plants are kept. The spikes of flowers being very fragrant, the ladies often make imitation scent-bottles of them. Frequently they are put in paper bags, and placed among linens to perfume them. In physic gardens, the plant is extensively cultivated for the sake of the flowers, from which lavender water is distilled. It is propagated by cuttings, or young slips, any time in the spring months. In large gardens it is sometimes used as an edging, but it is too bulky. If lavender be planted in a dry, gravelly or poor soil, its flowers have a powerful odour, and the severity of our winters has little effect on it; while, in a rich garden soil, although it grows strongly, it is apt to be killed, and the flowers have less perfume. In common garden soil, new plantations should be made every four or five years.

*Coriander.*

425. *Coriander* (*Coriandrum sativum*, L.; *Pentandria Digynia; Umbelliferæ*, Juss.) is a native of the East, but has naturalized itself in Essex, near places where it has long been cultivated for druggists and confectioners, and is therefore figured in *English Botany*, t. 67. It rises about a foot high, with doubly pinnated leaves. It is not often raised in private gardens. Formerly the young leaves were used in salads, and in soups; but they have a strong and scarcely agreeable scent. The seeds are now chiefly in request for medicinal purposes. If these be wanted, the seed should be sown in autumn, and the plants afterwards thinned out to five or six inches asunder.

*Caraway.*

426. *Caraway* (*Carum carui*, L.; *Pentandria Digynia; Umbelliferæ*) is a biennial plant, a native of some parts of England, and figured in *English Botany*, t. 1503. The plant rises a foot and a half high, with spreading branches; the leaves are decompound; the leaflets in sixes. In former times, the tapering fusiform roots were eaten like parsnips, to which Parkinson gives them the preference. In the spring time, the under leaves are sometimes put in soups, But the plant is now principally cultivated for the seeds; these are used in making cakes, and are incrusted with sugar for comfits; they are likewise distilled with spirituous liquors, and for this purpose large quantities are raised in fields in Essex. Nicol and others direct its being sown in the spring; but it is much better to sow in autumn, soon after the seed is ripe; the seedlings quickly rise, and, the plant being biennial, a season is thus gained. A moist rich soil answers best. The seed is generally sown in rows; and in the spring, the plants are thinned out to four or six inches apart. In the end of summer, when the seeds appear to be nearly ripe, the plants are pulled up, and set upright to dry, the seed being then more easily beat out.

*Tansy.*

427. *Tansy* (*Tanacetum vulgare*, L; *Syngenesia Polygamia superflua; Corymbiferæ*, Juss.) is a well known perennial plant, a native of most parts of Britain, generally growing on the banks of rivers; it is figured in *English Botany*, t. 1229. In a cultivated state, it rises to the height of three or four feet; the stem leafy, the leaves alternate, deep green, finely divided; the flowers appear in terminating corymbs, and are yellow. It has long had a place in the garden, partly on account of its medicinal virtues, being in high estimation as a vermifuge, and partly for the sake of its young leaves, which are shredded down, and employed to give colour and flavour to puddings. There is a variety with curled leaves, which is rather ornamental; this is often called Double tansy. There is likewise a sort with variegated leaves, which is sometimes admitted into shrubberies. Tansy is extremely hardy, and will grow in any soil or situation. A few plants are sufficient; and it is very easily propagated at any time by parting the roots. Tansy leaves may be procured very early in the spring, by laying two or three tufted roots of the plant upon a slight hot-bed about mid-winter, arched with hoops and covered with mats in severe weather. The young leaves may also be had throughout the summer, by cutting down the flower-stems close, so as to encourage a new growth.

*Costmary.*

428. *Costmary*, or *Ale-cost*, (*Balsamita vulgaris*, Hort. Kew.: *Tanacetum Balsamita*, L.; *Syngenesia Polygamia æqualis; Corymbiferæ*, Juss.) is a native of Spain, Italy, and the south of France: it is however a hardy perennial, and has been cultivated in our gardens from the earliest times. The lower leaves are large, ovate, of a greyish colour, and on long footstalks; the stems rise two or three feet high; they are furnished with leaves of the same shape, but smaller and sessile. The flowers are of a deep yellow colour, and appear in loose corymbs in August and September; in indifferent seasons or in cold situations, they scarcely expand, and the seeds very seldom come to maturity in this country. The whole plant has a pleasant odour. Costmary was formerly more used in the kitchen than it is at present. In France it is an ingredient in salads. It was also put into ale, and hence the name Ale-cost. The other name, cost-Mary, intimates that it is the *costus* or aromatic plant of the Virgin. A few plants are enough in a garden. They do best in a dry soil, and will remain good for several years. It is readily propagated by parting the roots in autumn. There is a variety with deeply cut and very hoary leaves, but this sort is less fragrant.

*Hyssop.*

429. *Hyssop* (*Hyssopus officinalis*, L.; *Didynamia Gymnospermia; Labiatæ*, Juss.) is a perennial evergreen undershrub, a native of the south of Europe, and has been long cultivated in our gardens. The stems rise a foot and a half high; the leaves are lanceolate, narrow like those of lavender, but shorter. There are several varieties, blue, red, and white flowered, and hairy leaved; but the first is the most commonly cultivated. The whole plant has a strong aromatic scent. The leaves and young shoots are sometimes used for culinary purposes, in the way of a pot-herb; and the leafy tops and flower-spikes are cut, dried, and preserved for medicinal uses. It is sometimes planted as an edging in the kitchen garden, the plants being set

only about ten inches distant from each other: in a separate bed, they should be two feet asunder. It may be propagated by seeds, by roooted slips, or by cuttings, in the spring months. In a poor dry soil it is not only more hardy, but more aromatic, than in a rich soil. It often grows on old walls; but the "hyssop that springeth out of the wall" of Solomon, is supposed by Hasselquist to have been a small moss, which he observed covering the ruins of Jerusalem.

*Rue.*

430. *Rue* (*Ruta graveolens*, L.; *Decandria Monogynia; Rutaceæ*, Juss.) is a perennial evergreen undershrub, a native of the south of Europe. It was early cultivated in our gardens, and was in former days called Herb of Grace, from the circumstance of small bunches of it having been used by the priests for the sprinkling of holy water among the people. There is a tall growing and a small kind; the latter is now chiefly cultivated. Formerly border edgings were frequently made with it; but it is now seldom employed for that purpose. It ought, however, to be occasionally pruned down, and kept from flowering too much; in this way it continues in a fresh bushy state for a number of years. It is easily propagated by slips or cuttings in the spring; and a few plants are generally thought sufficient in a garden. Like rosemary, lavender, hyssop, and other similar aromatics, it does best in poor dry soils. The leaves are sometimes used as a medicine, and often given to poultry afflicted with croup.

*Chamomile.*

431. *Chamomile* (*Anthemis nobilis*, L.; *Syngenesia Polygamia superflua; Corymbiferæ*, Juss.) is a well known perennial plant, which grows naturally in Surrey, Cornwall, and some other parts of Britain, and is figured in *English Botany*, t. 980. Few gardens are without a chamomile bed: it is certainly a highly aromatic plant, and an infusion of the dried flowers makes a safe bitter and stomachic, much used under the name of Chamomile-tea. The double-flowering variety is ornamental, and is generally kept in gardens; but the single-flowered sort is preferable for use; the useful principle not residing in the floscules of the ray, which are multiplied in the double flower. The flowers are gathered when in their prime, dried slowly in the shade, and preserved in paper bags till wanted. The plant is easily propagated by slips or rooted shoots in the spring months. It delights in a poor soil: the plants may be placed ten inches or a foot apart, and should be watered in dry weather till they be established. It is sometimes employed to form rustic green seats, and it answers very well, if the seats be not very much used.

*Scurvy-grass.*

432. *Scurvy-grass* belongs to the same Linnean genus as the horse-radish, § 396, although in general habit the plants have no resemblance. It is the *Cochlearia officinalis*, L. an annual or at most a biennial plant, indigenous to most of our sea-shores, and, like the plant called thrift or sea-pink, growing also on many of our mountains, particularly in Scotland. It is figured in "English Botany," t. 551. A thick-leaved variety, called Dutch Scurvy-grass, is sometimes cultivated in gardens for medicinal purposes. The smaller leaves are occasionally eaten between slices of bread and butter. It is sown in July, or as soon as ripe seeds can be gathered; it requires little attention, needing only to be thinned and kept clear of weeds. If the seeds be not wanted, the flower stems may be cut over, and the plants will thus continue for two or more years. Common scurvy-grass thrives uncommonly well on the top of an old wall, where it will sow itself, and remain many years.

*Elecampane.*

433. *Elecampane* (*Inula Helenium*, L.; *Syngenesia Polygamia superflua; Corymbiferæ*, Juss.) is a native of different parts of the south and west of England, and figured by Sowerby in "English Botany," t. 1546. It is a perennial plant, with a thick fusiform aromatic root; it rises from three to five feet high, being one of our largest herbaceous plants; the lower leaves are a foot long, and perhaps four inches broad in the middle; the yellow flowers appear in large heads in July and August. In former days the root had many virtues ascribed to it; the plant was therefore cultivated in village-gardens throughout Europe: now, it is much less in repute, but it still keeps its place in the physic-herb corner. As a few plants only are wanted, they are generally procured by offsets in the autumn. The root is fit for use the second year: and roots of this age, it may be noticed, are better than those of old plants.

*Anise.*

434. *Anise* (*Pimpinella Anisum*, L.; *Pentandria Digynia*; nat. ord. *Umbelliferæ*) is an annual plant, a native of Egypt, but cultivated in Malta and Spain, for the seeds, which are medicinal, and a good deal in demand. In this country the plant requires a warm border. The seed is sown in April, where the plants are to remain; and they are thinned as they come up. It is only in very favourable seasons that the seeds are perfected. Mr Lysons mentions it as one of the plants raised by the physic gardeners near London, probably by mistake: for it is certainly too tender to be cultivated in this country for profit.

*Blessed Thistle.*

435. *Blessed Thistle* (*Centaurea benedicta*, L.; *Carduus benedictus* of the old writers; *Syngenesia Polygamia frustranea; Cinarocephalæ*, Juss.) is an annual plant, growing naturally in the Levant. It was formerly cultivated with care in our gardens for its supposed extraordinary virtues. An infusion of it is still sometimes used; and a few plants are therefore raised from the seed, which is generally sown in autumn.

It seems unnecessary to swell the list of these simples, or medicinal plants; but it may be proper slightly to mention a few esculents or herbs, principally native, the cultivation of which is either seldom attended to in this country, or has fallen into disuse.

436. *Garden Rocket* (*Brassica Eruca*, L.) is an annual plant, a native of Switzerland, which was in former times used as a salad herb, but is now seldom to be met with, unless in botanic gardens. When in flower it has a strong peculiar smell, which some would not hesitate to call fetid; but in a young state the flavour is just perceptible, and the leaves then form a very tolerable salad ingredient. It is still cultivated in some parts of the continent.

437. *Wild-rocket*, or Hedge-mustard, (*Sisymbrium officinale*, Hort. Kew.; *Erysimum officinale*, L; English Botany, t. 725.) has been sometimes sown and used as a spring pot-herb. When young, it has a warm and not disagreeable taste.

438. *Winter-Cress* (*Barbarea vulgaris*, Hort. Kew.; *Erysimum Barbarea*, L.; English Botany, t. 443.) is a well known perennial plant, which has long been occasionally used as an early spring salad. Some still consider the American cress of gardeners as merely a variety of this: but after cultivating both for several years, we have found those to be right who regard them as distinct. (See § 382.) It may be remarked, that a double flowered variety of Barbarea vulgaris is admitted to the flower-border, under the name of Yellow rocket.

439. *Sauce alone*, or Jack by the hedge, (*Erysimum Alliaria*, L.; English Botany, t. 796) is sometimes used, either in sauce, as a salad, or boiled as a pot-herb. When gathered as it approaches the flowering state, boiled separately, and then eaten to boiled mutton, it certainly forms a desirable pot-herb. To any kind of salted meat it will be found an excellent green. Being not unfrequent by the sides of hedges, in a natural state, it has seldom been raised in gardens.

440. *Samphire* (*Crithmum maritimum*, L.; English Botany, t. 819.) is well known as forming a very good pickle, and also a piquant addition to a salad. It grows among rocks on the precipitous shores of some parts of England, particularly Kent and Cornwall, and of Galloway in Scotland. It is the plant alluded to by Shakespeare in his celebrated description of Dover cliffs:

> ——"Half way down
> Hangs one that gathers samphire; dreadful trade!"

It is a perennial plant, and is propagated by parting the roots, or by seed sown in the spring. It is not easily cultivated. It seems to succeed best on a rich light soil, having sand and gravel mixed with it. It must be in a well sheltered situation, and requires to be freely watered in dry weather, till the roots have struck deep among the soil and gravel. Mr Marshall mentions, that it has been found to do well in pots, set for the morning sun only. If a few plants can be got to take deep root in an old wall, or on an artificial rock-work, they will have a much better chance to remain. The name samphire is a corruption of *sampier*, and this again is derived from the French name of the plant *Saint Pierre*. It may be observed, that what is called *golden samphire* in Covent Garden market, is the Inula crithmifolia, Eng. Bot. t. 68; and that the *Marsh samphire* of the same market, is the Salicornia herbacea, Eng. Bot. t. 415.

441. *Buck's-horn Plantain* (*Plantago coronopus*, L.) was formerly cultivated as a salad herb, but is now neglected, the smell being to many rank and disagreeable. It is still, however, regularly sown in French gardens as a salad herb, under the name of *Corne de Cerf*.

442. The young leaves of the *Ox-eye Daisy* (*Chrysanthemum leucanthemum*, L.) are noticed by Dr Withering as fit to be eaten in salads; and John Bauhin mentions that they were much used for that purpose in Italy.

443. The *Cotton Thistle* (*Onopordum acanthium*, L.; English Botany, t. 977.) is a biennial, growing naturally in different places, and remarkable for its large downy leaves and lofty stem. It was formerly cultivated and used like the artichoke and cardoon; the receptacle, and the tender blanched stalks, peeled and boiled, being the parts used.

444. *Alexanders* (*Smyrnium Olusatrum*, L.; English Botany, t. 230.) is a biennial plant, rising about two feet high, and flowering in the spring; the leaves of a pale green colour, and the flowers yellowish. It grows naturally near the sea in several places, and may often be observed to be naturalized near old buildings. It was formerly much cultivated, having been used as a port-herb and salad. In flavour it has some resemblance to celery; by which it has been entirely supplanted.

445 *Water Cress* (*Nasturtium officinale*, Hort. Kew.; *Sisymbrium Nasturtium*, L.; English Botany, t. 855.) is a well known perennial inhabitant of our ditches and slow running streams. It forms an excellent spring salad; and it is easily cultivated in any marshy spot, or by the side of a garden pond, by introducing a few plants from ditches where it grows wild. The popular remedy called *spring juices* consists of its juices, with those of Brooklime, scurvy-grass, and Seville oranges: it is therefore cultivated by a few market gardeners for the supply of Covent Garden. In France, the sprigs are used as a garnish to roast fowl.

446 *Brooklime* (*Veronica beccabunga*. L.; English Botany, t. 655.) is a perennial plant, growing in wet places near springs, and in slow running streams or ditches, very generally associated with the water-cress. The leaves are mild, or have only a slightly bitterish taste, and form a very tolerable salad ingredient in March and April. In Scotland the plant is called *water purpie*, and the sprigs are gathered for sale along with *wall-cresses* (well or water cresses.)

447 The young tops and leaves of the *Great Nettle* (*Urtica dioica*, L.; English Botany, t. 1750) are gathered in early spring, about February, as a pot-herb, and form a tolerably good one. *Nettle-kail* is an old Scottish dish, now known only by name. If nettle-tops be wanted, they can readily be had without cultivating the plant.

448. *Sow-thistle* (*Sonchus oleraceus*, L.; English Botany, t. 843.) is a common annual weed in our gardens. There is a prickly and a smooth variety. The latter is in some countries boiled and eaten as greens; hence the Linnean trivial name *oleraceus*. The tender shoots boiled in the manner of spinach are very good, superior perhaps to any greens not in common use.

449. *Dandelion* (*Leontodon taraxacum*, L.; English Botany, t. 510) is a well known perennial, generally despised as a troublesome weed: yet the leaves, in early spring, when they are just unfolding, afford a very good ingredient in salads. The French sometimes eat the young roots, and the etiolated leaves, with thin slices of bread and butter. Blanched dandelion loses its disagreeable flavour, and considerably resembles endive in taste.

450. *Bladder Campion*, or Spatling Poppy (*Silene inflata*, Hort. Kew.; English Botany, t. 164.; *Cucubalus behen*, L.) is a hardy perennial, growing naturally by the sides of our corn-fields and pastures. Its young tender shoots, when about two inches long, are excellent when boiled, having something of the flavour of peas. The plant sends forth a great number of sprouts, and when these are nipped off they are succeeded by fresh ones.

451. The *Hop* (*Humulus Lupulus*, L.; Eng. Bot. t. 427.) is well known as being cultivated for the sake of its flowers for preserving beer; but for use as a kitchen-herb it is little regarded. The young shoots, however, which, early in the spring, rise abundantly from old stocks, are not much inferior to asparagus. They are sometimes, but not often, sent to market, and sold by the name of *hop-tops*.

For further particulars regarding esculent plants which have fallen into neglect, the reader may be referred to the "Flora Diætetica" of Bryant.

### *Fungous Plants.*

Of the tribe of Fungi several esculent species occur in this country, belonging to the genera Agaricus, Tuber, and Phallus. Only one is cultivated, the Common Mushroom, *Agaricus campestris* of Linnæus, *A. edulis* of Bulliard and others.

*Common Mushroom.*

452. This is well known. It is most readily distinguished, when of middle size, by its fine pink or flesh-coloured gills, and pleasant smell: in a more advanced stage the gills become of a chocolate colour, and it is then more apt to be confounded with other kinds, of dubious quality; but the species which most nearly resembles it, is slimy to the touch, and destitute of the fine odour, having rather a disagreeable smell: further, the noxious kind grows in woods or on the margins of woods, while the true mushroom springs up chiefly in open pastures, and should be gathered only in such places.

The uses of the mushroom are familiar; it is eaten fresh, either stewed or broiled; and preserved, either as a pickle, or in powder. The sauce commonly called *ketchup* (supposed from the Japanese *kit-jap*) is, or ought to be, made from its juice, with salt and spices. Wild mushrooms from old pastures are generally considered as more delicate in flavour and more tender in flesh, than those raised in artificial beds. But the young or button mushrooms of the cultivated sort are firmer and better for pickling; and in using cultivated mushrooms, there is evidently much less risk of deleterious kinds being employed.

Mushrooms are most speedily and certainly propagated, by placing the germinating seeds,—or rather the white fibrous radicles, which produce tubercles in the manner of potatoes, called the *spawn*,—in a situation proper for the developement of the plants. Without at all abetting the doctrine of equivocal generation, we may assert our power to produce this spawn at pleasure. Some long stable dung, which has not lain in a heap, or undergone any degree of fermentation, is mixed with strong earth, and put under cover from rain: the more the air is excluded, the sooner does the spawn appear: a layer of old thatch, or any kind of litter that has lain long abroad, and so is not apt to ferment, is proper for excluding the air. In about two months the white threads of the spawn will be found penetrating the dung and earth. When spawn is once procured, it may be extended or propagated, as spawn, without producing mushrooms. A mode of doing this, practised by Mr John Hay, may here be mentioned. A quantity of cow droppings is to be gathered from the pastures; some rotten wood, or spray from the bottom of a hedge, is to be collected, with a little strong loam. These are mixed, and formed into a moist ductile sort of mortar or paste, of such consistence, that it can be cut into pieces like bricks. When these are so far dried that they can conveniently be lifted, a row is laid in some dry place, under cover, perhaps in a shade at the back of a hot-house; a little spawn is placed upon the layer; then another layer of the spawn bricks, and so on. In a few weeks the whole mass is penetrated by the spawn. The spawn bricks may then be laid aside for use; they will keep many months; and the drier they are kept, the more certainly do they afford a crop of mushrooms, when placed in favourable circumstances for doing so.

The usual mode of raising mushrooms, in beds prepared with layers of horse-droppings and fine mould, is generally understood, and has been fully described in a preceding part of this work, (art. FUNGI.) It may be proper, however, in addition to what is there said, to give an account of what is called Oldacre's plan, this being generally considered as an improvement on the culture of mushrooms.

453. Mr Isaac Oldacre is an Englishman, who for many years held the office of chief gardener to the Emperor of Russia at St Petersburgh. In 1814, he visited his native country; and on that occasion, at the desire of Sir Joseph Banks, put in practice at Spring Grove his improved mode of raising mushrooms. In forming the compost for the beds, he prefers fresh short dung, from a stable or the path of a horse-mill. The dung must neither have been exposed to wet nor to fermentation. About a fourth or a sixth part of cow or sheep's droppings is added, and the whole ingredients are well mixed and incorporated. The beds, if they may be so called, are formed on shelves, or in drawers or boxes, in the mushroom-house, or in any outhouse, where a slight increase of temperature can be commanded. A stratum of the prepared mixture, about three inches thick, being deposited, is beat together with a flat wooden mallet. Another similar layer is added, and beat together as before; and this is repeated, till the beds be six inches thick, and very compact. A degree of fermentation soon takes place in this mass; but if the heat arising from this process be not quickly perceptible, another layer must still be added, till sufficient action be excited. When the beds are milk warm, (or between 80° and 90° Fahr.) some holes are dibbled about nine inches apart, for receiving the spawn. These are left open for some time; and when the heat is on the decline, but before it be quite gone, a lump of spawn is inserted into each opening, and the holes are then filled up with the compost. Ten days afterwards, the beds are covered with a coating of rich mould, mixed with a fourth or sixth part of droppings, to the depth of an inch and a half. This is beat down with the back of a spade, and the bed may then be accounted ready for producing. The mushroom-house is now kept as nearly and equally at 55° Fahr. as circumstances will allow. When the beds become very dry, it is occasionally found requisite to sprinkle over them a little water, taken from a pond or river; but this must be done with great circumspection.

Beds thus prepared, we are assured, yield abundant crops of mushrooms. If a number of shelves or drawers be at first prepared, a few only, at a time, may be covered with mould, and brought into bearing; the rest of the shelves or drawers being cropped in succession, as mushrooms may happen to be in demand. It is evident that they may thus be procured at all seasons. The more that free air can be admitted into the mushroom-house, the flavour of the mushrooms will be found to be improved.

In what particulars the advantage of Mr Oldacre's plan over former modes chiefly consists, does not very clearly appear. Beds made up in the usual way are much less compact, and are more damp: compactness and dryness may therefore be considered as important. Indeed, the beneficial effects of keeping the spawn dry were long ago noticed by Miller, in his Dictionary, who found, that spawn which had lain for four months near the furnace of a stove, yielded a crop in less time and in greater profusion than any other.

In some old authors, a very sage advice is given for promoting the fecundity of mushroom beds constructed on the ordinary plan, viz. to take a few full grown mushrooms from pastures, and, breaking them down in the watering-pot, to water the beds with the infusion. This is plainly nothing else than sowing mushroom seed, the minute seeds lodged in the gills being thus suspended in the water, and introduced along with it into the bed.

454. Although the Agaricus campestris is the only species cultivated, it is not the most delicate of the tribe as to flavour, nor perhaps the best deserving of culture. Some of the others should be tried, and there seems no reason to doubt of ultimate success. A. aurantiacus possesses ex-

cellent qualities; the flesh is tender, and the flavour delicate: it is in high repute on the Continent, where it is gathered in pine forests, about the end of summer. It is the *oronge* of the French, and is distinguished from another species, called the false oronge, by having a complete volva. A. solitarius is remarkable for its fine flavour. A. procerus is a great favourite in France, where it is known by the name of *grisette*. A. deliciosus is much used in Germany and Italy; but though it is not uncommon in our fir plantations, it is scarcely ever eaten in this country. The Champignon (*A. pratensis*) is used in soups, and is therefore occasionally brought to market; but, as remarked by Mr Sowerby, in "English Fungi," it is apt to be confounded, by the common mushroom gatherers, with A. virosus, one of the most to be avoided. A. violaceus is sometimes sold in Covent Garden, under the name of Bluets: it is a harmless kind, but has no other merit. The species which most commonly forms the circles and semicircles on downs near the sea-shore, called *fairy-rings*, is A. oreades. This Mr Lightfoot, in his *Flora Scotica*, considers as the *mousseron* of the French; but their mousseron is A. virgineus of Persoon, a fleshy species, nearly of a pure white colour, while our plant is coriaceous and buff-coloured.

### *Truffles and Morels.*

These have already been described under the article Fungi, and are figured in Plate LXXV. of this work.

455. The *Truffle*, or subterraneous puff-ball, (*Tuber cibarium*,) is one of the best of the esculent fungi. It grows naturally in different parts of Britain, but is most common in the downs of Wiltshire, Hampshire, and Kent, where dogs are trained to scent it out; the plant growing and coming to perfection some inches below the surface. The dogs point out the spot by scraping and barking, and the truffles (for several generally grow together) are dug up with a spade. They are principally sent to Covent Garden market. No attempt, it is believed, has hitherto been made to cultivate truffles; but of the practicability of the thing, there seems no reason to doubt. In their habits of growth, indeed, they differ essentially from the mushroom; but it is certainly possible to accommodate the soil and other circumstances to the peculiar nature of the fungus. It has been said, that the tubercles on the surface of truffles are analogous to the eyes or buds of potatoes, and that they have been propagated, like potatoes, by means of cuts furnished with tubercles: it may however be suspected, that the pieces thus planted contained ripe seeds. Truffles, we may add, seem to delight in a mixture of clay and sand; and a moderate degree of bottom heat, such as is afforded by a spent hot-bed, might probably forward their vegetation.

456. The *Morel* (*Phallus esculentus*, L.; *Helvella esculenta* of Sowerby, and *Morchella esculenta* of Persoon) rises, in the spring months, generally in woods, but sometimes on commons. It frequently appears for sale in Covent Garden market in May and June; but it has never been cultivated. The cultivation of morels, however, would probably be more easily accomplished than that of truffles. Morels are used either fresh or dried, commonly as an ingredient to heighten the flavour of gravies or ragouts. If intended for keeping, they should not be collected when wet with dew, nor soon after rain; if gathered in a dry state, they may be kept for many months.

Having treated at great length of the Kitchen Garden, and of culinary plants suited to our climate, we now turn to the Flower Garden; and here we shall study brevity as much as possible.

## FLOWER GARDEN.

457. The flower garden, it has been already observed, § 55. has a separate situation, generally at some distance from the fruit and kitchen garden. It should indeed form an ornamental appendage to the mansion, and be easily accessible in all kinds of weather. There is no objection to the flower garden being seen from the windows of the house: on the contrary, this is sometimes considered as desirable. In some places, the flower garden consists of parterres of various shapes, generally curved, separated from each other by little grass lawns. Such insulated parterres look very well from the windows of the house; the turf, in our moist climate, being always of a lively green, and forming a fine contrast with the dressed ground, and with the gay hues of the flowers. But for many days in the year these grass-girt parterres are inaccessible to the proprietors, more especially to ladies, it being impossible to pass along the turf without getting wet, at times when well made gravel walks are comfortably dry. Wherever, therefore, this kind of flower garden amidst turf is formed, there should be another, which may be considered as the winter garden, and which may contain one or more of the glazed houses for preserving plants.

In many cases the flower garden is defended by low walls or by close pales, covered by shrubs. If there be little room, they may be concealed by a single row of some evergreen, such as phillyrea, alaternus, pyracantha, laurustinus, or tree-box. The wall on the north side of the garden, however, is in some places used for a double purpose; the more tender kind of shrubs being trained against it on the south aspect. In situations where a wall would be unsuitable, an "invisible fence" of wire is employed, this proving sufficient to exclude hares and rabbits, while it nowise offends the eye, and scarcely interrupts the view. Evergreen hedges, of laurel, yew, or holly, make excellent fences, especially if united with a sunk fence.

458. The shape and size of the flower garden can be regulated only by the taste and the means of the owner. If the eye embrace the whole at once, the garden should evidently be of some regular figure. But if the size be considerable, it is advantageous that the ground should be unequal in surface, and irregular in shape. In general, a green-house, conservatory, and stove, should form prominent objects in different parts of it: it should abound with evergreen trees and shrubs, so as to maintain its verdure even at midwinter; the principal borders should be destined for mingled perennial flowers, of the most ornamental kinds; a few may be devoted to showy annuals; and particular beds should be appropriated for the different kinds of flowering bulbs, as well as for pinks, polyanthuses, and auriculas. These borders and beds, it may be remarked, should be so placed, that from the windows of the house, or from the principal entrance of the garden, they may be seen across or laterally, so that the colours of the flowers may appear in mass, without being broken by the alleys.

A rock-work is generally formed; and if the situation admit of it, or if curiosity in plants be indulged in, a small piece of water for aquatics is proper. A circular or oval plat is commonly devoted to a collection of roses; and a damp border with peat soil is set apart as an "American ground." One of the walks is often arched over with strong wire, or with slight spars, on which climbing shrubs may be trained, so as to form a berceau. Covered seats of various kinds are constructed, under the names of heath and moss houses, arbours, and grottoes. If, however, the garden be regular in surface, bowers of light lattice-work, covered with climbing plants, are to be preferred. In very few places do fountains or statues now enter into the composition of the flower garden; and urns, busts, or inscriptions, are not to be introduced without caution.

Taking it for granted that the flower garden should have a ready communication with the principal gravel-walks near the house, and also with those leading to the shrubberies, and likewise that it is extremely desirable to have the walks at all times dry, we shall first make some remarks on the formation of such walks in general, and shall then consider some of the principal constituent parts of the garden more in detail.

*Garden Walks.*

459. Formerly grass walks were common in gardens; but the inconveniences attending them, especially dampness, and liability to wear bare in the middle, have caused them to be in a great measure relinquished; and they are now to be seen only in a few old gardens. Walks, at the present day, are principally made with gravel. If gravel walks be properly formed at first, much future labour is saved. If judged necessary, a drain should be made to pass below them; but at all events a quantity of lime-rubbish or very coarse gravel should form the foundation. In the flower-garden it is not necessary to have a fine permeable bottom of earth, such as is proper under gravel-walks next to fruit-tree borders. Lime-rubbish prevents the lodging of earth worms, which are so apt to disfigure walks, and also tends to drain the walks and keep them dry. Over the rubbish is laid screened gravel. In some places *gingle* from the sea-shore is used; but this does not bind without the addition of a little clayey matter. Good gravel may often be got from some inland pit, where there is naturally a slight mixture of clay. The gravel pits of Kensington and of Blackheath have long been celebrated. If gravel be liberally laid on at first, the face of the walk may afterwards be more easily refreshed, by turning over the surface gravel, and then using the roller.

If the walk be five or six feet broad, it should rise about an inch and a half in the centre. It is often made to rise considerably more; but the appearance is thereby impaired, and the walker is annoyed. If the walk be of large dimensions, the height in the centre may increase in proportion: so that in ten feet of breadth, a rise of two or three inches is quite allowable. The walks of the flower garden should scarcely be less than five or six feet wide; nor can there in general be any good reason for their exceeding eight feet. They should be two or three inches lower in level than the flower-borders, otherwise these last would look flat and mean.

The rollers used for levelling and smoothing the walks, are formed sometimes of wood, sometimes of stone; but the largest and best are of cast iron. Rolling immediately after rain is practised, the gravel binding readily at that time.

460. In many places only the principal walks are covered with gravel; all the subordinate ones, and the paths through woods or large shrubberies, being merely laid with sand. Gravel walks are much injured by the drip of trees in rainy weather, and are not easily repaired; while sand walks require only to have their surface stirred with a Dutch hoe, and to be raked smooth again. It is, however, of importance to have a foundation of very coarse gravel, broken field stones, or lime rubbish, below the sand. Sand from an inland pit, having commonly a tendency to bind, is preferable to pure sea or river sand. In places near the sea, and where banks of shells occur on the beach, sea-shells, when broken, will be found to form a very neat walk, also susceptible of binding to a certain degree. The utility of the binding quality is manifold; it gives the walk a neat appearance; it renders it more pleasant for walking on; and it permits of sweeping, without deranging the surface.

461. If the flower garden is to consist of parterres separated by grass-turf, the first formation of these little lawns requires particular attention. When the ground is delved over and levelled, a stratum of sand or very poor sandy earth, perhaps three inches thick, is laid on, and over this an equal depth of good earth, on which to sow the grass seeds. The use of the poor soil below is to prevent the grass from getting rank. This is particularly necessary, where a mixture of rye-grass and brome grasses (particularly *Bromus squarrosus* and *multiflorus*) is sown; and all the grass seed, it may be observed, sold in this country, consists of such a mixture. Were only fescue grasses sown (*Festuca duriuscula* and *ovina*,) with perhaps crested dog's tail (*Cynosurus cristatus*), there would be much less danger of over-luxuriant patches appearing, while their fine wiry leaves and slightly glaucous hue, would render the turf highly beautiful. The selection of grasses for lawns is too little attended to. The same kind of seed is sown indiscriminately in exposed and in shady situations. If white clover and rye-grass be sown under trees, it is little wonder that the ground should remain bare: if the seeds of *Poa nemoralis* were scattered in such situations, the bare spaces would soon be covered with a lively green sward. A judicious little essay on the employment of the gramina, and particularly of the species last mentioned, presented to the Highland Society by the late Mr George Don of Forfar, may be seen in the third volume of the Transactions of that Society, p. 194, *et seq.*

*Soil.*

462. The *soil* of the flower-garden should of course be various. For the general borders a loamy soil is preferable. The surface earth from old pastures, taken along with the turf, is accounted excellent. There may be mixed with it a quantity of old hot-bed dung, or other rotten manure; a third or a fourth, according as the earth is naturally rich or poor. If the compost seem apt to bind, a small proportion of sea-sand is the remedy. If a poor soil be wished for, which at the same time is open, then half-rotten tan from the bark stove is substituted for dung.

It may here be remarked, that various composts should always be in readiness, and others in a state of preparation; and for this purpose a convenient spot, as much hid from view as possible, but near to the garden, should be set apart as a compost yard.

Peat-soil is very useful in the flower-garden. It is of two sorts, boggy peat, and sandy or surface peat; the former adapted only to the larger and more hardy kinds of American plants; the latter, to other American plants, to alpine plants, to Cape heaths, and to many green-house plants. The best sort of peat-turf is frequently to be found constituting a mere skin over a bed of sand. The turf or sod should be taken with what peat-soil adheres to it, and should be allowed to moulder in the compost yard. Spots where wild heath grows luxuriantly, or where it closely covers the surface, are likely to afford excellent light or sandy peat. It may be added, that at the points where mountain rivulets enter the flat country, accumulations of peat earth and sand may often be found, the peat being freed, by the washing of the rivulet, from the chief part of the salts and other principles likely to prove hurtful to vegetation. A mixture of nearly equal parts of peat soil and loam is suitable for very many kinds of plants. For the succulent tribe Miller recommends a compost prepared of one-half earth from the surface of a common, where the soil is light; and the other half drift sea sand and old lime rubbish screened, in equal parts. Decayed leaves of trees have long been considered as forming the most suitable ingredient in composts, where it is wished to imitate a vegetable soil. Large pits are dug in convenient parts of the woods, and into these the heaps of leaves and small spray are raked during winter, as light sprinkling of the surface soil being thrown over all, to prevent the leaves from being blown about. After the lapse of a year, a very light vegetable soil is thus procured; while the half rotten spray forms an appropriate soil for some kinds of epidendrum, cultivated in the stove.

In the first forming of composts, considerable attention should be paid to the thorough mixing together of the ingredients. The heaps should not be round and of great bulk, but should rather be formed into long and narrow ridges, the sides of which may more effectually be exposed to the influences of the atmosphere. The compost should remain for at least a year before being used, and should be several times turned over and mixed in the course both of summer and winter.

The best kind of rich manure for the flower-garden is found in old hot-beds which have been formed of stable dung and litter; but even this should not be delved into the borders without being mixed with a portion of good loam; for there are few *flowers* to which very rich manures do not prove detrimental.

A quantity of pit sand should always be in readiness for mixing with other soils, or for *striking* cuttings of different plants. The purest and finest pit sand is preferred. However pure to appearance, it still contains a portion of very fine vegetable matter; sea-sand being destitute of this, is not nearly so proper.

To enlarge further on soils for the flower-garden seems unnecessary. In Cushing's *Exotic Gardener* may be seen a table of genera, shewing the peculiar soil most suitable, in a general way, to each genus; and the same little book contains some very useful remarks on the preparation and use of composts.

It may here be observed, that for all border plants, as well as for tulips, ranunculuses, and other flowers kept in beds, the earth or the compost should not be screened fine. It is enough, if stones which the spade sensibly strikes against be cast out, and if clods be broken small at the time of delving. Screened earth is apt to bind after heavy and continued rains, and thus to impede the progress of the roots which it was meant to facilitate. For plants kept in pots, and particularly for seedlings and cuttings, the matter is quite otherwise; the soil for most of these should be made fine by passing it through a sieve.

## *Edgings.*

463 In the formal style of gardening which prevailed in the 17th and the early part of the 18th century, *edgings* of various kinds were much more needed and more attended to than they now are. The compartments of parterres were generally divided by box, and on the margins of the walks were frequently small hedges of lavender, or rue. Thyme, savory and hyssop, were also in those days employed as ornamental edgings.

464. For the general gravel-walks in gardens, the best edging is without doubt the *dwarfish Dutch box* (*Buxus sempervirens* var.) A compact low hedge of this effectually keeps the walks clean, by preventing the earth of the border from falling down into them, or being washed into them by heavy rains. If the box be kept low and regularly clipped, it endures in good repair and beauty for several years. It is commonly clipped twice in the year, in April and July. It should be kept about three inches broad at the base, and tapering upwards to a sharp ridge. A linear and continuous edging of this kind pleases every eye. Box is planted either in the beginning of autumn, or in the spring about the month of April. If slips having few or no roots be used, watering is proper till the plants be fairly established.

Next to box, the plant which forms the best retaining edging is perhaps *thrift* or *sea-pink* (*Statice armeria.*) In June and July, when in flower, it makes a showy edging; and it answers the purpose during the rest of the year with its dense tufts of leaves. It should be replanted every year, or at farthest every second year.

The double-flowered *daisy* (*Bellis perennis*, var. fl. pl.) has very long been used in this way. When kept in repair, it forms an edging very pleasing to the eye. The plants should be separated and transplanted every season, in the beginning of September, and only one strong stem or bud left to each bunch of roots.

Double *catchfly* (*Lychnis viscaria*, fl. pl.) is sometimes employed; but it seldom makes a neat edging: the flowers are ornamental, but the stems are too tall. *Dwarf gentian* (*Gentiana acaulis*) of all other plants forms the most brilliant edging, while in flower in the spring; but it is necessary that a continuous azure line be kept up, and for this purpose the verge must be of some breadth: It is applicable therefore only to large or broad borders, and it succeeds best in a strong or clayey soil. *London-pride* (*Saxifraga umbrosa*) forms a loose and straggling verge, but is very pretty while the plants are in flower: It is fittest for a shrubbery walk. *Lady's cushion*, or Indian moss as it is sometimes called, (*Saxifraga hypnoides*) is occasionally planted as an edging, and makes a pretty enough appearance. Some other similar species of Saxifraga, such as *palmata* and *cæspitosa*, may be used in the same way.

For gay parterres, the large blue-flowered *pansy violet* (*Viola tricolor* var.) makes a beautiful slight edging. Although strictly speaking, an annual plant, if it be parted every season, it endures for several years. It is very commonly used for adorning the margins of elegant flower-borders in the neighbourhood of Dublin.

*Dwarf bell-flower* (*Campanula pumila*, or *C. rotundifolia* var.) makes a fine edging for little borders where nicety and beauty are studied. Sometimes a few feet of the edging are formed alternately of the blue and of the white variety. For small borders, also, a very ornamental edging may be formed of *Stone crop* (*Sedum acre*), preferring the variety which has the tops of the shoots of a yellowish colour; this, even during winter or very early in the spring, having the appearance of being in flower.

It may be remarked, that patches of several of the different edging plants which have been enumerated, perhaps a few yards alternately of each, have an agreeable effect, especially in a long or extensive border.

Most kinds of edgings may be planted early in the spring. In planting them, it is more proper to use the spade than the dibble. The ground being slightly beat, a drill is cut by the garden-line, perpendicular on the side next the border; the plants are then placed against the perpendicular side, their roots spread out, and the earth closed upon them.

For edgings to square or oblong beds intended for tulips, ranunculuses, or similar plants, thin boards painted of a lead colour, are perhaps better than any other. Edgings to endure only for one season are sometimes formed of annual plants, sown in the spring; such as the dwarfish stock (*Malcomia maritima*, H. K.), or candy-tuft, purple or white, (*Iberis umbellata*.)

465. A simple and elegant edging may be formed of sheep's-fescue (*Festuca ovina*,) the very fine foliage of the plant being highly ornamental. In the extensive nurseries at Gateside, Newcastle, this sort of verge has been adopted, F. duriuscula being mixed, however, in some places, with the true sheep's-fescue. If very carefully sown or planted in a narrow straight line, it has a slender linear appearance, and does not occupy more space than a small box edging. For a temporary edging, another kind of grass, the large cow-quakes, (*Briza maxima*,) is sometimes very happily employed, the loose racemes, with their nodding spikes, having a pleasing and uncommon effect. If sown in autumn, soon after the seeds ripen, the plants become larger and stronger than those sown in the spring. Common grass verges can scarcely be less than a foot in breadth, and are not therefore adapted for small borders: if formed of fine turf laid upon sand to keep the plants dwarfish, such simple verges are very proper for the margins of shrubbery borders.

*Evergreens.*

466. Near the house, and about the flower garden, evergreen shrubs should abound. There should be at least one evergreen for two deciduous shrubs. The transplanting of evergreens requires some attention. It is often desirable to have them at once of considerable size; and fine large specimens may sometimes be found in public nurseries, or in market gardens. A year before these are to be removed, the roots should be cut, by passing a sharp spade all around and below them; thus encouraging the setting out of new and tufted roots, and greatly facilitating the subsequent removal of the plant. The roots of any kind of evergreen should be as little as possible exposed to the air. Nicol, in his Calendar, makes some judicious observations on the best time for transplanting of evergreens: He prefers the middle or end of April, or rather the precise time when the plant begins to grow for the season, when the buds swell, and the new leaves are about to be unfolded: the roots are then also in an active state, and if the transplanting be speedily accomplished, no check is sustained. Next to this late period of the spring, the beginning of August is a good time; for a second growth then takes place, as careful observers must have remarked, occasioned perhaps by the showery weather which generally occurs at that season.—Only a very few of the principal hardy evergreens can here be noticed.

467. Of the Alaternus (*Rhamnus alaternus*) there are several varieties, particularly the jagged and the plain leaved, and the gold and the silver variegated. Resembling this is the *Phillyrea*; but the genera may at once be distinguished, without seeing the flowers, by observing, that in the former the leaves are alternate, while in the latter they are opposite. Of phillyrea there are three species, privet-leaved (*P. media*), narrow-leaved (*P. angustifolia*), broad-leaved (*P. latifolia*), and several varieties of each of these: these were, in former days, among the most favourite tonsile evergreens.

The Chinese Arbor vitæ (*Thuja orientalis*) and the American (*T. occidentalis*) are large, and rather suited for extensive shrubberies. The same may be said of the common laurel (*Prunus laurocerasus*), and the Portugal laurel (*P. lusitanica*.)

468. The Sweet Bay (*Laurus nobilis*), which is a considerable tree in the south of Europe, appears but as a shrub in this country, producing its flowers only in sheltered situations and good seasons. The common laurel above mentioned, we may remark, is often mistaken for the bay, and regarded as the plant which furnished crowns for the Roman heroes. The error is perhaps fortunate, our bays thus escaping mutilation on occasions of public rejoicing. There is no doubt, however, that it was the sweet bay which furnished the wreath worn on the brow of the victor, and of the priestess of Delphi. The mistake has arisen from the bay having formerly been called laurel, and the fruit of it only named *bayes*. The Alexandrian Laurel (*Ruscus racemosus*) has also been mistaken for the heroic plant; but although destitute of this honour, it is a most elegant shrub, worthy of a prominent station.

The different varieties of Laurustinus (*Viburnum tinus*) are very ornamental, as they not only enliven the winter scene with their green leaves, but delight us with their flowers at that dead season. These last, however, are produced only in sheltered situations.

469. The Strawberry-tree (*Arbutus unedo*) is an elegant plant at all times; but when at once covered with fruit and flowers, the appearance is not only beautiful, but curious. In Ireland, about the Lakes of Killarney, this species, which ranks as a shrub in Scotland and the north of England, attains the size of a lofty tree. In the Transactions of the Dublin Society for 1806, a gigantic specimen is described by Mr J. T. Mackay as growing in Rough Island, an islet in the lower lake, entirely composed of limestone. In 1805, this tree measured nine feet in circumference at two feet from the ground; at the height of five feet it branches off into four limbs, each of which then measured two feet and a half in circumference; from the base of the trunk to the extremity of the branches, the length was 36 feet; and the tree has a fine spreading head. The *andrachne* (*A. andrachne*) is a beautiful shrub or small tree, but liable to be injured by severe frosts, and suited only to the milder counties of England and Ireland.

The superb Yucca, or Adam's needle, (*Yucca gloriosa*) may here be mentioned, as it retains its leaves at all times. When in flower it makes a magnificent appearance. Young plants are at first rather tender; but when fairly established, they prove sufficiently hardy for the open border. A fine specimen has stood for about a century in the pleasure-grounds of Kilochan, belonging to Sir Andrew Cathcart in Ayrshire; and it flowers every second or third year.

The Aucuba, or gold plant, (*Aucuba Japonica*) was formerly kept in the green-house; but it now ornaments the flower-garden with its fine spotted yellow leaves; and in a sheltered situation it sustains no injury from our ordinary winters.

470. Rhododendrons of different species are highly ornamental, particularly R maximum, Ponticum, hirsutum, and ferrugineum. These grow well in any loamy soil, although they no doubt flourish more among sandy peat. If a rivulet pass the flower garden, the banks of it should be planted with them. *Kalmias* may also be introduced, particularly K. latifolia, angustifolia, and glauca; together with *Ledum* palustre and L. latifolium, or the Labrador tea plant; likewise different species of *Vaccinium*, and of *Andromeda*, particularly pulverulenta and cassinefolia; and *Gaultheria* procumbens.

471 Among low evergreens for the front of the borders, different species of Cistus or rock-rose are excellent; and several hardy exotic Heaths, which shew their flowers early in the spring, particularly Erica mediterranea and carnea. E. arborea, the flowers of which are fragrant, sometimes attains the size of a considerable shrub, and is very ornamental, but it succeeds only in the milder parts of England. Even our four native species deserve a place

The most common is E. vulgaris, of which there is a white-flowered variety, and one with double flowers. E. cinerea, fine-leaved heath or *bell-heather*, is the next in point of abundance; it is more showy than the former, and there is a variety with white flowers. E. tetralix, or cross-leaved heath, is the third species; it is an elegant plant, distinguished by the leaves growing in fours, and by the flowers coming in clusters on the tops of the stalks. E. vagans is a native of the south of England, found indeed scarcely any where but in Cornwall. These native heaths grow perfectly well in any poor soil; but the ground should not be delved close by them, as their roots are generally extended very near the surface. *Pittosporum tobira* is a beautiful glossy-leaved Chinese evergreen, which succeeds in a well sheltered border, but unless it be situated in a dry soil, is apt to be cut off by the damp at the surface of the earth. Several species of *Daphne* are very ornamental as evergreens, and produce their flowers in the spring months, particularly D. cneorum, collina and pontica; and although the mezereon (*D. mezereum*) is a deciduous shrub; yet as it displays its blossoms very early in the spring, generally in February, it deserves a place: there are three varieties, dark red, pale red, and white. The Periwinkles (*Vinca major* and *minor*), when regularly cut over every year, form neat evergreen bushes.

472. The Musk rose (*Rosa moschata*) may be considered as approaching to an evergreen; and there is an almost evergreen variety of the sweet-briar (*R. rubiginosa*). But of all others, *R. Indica* is the greatest acquisition to our gardens, being not only always in leaf, but flowering both late and early, in November and in March. The *Ayrshire Rose*, a species not well ascertained, deserves a place, especially for covering any wall, pale, or winter seat; it grows very rapidly, and always retains some of its leaves. It is said to be from America, and to have received the name of Ayrshire rose, from having been first cultivated at Fairfield, near Kilmarnock. A rampant native species (*R. arvensis*) has likewise obtained among nurserymen the name of Ayrshire rose, and is often sold instead of the other, to which it bears a considerable resemblance.

*Autumn, Winter, and Spring Gardens.*

473. It now very commonly happens, that the autumn and early part of winter are the only seasons in which families, swayed by the fashionable world, reside at their country mansions. The forming of an autumnal and a winter garden is therefore important. In the former, many late-flowering perennial plants, such as asters, solidagos, rudbeckias, hollyhocks, and many kinds of annual flowers, may render the borders gay till the frost prove too severe. The carnation shed may with propriety be situated in the autumn garden.

474. Addison, in one of his Spectators (No. 477.) sets forth the pleasures and beauties of a winter garden. "In the summer season," he observes, "the whole country blooms, and is a kind of garden, for which reason we are not so sensible of those beauties that at this time may be every where met with; but when nature is in her desolation, and presents us with nothing but bleak and barren prospects, there is something unspeakably cheerful in a spot of ground which is covered with trees that smile amidst all the rigour of winter, and give us a view of the most gay season in the midst of that which is most dead and melancholy. I have so far indulged myself in this thought, that I have set apart a whole acre of ground for the executing of it. The walls are covered with ivy instead of vines. The laurel, the hornbeam, and the holly, with many other trees and plants of the same nature, grow so thick in it, that you cannot imagine a more lively scene." A winter garden of much smaller dimensions than here suggested, would in general be found sufficient. The idea was taken up also by Lord Kames, in his "Elements of Criticism," (vol. ii. p. 448). "In a hot country," he remarks, "it is a capital object to have what may be termed a summer garden, that is, a space of ground disposed by art and by nature to exclude the sun, but to give free access to the air. In a cold country, the capital object should be a winter garden, open to the sun, sheltered from the wind, dry under foot, and having the appearance of summer by a variety of evergreens." All the evergreens which have already been mentioned would enter with propriety into the composition of such a garden. The *hornbeam*, it may be noticed, however, must have crept into the Spectator's list by inadvertency, it being a deciduous tree. Besides evergreen trees and shrubs, there are a good many humble herbaceous plants, which retain a greenness in their foliage over winter; such are, common daisies, thrift, pinks, none-so-pretty, burnet, and several others. These may also be admitted; and plants which flower in winter, or very early in the spring, may be scattered over the borders; such are Christmas rose and winter aconite (*Helleborus niger* and *hyemalis*); dog's-tooth violet, white and pink, (*Erythronium dens canis*); bulbous fumitory (*Fumaria bulbosa* and *solida*); and others. To the winter garden a Conservatory may be considered as an appropriate appendage.

475. A part of the winter garden may be appropriated as a spring garden, and planted chiefly with the early flowering shrubs, such as the common and the double dwarfish almond (*Amygdalus nana* and *pumila*), and the sweet almond (*A. communis.*) On the borders, the different species of narcissus, particularly the poetic, the daffodil, jonquil, and polyanthus-narcissus, may appear; these, even when rising through the ground, produce a lively appearance: And other early spring flowers might be added, such as the spring bitter-vetch (*Orobus vernus*); comfrey-leaved hound's tongue (*Cynoglossum omphalodes*); snowdrop, (*Galanthus nivalis*); the puccoon, (*Sanguinaria Canadensis*); and red, blue and white hepaticas (*Anemone hepatica.*) The *heathery* or heath-house might very properly form the principal object in the spring garden, many of the exotic ericæ flowering early in the year. The auricula frame might likewise be situate here.

*Border Flowers.*

476. The principal borders are of course dedicated to mingled perennial plants, sufficiently hardy to endure our ordinary winters. A very few only can here be specified: those mentioned shall be the most showy and desirable of their kinds. They are arranged in the borders partly according to size, and partly according to colour. The tallest are planted in shrubbery borders, or in the back part of broad flower-borders. Those of middling size occupy the centre; and those of humble growth are placed in front. The beauty of a flower-border when in bloom depends very much on the tasteful disposition of the plants, in regard to colour, or on mingling the reds, the purples, the blues, the yellows, and the whites, in due proportions. To increase the variety of colours, some biennial plants, and even a few annual kinds, are occasionally introduced. By intermixing plants which flower in succession, the beauty of the border may be prolonged for some weeks. In a botanic garden the same plant cannot with propriety be repeated in the same border; but in the common flower-garden, a plant, if deemed ornamental, may be often re-

peated with the best effect; nothing can be finer, for example, than to see many plants of double scarlet lychnis, double wallflower, double sweet William, or double purple jacobæa.

477. For the shrubbery border the following are a few of the fittest tall-growing herbaceous plants. Hollyhocks (*Althæa rosea*) of different varieties and colours; these shew their flowers in October, when other plants are fading, and they continue till the frosts cut them off; they are properly biennial plants, but if some of the stems be cut over, before flowering, the roots continue for several years. Herb Christopher (*Actæa spicata*) a native of the north of England, and *A. racemosa* from North America, with the goat's-beard Spiræa (*S. aruncus*), are plants which succeed in the shade, and are therefore very fit for the shrubbery, or for any shady situation. The white-flowered Fox-glove (var. of *Digitalis purpurea*) is ornamental; it is only biennial, but rises freely from seed sown by itself. Several species of Aconite or monk's-hood, with blue and with yellow flowers, may here be planted; but the most common kind (*Aconitum napellus*) it is to be remembered, is a poisonous plant. With the monk's-hoods may be united several species of perennial Larkspur, particularly Delphinium grandiflorum, and exaltatum; and the stavesacre, (*D. staphisagria*.) The common Columbine (*Aquilegia vulgaris*) when very double, and of good colours, makes a pleasing variety. All the large species of *Iris*, particularly the Germanica, sambucina and Sibirica, here deserve a place. The common and the white-flowered Willow herb (*Epilobium angustifolium*), and the double and double fistular varieties of Feverfew (*Pyrethrum parthenium*) are showy when in flower. Several tall species of Aster and of Solidigo are also proper for the shrubbery, as well as some of the perennial Sunflowers, particularly Helianthus decapetalus, and the single and the double flowered H. multiflorus. To these may be added Rudbeckia laciniata, and Thalictrum aquilegifolium or columbine-leaved meadow-rue.

Besides tall plants, some of humble growth may with propriety be placed in the shrubbery or shrubbery border. Patches of sweet Woodruff (*Asperula odorata*), for instance, have a pleasing effect; the stalks and leaves gathered when the plant is coming into flower in May, and kept in small bundles in paper under some degree of pressure, retain their fragrance for a long time. Patches of the double wood Anemone (*Anemone nemorosa*) are likewise very ornamental; and this is the appropriate place for the Lily of the Valley (*Convallaria majalis*), of which there is a double and a red flowered variety.

478. The borders for perennial flowers are seldom less than four or five feet in breadth. The plants are not placed immediately behind each other, but in the quincunx order; the distance between each plant varying, according to the size of their border, and in some measure according to the nature of the plant, whether it be apt to spread or to form a compact tuft. In regard to soil, it may be sufficient to observe, that most of the hardy herbaceous plants grow very well in a soil that is moderately light and mellow, such as a sandy loam. For certain plants, strong loam, turf mould, or vegetable earth, are proper; and this circumstance is generally noticed when treating of the particular plant.

479. Of the tall-growing perennials, one of the most ornamental is the double-flowered Scarlet Lychnis already mentioned (*Lychnis chalcedonica*, fl. pl.) The large heads of flowers have a most brilliant appearance in the back part of a flower-border. Every attention should be paid by those fond of fine flowers to the propagating of this plant. Several stems should with this view be cut down before the flower appear: these are to be divided into pieces five or six inches long, which are stripped of leaves, except at the top, and sunk up to the leaves in the earth; they are covered for a few weeks with a hand-glass, and may either be planted out in the autumn, or allowed to remain under the glass till the spring. There is a white-flowered single variety, which is also deserving of a place.

480. The hyssop-leaved Dragon's-head (*Dracocephalum Ruyschiana*,) and the great-flowered (*D. grandiflorum*,) are elegant blue flowers. The Silver-rod, or branched asphodel (*Asphodelus ramosus*,) is a good border plant, with fine white flowers. Two species of Mullein, the rusty-flowered and the purple (*Verbascum ferrugineum* and *phœniceum*,) may be admitted; together with the fine branched Lythrum (*L. virgatum*), which is covered for about three months with purple flowers. Two or three species of the extensive genus *Centaurea* deserve to be cultivated; such as C. orientalis, with yellow flowers; C. Caucasica, with white flowers, and C. montana, with blue flowers; all of them hardy perennials. The double Siberian Larkspur (*Delphinium elatum*) has flowers of a fine dark azure colour. *Phlox pyramidalis* and *P. paniculata* are handsome showy flowers, of a pale bluish purple colour; of the latter there is also a white variety. The linear-leaved Willow-herb (*Epilobium angustissimum*) is worthy of a situation in the border, the foliage being fine, and the flower large, of a beautiful purplish red colour. Black Masterwort (*Astrantia major*) being of a singular appearance, may perhaps also merit a place. *Coreopsis verticellata* is an ornamental plant, and produces flowers of a fine deep yellow colour. Different species of Speedwell are elegant; particularly *Veronica Virginiana*, with blush coloured and with white flowers; and *V. longifolia* (formerly *maritima*) with blue, white, and flesh-coloured flowers. The variegated Wolf's-bane (*Aconitum variegatum*) is a very pretty plant; and the large flowers of *Rudbeckia purpurea* make a good appearance. *Liatris spicata* deserves a place in every collection.

The *Acanthus mollis* grows best when its roots get into the crevices of an old wall, near to the foot of which it may happen to be planted. In such a situation it will flower every year; while in a rich border soil, flowers seldom appear. The leaves of this plant accidentally surrounding a basket, are supposed to have given rise to the Corinthian capital.

Of the fine genus *Spiræa*, which is partly herbaceous and partly shrubby, two species are common natives. S. ulmaria or queen of the meadow, and S. filipendula or dropwort. Double flowered varieties of both these are kept in gardens; but it is worthy of remark, that while the single queen of the meadow is exceedingly fragrant, the double-flowered variety is quite destitute of odour. S. trifoliata is very elegant; it grows best in a peat soil, such as is generally prepared for American plants.

481. In the extensive genus *Campanula* or bell-flower, of which Persoon enumerates more than a hundred species, there are several showy perennials. Such are the peach-leaved or C. persicifolia, with single blue and single white flowers, and with double flowers of both colours: a very large flowered variety of the single blue, deserves particular attention; it has been figured in the *Botanical Magazine* as a distinct species, under the title of C. maxima. The nettle-leaved bell-flower, (*C. trachelium*), when double, forms a showy border flower. The pyramidal or steeple bell-flower (*C. pyramidalis*) is highly prized as an ornament in halls, being for this purpose often kept in pots. In the open border the plant requires a sheltered warm situation; and when seeds are wanted, it is found

useful to fix in the ground four stakes with niches at top, to receive a hand-glass to cover the plant during heavy rains.

482. The ornamental plants which are of middling size are so numerous, that it is somewhat difficult to make a selection.

Several species of Achillea are ornamental, particularly the Sweet maudlin (*A. ageratum.*) A double-flowered variety of our native sneezewort (*A. ptarmica*) very well deserves a place in the border. The spring Adonis (*A. vernalis*) is a perennial species, producing large yellow flowers in the beginning of April, when flowers are scarce. A double variety of Rose-campion (*Agrostemma coronaria*) is a highly elegant plant; it is properly only a biennial, but it may be continued for several years by parting the roots in autumn. The perennial flax (*Linum perenne*) is a very pretty native plant, deserving of a situation in the border. The round-headed Rampion (*Phyteuma orbicularis*) is another native, not less worthy of a place.

A curious variety of the common Toad-flax (*Linaria vulgaris*, H. K.), with five nectaries and five stamina to each corolla, is cultivated in some gardens, and much admired, it not being without reason that Miller styles it a "beautiful monster." It was first described in the "Amœnitates Academicæ," under the title of Peloria, and it is figured under the same name in "English Botany."

483 Several species of *Dianthus*, besides the carnation and pink, are much cultivated in gardens. D. barbatus, or bearded pink, more generally known by the name of Sweet William, is very common. It is a perennial, and may be increased by slips; but it is generally raised from seeds, seedling plants producing the strongest flowers: in this way, too, a great variety in the colours of the flowers is procured. When a very good kind occurs, it should be planted apart, at a considerable distance from all others, and the seed should be saved. The principal variations of colour are, deep red, pale red or rose-coloured, bluish purple, purple and white, white spotted; red with a white border, called Painted Ladies; purple with a white border, and pure white. Double flowers of several of these varieties are carefully preserved by the curious, and propagated by offsets and by cuttings; the double crimson and rose-coloured are particularly esteemed. The narrow-leaved bearded pink is called Sweet John. A very remarkable and beautiful variety is the Mule Pink, supposed to have proceeded from the flower of a carnation acted upon by the pollen of the narrow-leaved bearded pink.

484. Two species of *Eryngium* are very ornamental, E. alpinum, and E. amethystinum. In the former, the fine azure blue, with streaks of green and white, of the large involucrum, never fail to attract admiration. It generally ripens its seed in this country, and seedling plants may be observed near the parent plant, frequently under the shelter of the box edging. The other species has the upper part of the stem, as well as the head of flowers, of the richest amethystine colour, and therefore produces a very fine effect on the border. It is only in good situations, and in favourable seasons, that the seeds of this species come to maturity. Our natives species E. maritimum, or sea-holly, is admired for the glaucous hue of its leaves and stems: it may be planted in a mixture of sand and gravel: it is not easily dug up on the sea-shore, the roots running very deep into the sand: it should be removed in autumn. The roots of this species were formerly candied. Along with these eryngiums, may be classed several species of *Statice* or Thrift, in particular S. latifolia, scoparia, tatarica, and speciosa, all natives of Russia or Siberia.

485. Fraxinella or *Dictamnus albus* is a plant which merits a place, being both beautiful and curious. When gently rubbed the plant emits an odour like that of lemon peel. The pedicels of the flowers are covered with glands of a rusty red colour: from these a viscid juice or resin exudes, which is exhaled in vapour, and is said occasionally to produce a slight explosion: this phenomenon is to be observed in a warm, dry, and clear night in June, by approaching a lighted candle to the flower of the plant. The usual colour of the fraxinella is white; but there is a red variety.

486. The Cardinal's Flower (*Lobelia cardinalis*) is a very elegant plant: But it is now in a great measure supplanted by another species of the same genus, of still greater brilliancy, *L. fulgens*. The flower of this last is among the brightest scarlets of the vegetable kingdom. The plant is readily propagated by offsets, but it will scarcely endure our winters without protection. A few plants may be left to their fate, while others may be covered with hand-glasses in the borders; but it is safest to pot a number of plants, and keep them under a frame during winter.

487. *Catananche cærulea* requires a dry soil and sheltered situation; it is often indeed kept in pots, and placed under glass in winter. Its flowers are of a very fine blue; and there is a double variety, which however is not common. The Canadian Columbine (*Aquilegia Canadensis*) is a delicate looking flower, highly ornamental. Garden Wall-flower, (*Cheiranthus cheiri*) when double and of dark colour, is much prized; there is also a pretty variety of the native species, *C. fruticulosus*, with double flowers. The Red and the Scarlet Chelone (*C. obliqua* and *barbata*) make a pretty appearance in autumn, when flowers are beginning to grow scarce. A new species of chelone, (*C. major*) has of late been introduced, being figured in the "Botanical Magazine" for November 1816. It is, like the others, an American plant, and perhaps more hardy than them: it is at the same time the most showy of the genus, producing fine peach-coloured flowers in large and close spikes. German Goldilocks (*Chrysocoma linosyris*) has bright yellow flowers in the form of an umbel; when handled, the plant gives forth an aromatic agreeable scent. *Tritoma media*, although a native of the Cape of Good Hope, endures our winters, with a very slight degree of protection, and produces its beautiful spikes of orange flowers either in November or in March. Two species of *Monarda* should be admitted; the Oswego tea or M. didyma, which has scarlet flowers, and M. fistulosa, the flowers of which are purple. The perennial Lupine (*Lupinus perennes*) is now a rare plant; but a more showy species, from Nootka Sound, (*L. Nootkatensis*) has received the name, and is generally and deservedly cultivated. Of the Poppy genus two perennial species are worthy of attention; the Oriental (*Papaver orientalis*) with large bright orange flowers, and the Welch, (*P. Cambricum*) with flowers of a deep yellow. Red Valerian (*Valeriana rubra*), when of a dark colour, is highly ornamental, and there is a white variety which forms a fine contrast. Several kinds of Peony, particularly the double dark red and double blush (varieties of *Pæonia officinalis*), and the white-flowered, (*P. albiflora*), are magnificent border plants. The smooth-leaved Bell-flower (*Campanula nitida*) is very ornamental, appearing for some weeks completely covered with its blue flowers; the Dutch, it may be observed, have a double variety of this, which has not yet found its way into our gardens. Of the numerous genus *Aster*, three species are of proper size for the middle of a border, and shew fine lively blue flowers; the Italian starwort, or A. amellus; the alpine, or A. alpinus; and the A. spectabilis.

Ragged-Robin, or *Lychnis flos cuculi*, a native of our meadows, when double-flowered, makes a beautiful appearance, and is, of course, perfectly hardy. The varieties of L. dioica, with double red and with double white flowers, are also very showy: In England, these often get the name of red and white Bachelors' Buttons, while in Scotland this name is more commonly given to the double varieties of Ranunculus aconitifolius and acris. The plantain-leaved crow-foot (*Ranunculus amplexicaulis*) may be mentioned as a desirable spring plant, displaying its pure white flowers in April and May: it succeeds best in a strong loam.

Of the Garden Rocket or dame's violet (*Hesperis matronalis*,) there are are double white and double purple varieties; the former is the kind generally seen in gardens, the latter being rare. They are both excellent border flowers, being at once showy and fragrant. If the stock-plants be allowed to remain long without transplanting, they are apt to die off; a supply should therefore be prepared by slips or cuttings every year.

The Virginian Spiderwort (*Tradescantia Virginica*) with fine blue flowers, and the varieties with red and with white flowers, should not be omitted; they grow best in a mixture of loam and peat-earth. The bell-flowered Pentstemon (*P. campanulata*) is a fine peach-coloured flower; the *Uvularias* are uncommon looking yellow flowers, particularly U. grandiflora and sessilifolia; and some species of Solomon's-seal, particularly Convallaria polygonatum and multiflora, afford greenish-white blossoms.

If the Asiatic Globe-flower (*Trollius Asiaticus*) be not planted in a bed by itself, it may be introduced into the border, where its rich orange flowers are very brilliant; it requires a strong loam. The common globe-flower of our upland meadows (*T. Europæus*) may also have a place, the flowers being handsome and of a fine yellow, and being the *lucken gowans* mentioned by Burns in his poems.

In any moist and rather shady situation, the American cowslip (*Dodecatheon Meadia*) will grow and freely display its very elegant flowers in the month of May. If some peat-earth be mixed with the soil, the plant becomes more strong. Barrenwort (*Epimedium alpinum*) is a plant of considerable beauty, which thrives in similar situations.

488. Among *low-growing flowers* for the front of the border, the double purple Jacobea (*Senecio elegans*) holds a distinguished place. It is, strictly speaking, only an annual; but the double variety is continued by cuttings. If a few small plants be preserved in the green-house during winter, they will afford cuttings in the spring, which, as soon as they are well established, are to be planted out in the borders. There is also a variety with double white flowers, which is not uncommon in gardens in the vicinity of London.

Several Phloxes are very ornamental, particularly the common Lychnidea (*P. suaveolens*) with variegated leaves; the early flowering, P. divaricata; P. subulata or awl-leaved, and P. setacea or fine-leaved; with P. ovata, and P. stolonifera or creeping. Phlox subulata should be allowed to form a large patch on the ground in front of the border, being in this way extremely brilliant when in flower; in this way, too, the plant suffers less during winter. This species and the P. setacea are best propagated by cuttings; the others, by parting the roots in autumn.

The great flowered Siberian Fumitory (*Fumaria nobilis*) is very handsome, and continues long in flower. *F. formosa*, remarkable for its delicate blush coloured blossoms, may also be noticed; and the yellow species (*F. lutea*) is valuable, as affording a patch of this colour in the border from April to November.

Our common Bloody Crane's-bill (*Geranium sanguineum*) is not unworthy of a place; and the same may be said of the striped variety, commonly called Geranium Lancastriense. The streaked crane's-bill (*G. striatum*) is a delicate looking flower, which generally pleases.

The yellow species of Monkey-flower (*Mimulus luteus*) introduced about 1812, is an acquisition, as it is rather pretty, and continues several months in flower: Though a native of Chili, it proves quite hardy. Different species of *Oenothera* are of humble growth, and produce fine yellow flowers, particularly Œ. Fraseriana, fruticosa, and pumila. Patches of the purple Alyssum (*Farsetia deltoidea*) are very beautiful in the spring and early part of summer, when covered with flowers. A common native plant, Marsh-marigold (*Caltha palustris*) is likewise very showy in the early part of the year; a large patch of it makes a brilliant appearance for several weeks; being naturally a marsh plant, it grows best in a moist border. Feather-grass (*Stipa pennata*,) when its long and delicate awns are displayed in August and September, is justly admired for its light and airy appearance.

Violets of different kinds are well known ornaments; the Canadian (*Viola Canadensis*) is particularly elegant; and the Sweet, or March violet, (*V. odorata*) is not only desirable for its fragrance, but the large flowered double variety is beautiful.

Different species of Anemone, chiefly with blue flowers, may adorn the front of the border; such as the splendid Pasque-flower (*A. pulsatilla*;) different varieties of the star anemone, (*A. hortensis*;) the blue mountain and the meadow anemone (*A. apennina* and *pratensis*.) Some of the Gentians are also fine border plants, especially Gentiana asclepiadea and cruciata, both with blue flowers.

489. Among the flowers which have now been enumerated, a good many are natives of North America, such as all the species of the elegant genera Phlox and Chelone. A separate *American Garden* is, however, a desirable thing. Into this the trees, shrubs, and herbaceous plants of the New World are only to be admitted; so that, on entering the garden door, a person possessed of a botanical eye will find himself transported, as it were, across the Atlantic. One of the most complete American gardens in this country is at Milburn Tower, near Edinburgh, the seat of Sir Robert Liston, Bart. formerly British ambassador to the United States.

490. Flowers which are cultivated in beds by themselves are now to be considered. These are in a peculiar manner distinguished by the title of *Florists' flowers*. The principal are, the tulip, ranunculus, anemone, iris, dahlia, pink, carnation, polyanthus, auricula, hyacinth, polyanthus-narciss, and crocus.

### *Tulip.*

491. The tulip (*Tulipa Gesneriana*, L.) is a native of many parts of Turkey and of Persia, where the flower is principally of a red colour, each petal having a black mark at its base. It was not brought into the north of Europe until after the middle of the 16th century; and it was first cultivated in this country by a Mr Garret, an apothecary of London, about the year 1577. A hundred years after its introduction, the *tulipomania*, or rage for fine tulips, attained its height: it prevailed chiefly at Haarlem, and other parts of the Netherlands. High sounding and bombastic names were bestowed on the favourite varieties, a practice which is still continued by florists. The Viceroy and Semper Augustus were two sorts, the bulbs of which sold at the most extravagant prices, or rather gave occasion to the most foolish gambling speculations. Twelve acres of land were covenanted to be given by one person, and 4600 florins, besides a new carriage, with horses and harness, by

another, for a single tulip bulb, the flowers of which should possess certain almost ideal perfections. In the present day, tulip collectors possess a few sorts on which they place a high value; but in general the very finest varieties may be procured at 5 guineas a bulb; and a great many of what are reckoned prime kinds at perhaps 5s. a piece.

Tulips were formerly divided into *præcoces*, or early flowering; *mediæ*, or middle-timed: and *serotinæ*, or late flowering. One of the præcoces, it may be noticed, is a distinct species, T. suaveolens; this is the early dwarfish sweet-scented tulip, or Duke Van Thol of the catalogues: when planted in a small bed by themselves, these Van Thol tulips, when in flower in April, form one of the most resplendent scenes presented by the flower garden. Parkinson, so long ago as 1629, enumerates 140 varieties of tulips, and hints that there were many more. Maddock, in his catalogue, gives the names of 665 choice late tulips, independent altogether of early sorts, double flowered, and what are called parrot tulips.

492. Late tulips are the only kind now attended to by florists, the double and parrot sorts being in little esteem with them. They are divided into six families, distinguished by barbarous titles, a mixture of French and Dutch. 1. *Primo baguettes*, very tall, (the term *baguette* inferring that they resemble a small walking-stick, or switch,) cups with a white ground broken with fine brown; and all from the same breeder. 2. *Baguettes rigauts* (or *rougeaudes*,) with strong stems, though not so tall, very large cups, with a white ground, likewise broken with fine brown, and all from the same breeder. 3. *Verports*, (or, as they are more commonly called in this country, Incomparable Verports, or simply Incomparables,) with very perfect cups, having a beautiful white ground, or bottom, well broken with shining brown approaching to rose colour, and all from the same breeder. 4. *Roses*, allied to the verports, the petals streaked with cherry and rose colours, on a white ground. 5. *Bybloemens*, sometimes contracted into *bybloems*, with the ground white or nearly so, from different breeders, and broken with variety of colours. 6. *Bizarres*, (probably a corruption from *bigarée*,) with a yellow ground, from different breeders, and broken with variety of colours.

The terms *breeders*, *whole blowers*, and *seedlings*, are all applied to such flowers, raised from seed, as are plain or of one colour, have a good bottom or ground colour, (visible at the base of the petal,) and are well shaped. They may thus be either bybloemens or bizarres. The petals of these, in the course of time, break into various elegant stripes, according to the nature of their former self-colour. In correct language, the term *breeders* would mean plants, from the seed of which young tulips are to be raised.

493. The florist's criterion of a fine flower is frequently at variance with that of the world at large. Many tulips which would excite the admiration of thousands, are rejected by the connoisseur. The properties of a fine tulip, as set forth in the Florist's Directory, are the following. The stem should be strong and tall, two feet or more. The flower should be large, with six petals; the petals at the base proceeding for a little way almost horizontally, and then sweeping upwards so as to form an elegant cup, with a rounded bottom, and somewhat wider at top than below. The three outer petals should be rather larger, or broader at the base, than the three inner ones; all the petals should have the edges perfectly entire; the top of each should be broad, and well rounded; the ground colour at the bottom of the cup should be clear white or yellow, free from stain or tinge; and the various rich stripes, which are the principal ornament of a fine flower, should be regular, bold, and distinct on the margin, terminating in fine broken points, elegantly feathered or pencilled; while the centre of each petal should contain one or more bold blotches or stripes of colour mixed with small portions of the original or breeder colour, broken into irregular obtuse points; this last character, however, of central stripes or blotches, not being indispensable, and any trace of the breeder colour displeasing many florists.

494. The raising of tulips from the seed is a tedious process; but in this way alone are new varieties and vigorous bulbs to be expected. Seed is collected only from flowers of one uniform colour, or which are self-coloured, and at the same time of good shape; for, contrary to what might naturally be expected, experience, it seems, has shewn that the seed of the most beautiful striped tulips does not yield so fine a produce as is got from the plain coloured. The tulips intended for seedling are planted deeper than usual, perhaps eight or nine inches deep, in order that the stem may be kept longer in a vigorous state; and they are placed in a border where they may enjoy the full benefit of the sun. Towards the end of July the pods begin to open; they are then cut off, and kept, with the seeds in them, in a dry place, till the beginning of September, when the seed is sown. This is generally done in shallow boxes containing fresh light earth; a covering of about half an inch thick, of the same light or sandy earth, is sifted over them. These boxes are placed in a sheltered situation for the winter. By the middle of March the seedling tulips shew their grass-like first leaves; these continue green for about two months, and then gradually decay, so that they entirely disappear in June. After another year, the small bulbs are raised, and transplanted into a nursery bed, two inches deep and at two inches apart. If the bed be in an exposed situation, haulm or mats are placed over it during the severity of the winter. In this bed the bulbs remain for the third and fourth years. They are then raised, kept some short time out of the earth, and transplanted to another bed, in which they are placed four inches separate. Here they remain other two years; and in this interval many of them begin to shew flowers. Such as have tall stems and rounded petals are now transferred to a separate bed, and treated like full grown bulbs; and after they have flowered for two or three years, their real value may be pretty nearly ascertained: If they be very promising, that is, tall, well shaped, with clear bottoms, and self-coloured. they are retained for a longer time, in expectation of improvement. A few come finely striped at once, and are of course retained; but these are apt quickly to degenerate. Those that appear with short stems and sharp-pointed petals are rejected without hesitation.

The tendency to break is promoted in the breeders, by shifting the bulbs every season into different kinds of soil, and placing them in different situations. The soils preferred are such as are fresh, but poor, dry, and sandy. The compost recommended by Miller consists of a third part fresh earth from old pasture land, having the sward rotted with it; a third part sea-sand; and a third part old lime rubbish sifted, all well mixed and frequently turned. The beds are made two feet deep, and the bulbs are planted in drills about four inches deep, and six or seven inches from each other in every direction. When a breeder breaks completely, losing all traces of its self-colour, and continuing till the petals decay without shewing any tendency to return to its former colour, it is marked, named, and enrolled among the choice tulips, and its offsets are carefully preserved. A tulip, when it breaks, never attains the height or size of the breeder; if a breeder be three feet high, its variegated progeny does not exceed two, and the flower is proportionally less. Whether the breaking is the cause or the consequence of debility, does not appear; but it seems to be a general fact, that variegated flowers or plants are more tender than such as are plain.

The directions for the planting and management of breeders are applicable to striped tulips in general. A practice not uncommon with gardeners must here be condemned; it is the planting of tulip bulbs with a dibble. This ought never to be done. The pressure of the dibble renders the earth compact where it ought to be loose, and in many cases a partial hollow must remain below the bulb, which is particularly injurious when wet weather follows, and moisture lodges about the root. It is better when drills are formed six or seven inches deep, and the bulbs covered in with the loose earth. A still more proper way is, to prepare the bed some inches lower than it is intended ultimately to be; to put the bulbs in their places on the surface; and then to add the necessary quantity of soil. The bed is improved by being made to slope a little from the centre to each side; the stronger bulbs should be situated in the middle, as they thus receive the thickest covering of soil which they ought to have. In all the modes of planting, it is a good rule to put a little dry and fine sand around each bulb.

495. The bed of choice tulips is, by the true florist, at first protected by hoops and mats, from hail showers and storms, and afterwards, when the season of flowering arrives, covered by an awning of thin canvass. In this way only can the delicate colours be fairly brought out; even half an hour's full exposure to the sun's rays has been known to alter them; besides, the enjoyment of the fine sight is prolonged for near a month. Though the scent of the tulip is so slight as scarcely to be perceptible in single specimens, the united odour of so many, confined in some measure by the cover, becomes quite evident. Watering is scarcely ever necessary for tulips. The seed-pods of all fine tulips are cut off as soon as they appear; for these, as already said, are by no means the best from which to procure seed, and the bulbs exhaust themselves in forming them. The bulbs are lifted in the course of the month of June, the proper time being ascertained by observing when the foliage has decayed, and two or three inches at the top of the stem begin to acquire a purple tinge. If they be left longer in the earth, the flowers are apt to become foul the next season. The bulbs are cleaned, and laid in a dry place till October. The offsets, chives, or babies, are taken off and marked, in September; these are planted in a separate bed, not so deep as the parent bulbs, and about a month earlier. It may be remarked, that all young bulbs or offsets that are of a round shape, though small, may be considered as likely to produce flowers. The general time of planting old bulbs is the end of October or beginning of November. At this time the outer brown skin is carefully stripped from the bulb, which is committed to the ground in a bare and clean state. By the end of February most of the tulips appear above ground: the surface is at this season gently stirred with the fingers, aided perhaps by a little bit of stick; this stirring tending greatly to promote their health and growth.

The finest and most extensive collections of tulips in this country, at present, are probably those of Davy, nurseryman, King's Road, and of Milliken, florist at Walworth, both near London. Some private collectors, however, principally near the metropolis, have small beds of very fine and select kinds.

### *Ranunculus.*

496. This well known flower (*Ranunculus Asiaticus*) is a native of the Levant and of the Greek Islands. It was cultivated by Gerarde in the end of the 16th century. Very many new varieties of singular beauty have been raised from semi-double flowers, both in this country and in Holland: some of these possess also a considerable fragrance. A judicious and industrious cultivator of this plant near Edinburgh (Mr John Fletcher, superintendant of experiments to the Caledonian Horticultural Society) has excelled many of his cotemporaries in the number of his distinct and well marked varieties, and the beauty of his flowers, many of which have been raised from seed by himself during the last thirty years. He plants each variety in a row, or sometimes in two rows, by itself, in narrow beds, divided by small paths; each distinct variety has a numbered tally, and the number of choice sorts exceeds 180; the proper contrast of colours is studied, and the whole, when in full flower, produces a very brilliant effect. By some florists the varieties are split down till they extend to many hundreds, so that it has been found difficult to invent names for them. Mr Maddock divides the colours into twelve families: Dark and dark purple; light purple and grey; crimson; reds; rosy; orange; yellow and yellow spotted; white and white spotted; olive; purple and coffee-coloured striped; red and yellow striped; and red and white striped. The Turquoy, or turban-shaped ranunculus, is a very distinct sub-variety.

497. The qualities of a fine double ranunculus, as described by him, consist in the flower being of a hemispherical form, at least two inches in diameter, the numerous petals gradually diminishing in size to the centre; the petals broad, with entire, well rounded edges; their colours dark, clear, rich, or brilliant, either of one colour, or variously diversified on an ash, white, sulphur, or fire-coloured ground, or else regularly striped, spotted, or mottled. The stem should be strong and straight, and from eight inches to a foot in height.

The root is composed of several thick fleshy fangs or claws, uniting at top into a head. When the plant becomes strong, several subordinate or lateral heads are formed, and each of these may be taken off with their proper claws, to form a new plant. These offsets, it may be observed, form better flowering plants than the central head, which is exhausted by flowering.

The soil preferred for the ranunculus bed is fresh rich loam, inclining to clayey. It should be deep, perhaps little short of three feet; for it is surprising to what a depth the fine fibres from the tubers penetrate downwards. Some gardeners raise the bed a few inches above the surrounding ground. If manure be at any time added, it should be well rotted, and must be introduced at the very bottom of the bed at least two feet and a half below the tubers. Miller mentions three feet as the proper depth of soil for the beds, adding, that on such beds plants will produce forty or fifty flowers, which in a shallow soil would not afford a dozen. The beds are kept flat on the surface, not raised in the middle as for tulips. Miller directs, that the roots should be planted six inches apart each way; but this is too wide: Five inches between the rows, and three or four inches between each plant in the rows, are sufficient. In some situations, the plants grow stronger than in others; and a good general rule is, to observe the size which the leaves commonly acquire, and then, in that garden, to plant so close as that the grass or foliage of contiguous rows may just meet; the ground being kept in a desirable state of moisture by this close covering of leaves. The tubers should not be more than an inch and a half deep in the earth; and they should be placed with the claws pointing downwards or the bud upwards. It is not right to plant ranunculuses year after year in the same bed. If a little fresh soil be introduced, they may do twice; but after this, the earth of the bed should be entirely changed, or a new bed should be made in a different part of the garden.

The time of planting is either the latter end of October, or the first mild and dry weather in February. When put in in October, the buds sometimes appear above ground in November; in this case, a thin covering of half an inch of light soil is cast over them before severe weather sets in. Autumn planted ranunculuses also require attention in the spring; if hard frosts occur when the flower-stems appear, a covering of hoops and mats may be proper for a few days.

The beds are weeded with the hand, and by careful cultivators the earth between the rows is stirred up only with the fingers, a hoe being very apt to cut and injure the tubers, or break too many of the fine roots. When the flowers begin to expand, the florist does not fail to guard equally against nightly frosts and scorching sun-beams, by means of a canvas awning, or at least of mats laid over large hoops. When drought occurs, liberal watering proves very beneficial to the ranunculus bed.

When the flowering is over, and the leaves have begun to decay, the tubers are carefully lifted on a dry day; being thoroughly cleared of earth, they are dried in the shade, and then deposited in separate drawers or boxes, or in paper bags, till wanted for replanting.

When it is wished to raise seedling ranunculuses, the seed is collected from flowers having not fewer than five or six rows of petals, of good colour. It is sown in August, in boxes or pots, on the very surface of the earth, and a little very fine mould is sifted over it, so as hardly to cover the seeds. The young plants are kept under a glass frame during winter; and most of them flower the second year.

*Anemone.*

498. The garden anemone is of two kinds, the broad-leaved, (*A. hortensis*,) and the narrow-leaved, (*A. coronaria*.) The former is the more hardy, being a native of Italy and the south of France; the latter grows naturally in the islands of the Archipelago, where it appears of all colours.

499. A fine double anemone should have a strong upright stem, eight or nine inches high; the flower should be from two to near three inches in diameter; the outer petals should be firm, spreading horizontally, except that they turn up a little at the end, and the smaller petals within these should be so disposed as to form an elegant whole. The plain colours should be brilliant and striking; the variegated ones, clear and distinct. The flowers are generally divided by florists into red and pink, rosy and crimson, white and white spotted, dark and light blue.

In preparing an anemone bed, the surface soil of some old pasture, with the turf itself, is to be mixed with some well rotted cow-house dung, and allowed to lie for a year in heap, but occasionally turned over. Large stones are to be cast out, but the soil should not be screened, or at least should not be made too fine.

The roots are tuberous, and very irregular in shape. They are commonly planted six inches apart in each direction, and about two inches deep, taking care to place the bud uppermost. The best season for planting is considered to be the month of October; but some roots are generally kept back till December; and others are not put in till February, in order to render them later in coming into flower, and thus to prolong the anemone show. Where the flowers are prized, the beds are sheltered during the severity of the early spring, by mats laid over hoops; for it is remarked by practical men, that double flowers often become single, by "the *thrum* (collection of narrow thread-like petals) that is in the middle of the flower being destroyed." In April and May, if the weather prove very dry, they are regularly refreshed with water.

In July, when the leaves decay, the roots are taken up, but always in dry weather. They are cleared of earth, either with the fingers, or by washing. They are then packed in baskets or drawers till the planting season recur. Of choice sorts, the smallest offsets are valuable; and as these are minute, and very much of the colour of the soil, great attention is requisite to have them all picked up at the time of lifting.

500. New varieties are raised from the seeds of single garden anemones, commonly called Poppy Anemones, preferring those of good colours. Some care is necessary towards the separating of the seeds, which stick together like those of carrots; it is most effectually done by rubbing them among dry sand. The seedlings require attention and protection for the first year, particularly in the spring months, when the frost is apt to throw them out of the ground. In the second year, many of them flower; and the rest probably in the third year. The most promising are then selected.

The poppy anemones themselves, of bright red and blue colours, are highly ornamental in the garden borders. They require little attention, being only taken up every second year. They generally flower in February, and form the gayest parterre ornament at that chill season. Double anemones likewise, if left in the border all the year, come very early into flower.

*Iris.*

503. The genus *Iris* or Flower-de-luce is extensive, containing about fifty species, many of which make very handsome flowers for moist and shady borders; but when a bed of irises is formed, only a few species enter into it. Different varieties of what are called the English or bulbous iris (large rooted and small rooted, or *Iris xiphioides* and *I. xiphium*) form a principal part. The seed of these is gathered and sown by florists, and in this way new and sometimes curious varieties are obtained. The most common colour is blue, deeper or lighter; but the colour is often yellow, or white; sometimes blue, with white or yellow shades, or violet with blue shades; and it is variegated in many other ways. I. pallida or pale Turkey iris, with I. variegata and cristata, are sometimes admitted into the bed. I. tuberosa or snake-head iris, is a singular species, both in regard to foliage and flower, and is likewise occasionally planted.

The soil of the iris bed should be a light loam, with a mixture of sandy peat. The loam should, if possible, be procured from an old pasture, and the sward should be taken along with it. No manure should be added. On an east border, the flowers make a finer appearance than if fully exposed to the south.

The Chalcedonian Iris (*I. susiana*) is yearly imported from Holland, and produces its magnificently rich and large flowers the first summer, but seldom shews flower till three years afterwards. It too agrees with a light loamy soil, but must have a warm sunny situation; and it is to be observed, that moisture, which agrees well with most of the species, is hurtful to this one. In severe winters it is apt to perish: the best roots should therefore be placed in pots, and kept under a frame during winter.

*Dahlia.*

504. There are two species of *Dahlia* mentioned in

*Hortus Kewensis*, D. superflua, and D. frustranea. Of the former there are purple and rose-coloured varieties; and of the latter, scarlet and yellow varieties. Seeds have repeatedly been ripened in this country; and the plants from these have become so far acclimated to Britain, that in a few years they are likely to be ranked as hardy perennials.

Till Mr R. A. Salisbury published his observations on the cultivation of Dahlias, they were little known in this country. Being natives of Mexico, they come into flower in October and November, the period corresponding to their usual time in their native country. They may, however, be brought to shew their flowers more early. This is accomplished by checking the luxuriance of the herbage, by means of planting the roots in very poor soil, sometimes even in screened gravel. Water is supplied only till the flower-bud be discernible in the heart of the leaves; after which none is given.

The roots, which are large and tuberous, like those of peony-rose or yellow asphodel, are taken up every year, and kept for some weeks in sand. Some cultivators always plant them in pots, the restraint thus imposed on the roots having the same effect as planting in gravel. The growth in the spring may, in this way, be forwarded, by placing them under a frame; and the pots may be sunk in the dahlia bed in June. If the bed be situate close to a south-east or south wall, the flowering of the plants is greatly promoted. The more tender sorts, such as the scarlet variety of D. frustranea, may be placed next to the wall, and have its branches nailed to it, in the way practised with love-apple. All secondary branches are pinched off while young and tender, and even some leaves are removed, if the plant shew a disposition to be very luxuriant.

*Pinks.*

505. The common pink and the carnation, though considered as distinct kinds of flowers by the florists, have originated chiefly from one and the same species of plant, the Dianthus Caryophyllus of Linnæus, or Clove Pink. It grows naturally in rocky situations in some parts of Germany; and Sir J. E. Smith has even given it a place (*English Botany*, t. 214.) as a native of Britain. Carnations and pinks seem to have been entirely unknown to the ancients; for Pliny does not describe them, and the classic poets make no allusion to them.

Pinks were not held in much esteem by our own ancestors; indeed they seem to have risen to distinction with florists only in the 18th century. They are divided by them into several classes; such as damasks, cobs, and pheasant's-eyes. The first are white, and flower early; the cobs are red, and flower late. Both of these kinds are considered as originating from D. caryophyllus; but the pheasant's-eye, of which there are numerous varieties, is regarded as having sprung from D. plumarius.

When it is wished to propagate good kinds of pinks, this is readily done either by layering or by using cuttings or pipings. This last mode is the most commodious, the pink growing freely in this way. The difference between a cutting and a piping consists in this, that in the former a joint is cut through horizontally, while a piping is drawn from its socket, leaving a pipe-like hollow. The proper time for gathering cuttings or pipings is when the plants begin to come into flower. They are best when between two and three inches in length; and they should be firm and compact, not *drawn*. Some part of a bed or border having been worked fine, or the surface soil having been screened by means of a sieve, the pipings are stuck into it at three inches square, and the earth is firmly applied to them with the fingers. A copious watering is then given, and hand-glasses are firmly pressed down over the plants: if the weather be bright, these may have some dry earth thrown against them while the glass is moist, in order to produce a degree of shade, or some large leaves may be laid on them for a few days. These hand-glasses are not removed till the new growth of the pinks be distinctly perceived, which happens generally in the course of a month or five weeks; water is however occasionally applied around the covers. The plants are afterwards transferred to a larger bed, or to a garden border, in time to permit them to become well rooted before winter. Slips of pinks, four or six inches long, drawn from the sides of main shoots, and planted any time in the spring, seldom fail to grow.

New varieties are procured by raising plants from seed: for this purpose the seed of the best sorts only is saved; it is produced sparingly in such flowers as are not perfectly double; it is procured more plentifully from semi-double flowers, and if these be of good colours, the offspring is frequently very promising. It is sown in the spring, and the plants are nursed up in beds, and afterwards planted out. From a considerable bed, only a few can be expected worthy of being preserved; and these are likely to be found among the weakest plants.

506. Those flowers, the petals of which are elegantly laced with colours, while the edges are scarcely notched, or are as nearly as possible rose-leaved, are considered the finest. Being very double, and at the same time opening fairly or without bursting, are qualities highly prized. A clear white for the body of the flower is always desirable. In the lacing, a rich black, shaded toward the centre with red, is much esteemed. Scarlet lacings are most rare, and much in request. A purple lace is greatly admired, as in the variety known by the name of Davy's Duchess of Devonshire, which may be considered as the model of a perfect pink. Pinks are carefully tended by the zealous florist. When the flower-stalks rise, they are tied to a small stick to keep them up; and when the petals begin to appear in the pod, those pods which seem apt to burst on one side are restrained by a small piece of slit card-paper. The finest flowers, when expanded, are covered with pieces of tinned iron in shape of inverted funnels or little umbrellas, equally to save them from rain and from the sun's rays.

*Carnations.*

507. Formerly these were divided into *Carnations*, often called Bursters, having very large leaves and flowers, and into *Gillyflowers* (*girofliers*, F.), the leaves and flowers of which are smaller. The former are now called Tree-carnations; the latter, Common carnations. The florists of the present day distinguish carnations into four classes. 1. *Flakes*, having one colour only, on a white ground, the stripes large, and the colour extending through the substance of the petal: when the stripe is pink, and of high colour, the flower is called a Rose flake. 2. *Bizarres*, flowers with two colours, on a white ground: they are called scarlet, purple, or pink bizarres, as these colours happen to abound; when deep purple and rich pink occur together, the flower is accounted a crimson bizarre. 3. *Piquettees*, with a white, and sometimes a yellow ground, spotted with scarlet, purple, or other colours, the edges of the petals generally notched or serrated. 4. *Painted ladies*, with the petals red or purple on the upper side, but white below. This last class is often associated with the pinks.

508. According to florists, the following are the chief

properties of a good carnation. The stem should be strong and straight, nearly three feet high; the flower should expand freely and equally, and should not be less than three inches in diameter; the outer circle of petals, or the guard leaves, should be strong, so as to support the interior petals; these should be numerous, but not crowded; they should regularly decrease in size as they approach the centre; the petals should be rose-shaped, or the edges should be entire, without notch or fringe; the colours should be bright and distinct, the stripes narrowing gradually to the base of the petal; and almost one half of each petal should be of a clear white.

In the culture of carnations, the preparing of a proper compost or soil is of some importance. For producing strong flowers, Maddock recommends a compost consisting of one half well rotted stable dung, one third fresh sound loamy earth, and one sixth sea or river sand; the ingredients to be thoroughly mixed by repeated turnings at intervals of several weeks. If, however, it is wished to preserve entire and brilliant the colours of the flowers, a compost containing much less dung and more loam is greatly to be preferred.

The finest carnations are planted in pots a foot wide at top, and are placed on the shelves of a stage at the time of flowering: they are hence often called Stage-flowers. The potting is performed toward the end of March. The plants are then placed in an open airy part of the garden, under an arch of hoops, so that they may be protected by a covering of mats in case of need. Watering is carefully attended to; the water is not sprinkled over the whole plant, but is applied only to the root. The stems are tied to stakes as they advance. In this situation the plants continue till their stems become too tall for remaining under the hoops. They are then placed on the stage for flowering. Here slender stakes, four feet in length, and sometimes painted, are employed, and the stems are neatly tied to them at the distance of every six inches. As the flower-buds advance, they who are nice watch any appearance of irregular bursting, and prevent it by slight ligatures, as already mentioned in the case of fine pinks. Only three or four principal flower-buds are allowed to come forward; the smaller lateral ones being cut off as they appear. When the earliest flowers begin to expand, tinned iron or common paper covers, such as those above described, § 506, are placed over them. When the flowering becomes general, a canvas awning is resorted to. A tulip-bed frame answers perfectly well for covering carnations; and tulip bulbs are raised and stored, before carnations come into flower: every one therefore, who delights in tulips, should also cultivate carnations, that his canvas frame may thus be occupied with vegetable beauties twice in the year.

Earwigs prove very injurious, sometimes almost destructive to carnations. They should be daily looked for, hunted out, and destroyed. Numbers may be entrapped in dried hollow stalk of rhubarb, reeds, or similar fistular plants. Some have been at the pains to insulate the raised stage, by setting its supporters in vessels filled with water; forgetting perhaps that earwigs occasionally take wing. When the flowers are heavy and apt to droop, bits of fine brass-wire are used as supports. Zealous carnation florists sometimes *dress* the flowers, by removing with a pair of pincers small or ill-coloured petals, and arranging the rest so as to hide the defect.

509. When the plants have passed the height of their bloom, *layering* must not be neglected. The lower leaves of the layers being stripped off, and the terminal leaves cropped, an incision is made below the second or third joint, and continued through the joint; the loose portion of stem below the cut joint is removed, so that the layer may bend freely. It is kept down by a slight peg of wood, or, what is more convenient and neat, of the brake-fern or pteris; such fern pegs are naturally formed in the stalk of the frond, and they decay of themselves when no longer needed. If the weather be dry, watering proves useful. In about a month most of the layers are found to be rooted, and may be transplanted, taking care not to plant too deep. Carnations may also be propagated by pipings; but this is a more difficult mode. The pipings being dressed, by cutting about half a line below the *second* joint from the extremity of the shoot, and shortening the foliage as for layers, are placed in water for some time, to *plump* them, as florists speak. They are then pricked into an exhausted hot-bed, and covered with hand-glasses. The soil is kept moist till fibres be sent out; but it is proper to observe, that after watering, the glass should not be replaced till the leaves of the pipings be dry. When they begin to shoot upwards, air is regularly but cautiously admitted. Layers or pipings, when properly rooted, are removed, and, if choice kinds, generally planted in pots, three or four in each pot. For the winter season, carnations, whether young plants, or surviving mother plants, are best preserved in a repository similar to that commonly used for auriculas. Here they remain till after the middle of March, when they are placed in pots singly for flowering, as already mentioned.

It is of course only by means of seed that new varieties can be obtained. When it is wished that carnation plants should perfect their seeds, they are removed from the canvas awning to a place completely exposed to the sun; or, in the northern part of the island, into an airy green-house; and the plant is not mutilated, by making layers or pipings. It may be remarked, that plants recently raised from the seed, are themselves most productive of seed, and that varieties which have long been propagated by layers and cuttings, scarcely produce any. In flowers approaching to the double state, but few seeds can in any case be expected, and these few often require to be fostered; the withered petals are drawn out from the pod, leaving the styles, or stigmata, which proceed from the top of the germen or seed-pod; an incision is also sometimes made in the calyx down to the base of the germen, so as to prevent any water from lodging there. The seed ripens in September, but it is kept in the pod till April, when it is sown in pots. The young plants are afterwards transplanted into a bed, where they are allowed to show flower; such as prove single-flowered, are cast out; and the best of the double flowers are layered.

It may here be noticed, that carnations are susceptible of the operation of grafting. A good double-flowered sort may be grafted on the stem of a healthy single kind; the most woody part of the stalk is to be preferred, and whip-grafting is best.

### *Polyanthus.*

510. Of the fine genus *Primula*, several elegant species are natives of Britain. Every one is delighted with the appearance of the common primrose (*P. vulgaris*) on our banks in the spring time, and many are the varieties cultivated in gardens under the name of Polyanthus. The well known cowslip or paigle (*P. officinalis*) decks the pastures and margins of corn fields, particularly in the south and west of England, and the gathering of the pips for the making of wine furnishes, in many places, a pleasing employment for children. The oxlip (*P. elatior*) is much less common than the cowslip, and is found chiefly in woods, and

by the margins of woods. It seems to be the parent of several of the small-flowered polyanthuses. The bird's-eye primrose (*P. farinosa*) is certainly one of the prettiest natives we can boast, and it grows on the poorest moors. Of the exotic species, the auricula or bear's-ear (*P. auricula*) is a well known favourite, of which we shall speak, after treating of the polyanthus.

511. According to the florist, the properties of a good polyanthus are the following: The tube of the corolla above the calyx should be short, well filled at the mouth with the anthers, and terminate fluted rather above the eye. The eye should be circular, of a bright clear yellow, and distinct from the ground colour below. The ground colour is most admired when shaded with a light and dark rich crimson, resembling velvet, with one mark or stripe in the centre of each division of the limb or border, bold and distinct from the edging down to the eye, where it should terminate in a fine point. The petal should be large, quite flat, and round, excepting the minute indentations between each division, which divide it into five (sometimes six) heart-like segments. The edging should resemble a bright gold lace; it should be bold, clear, and distinct, and nearly of the same colour as the eye and stripes.

Endless are the varieties of polyanthuses; and as they are easily raised from seed, they are generally the first kind of flower that a young florist cultivates. Seed is kept in the shops for sale; but by sowing this, very few good varieties may be expected. The seeds should be saved only from flowers with large upright stems, producing many flowers upon a stalk, which are large, finely shaped, which open flat, and are not pin-eyed; and all ordinary flowers near to these should be cut over, to avoid any intermixture of pollen. The seed is ready in June, and the pods should be gathered as they successively ripen. The seed is commonly sown in boxes in January. The seedlings are regularly watered in dry weather, and shaded from the forenoon sun. They are fit for pricking out in the end of May; and they are transplanted, in August and September, to the borders where they are to flower, which should be somewhat moist and shady, and exposed only to the east. A loamy soil answers best. Most of them will flower in the succeeding spring, and then those that are indifferent may be cast out, or transferred to the shrubbery. The select plants, being again transplanted, will bloom in full strength the second year; and, if the kinds be very good, will, in collective beauty and brilliancy, be little inferior to a show of auriculas.

After this, they must be yearly removed, and the roots must be parted, else the flowers will inevitably degenerate. The truth is, that seedling plants produce stronger and more brilliant flowers than offsets; and they who would have polyanthuses in perfection must save seed from their finest plants, and sow annually. The best way is, to raise two or three of the finest plants, with a ball of earth attached, and to plant them in another part of the garden, where they may be free from intermixture of pollen, and may be regularly watered, attention to watering being found very conducive to the production of vigorous and healthy seed. The plants which thus yield seed are much weakened, and often perish. In some gardens, the choice flowers are always kept in pots.

Snails and slugs infest polyanthuses in the spring of the year, and should be watched in the morning. In summer the red spider often forms its webs on the rough under side of the leaves, which is indicated by their becoming yellow and spotted. If the plants thus attacked be not removed, the whole polyanthus bed will be destroyed. An effectual cure is found in soaking the foliage of the diseased plants for two or three hours in an infusion of tobacco leaves, and planting them at a distance from the others.

### *Auricula.*

512. The Auricula is a native of the Italian Alps; and there the most common colour is yellow, but it occurs also purple and variegated, with a white powdery eye. The varieties raised by florists are innumerable; many of them are of great beauty, and some extremely curious. Parkinson, in 1629, names twenty varieties, and mentions that there were then many more. Rea, in his Flora, 1702, describes several new sorts raised by himself and cotemporary florists. A century afterwards, Maddock's catalogue enumerates nearly 500 varieties.

513. The properties of a fine auricula are the following: The stem should be strong, upright, and of such a height that the umbel of flowers may be above the foliage of the plant. The peduncles or foot-stalks of the flowers should also be strong, and of a length proportional to the size and number of the blossoms or pips: these should not be fewer than seven, in order that the umbel may be close and regular. A pip or single flower consists of the tube, eye, and border; these should be well proportioned; if the diameter of the tube be one part, that of the eye should be three parts, and that of the whole flower or pip six parts nearly. The circumference of the border should be round, or at all events not what is called starry. The anthers ought to be large, and to fill the tube; the tube should terminate rather above the eye; and this last should be very white, smooth, and round, without cracks, and distinct from the ground colour. The ground colour should be bold and rich, equal on every side of the eye, whether it be in one uniform circle, or in bright patches; it should be distinct at the eye, and only broken at the outer part into the edging. Black, purple, or bright coffee-colour, form excellent contrasts with the white eye; a rich blue or a bright pink are pleasing; and in a deep crimson or glowing scarlet, edged with bright green, are concentrated the hopes and wishes of the florist, which however are seldom realised. On the green edge much of the fine variegated appearance of the auricula depends, and it should be nearly in equal proportion with the ground colour. The dark grounds are generally strewed with a fine white bloom or powder, which gives a rich appearance: the leaves of many sorts are thickly covered with the same kind of powder, which seems destined by nature to save them from the scorching effects of the sun's rays.

Mr Maddock considers the forming of a proper compost for auriculas to be of great importance. The ingredients and proportions recommended by him are these: One half well rotted cow-dung; one sixth fresh sound earth, of an open texture; one eighth vegetable earth, from tree-leaves; one twelfth coarse sea or river sand; one twenty-fourth soft-decayed willow wood, from the trunks of old willow-trees; the same proportion of peat or bog earth; and a like proportion of the ashes of burnt vegetables, to be spread on the surface of the other ingredients. This compost is to be kept for at least a year, exposed to sun and air, several times turned, and passed through a coarse sieve. Mr Curtis properly remarks, that if the compost be rich and light, it is not necessary to adhere rigidly to the above prescription. He mentions, that two-thirds of rotten dung from old hot-beds, and one-third containing equal parts of coarse sand and of peat-earth, form a very suitable compost.

514. Choice auriculas are always kept in pots. The inner diameter of these at top may be six inches, at bottom four inches, and they should be about seven inches deep. A little gravel in the bottom is proper as a drain below the roots of the plants. Auriculas are annually repotted in May, soon after the bloom is over. The balls of earth are to be preserved around the roots, and only a certain portion of new mould given: Mr Maddock, indeed, advises the shaking of the earth from the roots; but this necessarily gives a check, from which the plant does not recover in the course of a year. At the same time offsets are taken, and planted in separate pots. The whole auriculas are then placed in an airy but rather shaded situation, not however under the drip of trees. The place is generally laid with coal-ashes, to prevent the earth-worm from entering the pots, and the pots are often set on bricks, to allow a freer circulation of air about them. Here they remain till October. They are then placed under a glass frame, or other repository, to shelter them for the winter months, giving as much air as circumstances will permit. In February they are earthed up; that is, the superficial mould, to the depth perhaps of an inch, is removed, and replaced by fresh compost, mixed with a little loam, to give it tenacity. This is found greatly to aid the flowering. When several flower-stems appear in one pot, a selection is made of one or two of the strongest, and the others are pinched off. As the flowers advance, the plants are arranged in the covered stage, which contains four or five rows of shelves rising one above another. The roof is generally of glass; and the front, which is placed facing the north or the east, is furnished with folding doors, which may be shut when desired. Here the plants are regularly watered two or three times a week, care being taken not to touch the flowers or foliage with the water. A good collection of auriculas, treated in this way, forms, when in flower, a very captivating sight. Sometimes the richness of the scene is increased, by introducing mirrors into each end of the frame, and by having a bed of hyacinths, and perhaps a row of fine polyanthuses, both of which flower at the same period, in front of the stage, and covered with a thin awning. The soft light, passing through the awning, heightens the effect of the auriculas. It may be mentioned, that in order to secure the filling of the stage with good flowering plants, which alone ought to appear there, it is necessary that the collector possess at least twice as many plants as the stage is calculated to hold.

The interest of the florist's pursuits receives in this, as in all other cases, a great increase, when he attempts the raising of new varieties from seed. To purchase auricula seed in shops is a bad plan. It is much better to encourage the ripening of the seeds of a few very good flowers, which may be done merely by exposing them fully to sun and air, and saving them by hand-glasses from heavy rains. The seed ripens about the end of June; but it should be kept in the umbels till sown. This may be done, either in autumn or early in spring, in boxes; and the seed should be very slightly covered with willow earth, or any light vegetable mould. The boxes are of course to be kept under shelter during the winter; but in good weather the seedlings should have plenty of air; they must not, however, be exposed directly to the sun's rays, which would destroy them in a short time,—at least the more weakly, which are always of the greatest promise. When of a proper size, they are transplanted into other boxes, and nursed till they be fit for pots. If one plant in thirty prove worthy of a place in the collection, the success is great; the rest may be planted out as border flowers, where they continue very ornamental for a few years.

*Hyacinth.*

515. The garden Hyacinth (*Hyacinthus orientalis*, L.) is one of the flowers to the culture of which florists have particularly devoted themselves. It is originally from the Levant, but has been brought to its present improved state in the Low Countries. Double hyacinths are now the only kind prized, though formerly these were as little sought after as double tulips are now, the beauty of the flower being then regarded as consisting in the regularity of the shape and disposition of the blossoms, and in the richness of the colour. Whole acres of nursery ground are covered with this flower near Haarlem and Utrecht in Holland. Here new varieties are annually produced from the seed, which is collected from multiplicate or semi-double flowers, and from very fine single flowers. When a new variety, of good qualities, is procured, it is named and enrolled in the select list. The choice flowers are divided into classes, according to their colours. John Kreps and Sons of Haarlem enumerate near one thousand varieties in their catalogue, classed in this way: Reds; rosy and flesh-coloured; white, with rosy and flesh-coloured eyes; yellow; white with yellow eyes; white with red eyes; pure white; white with violet and purple eyes; dark blackish blue; dark blue; porcelain and pale blue. The names of the finest and newest kinds are, as usual, high-sounding, and calculated to attract English curiosity,—the Monarch of the World; the Honour of Amsterdam; the Princess Charlotte; the Earl of Lauderdale, &c. &c.

516. The properties of a fine hyacinth are the following: the stalk tall, strong and upright; the blossoms numerous, large, well filled with petals, so as to appear rather convex, suspended in a horizontal direction; the whole flower having a compact pyramidal form, with the uppermost blossom quite erect; the plain colour should be clear and bright, and strong colours are preferable to pale; when the colours are mixed, they should blend with elegance.

The hyacinth grows best in a light sandy, but fresh earth. If manure of any sort be given, it must be placed far below the bulb. The time for planting is from the middle to the end of September. Old tanners'-bark is kept spread over the beds during winter, unless when mild weather seems to set in for some days. When the plants come into flower, a slight awning, which can easily be removed, is placed over them; and by this means they continue a month in glory. Hyacinths in beds never require any watering. When the flowering is over, the Dutch *move* their hyacinths with the spade, so as to break the root fibres, and prevent farther nourishment, but do not raise them completely from the ground for a fortnight. Even then they are laid in a bed nearly in a horizontal position, with their leaves and stems lying outwards; in this way, a great part of the juice in their thick succulent leaves and stems evaporates, instead of returning into the bulbs. This is called "ripening the roots." When choice hyacinths are cultivated in pots, as is commonly the case in this country, the pots are laid on their sides, after the flowering, till the leaves decay. Bulbs four or five years old flower most strongly in Britain, and they then gradually fall off; but in Holland they endure a great number of years. It is remarked, that they succeed best in situations near the sea. It is curious that bulbs imported from Holland flower more beautiful in this country the first year, than they ever do afterwards.

*Polyanthus-Narcissus.*

517. The Polyanthus-narcissus (*Narcissus tazetta*) is a

native of Spain and other parts of the south of Europe. The flowers are very ornamental, and come early. The plant has long been a favourite with the florists of Holland and Flanders. There are several principal varieties: Some have yellow petals, with cups or nectaries either orange or sulphur coloured,—others have white petals, with orange, yellow or sulphur coloured nectaries; in a third set, both the petals and the nectaries are white; and there are double flowers of all the varieties. The subordinate varieties are more than a hundred in number. A double variety, called the Cyprus Narcissus, is curious and beautiful; the outer petals are white; those in the middle partly white and partly orange; and it has a very agreeable scent. A pure white variety is called the Paper Narcissus.

The florists of this country generally depend on the supply of bulbs imported from Holland. The seed, however, often ripens in good seasons here, and there is no peculiar difficulty in raising the plants in this way. The seed is sown in shallow vessels in the manner of tulip seed. The seedling bulbs are not raised or transplanted till the third year; in other two years the flowers make their appearance. The beds containing young bulbs require to be defended from severe frost by means of a covering of peas-haulm, straw, or fern.

Full grown bulbs are planted in the beginning of September. They do not require to be raised every year; it is better indeed not to remove them oftener than once in three years. They flower in April and May; and if they be choice kinds, they should be saved from sun and rain by an awning, as practised in the case of tulips.

*Crocus.*

518. The crocus, though a well known flower, has only of late years been accurately studied as a genus. Miller admits only two species, the autumnal or saffron (*C. officinalis*), and the spring crocus, (*C. vernus*). Sir J. E. Smith mentions three species as natives of Britain, C. vernus, nudiflorus, and sativus. Of the former there are several varieties, blue and purple, yellow and white, and striped; and besides these, the following species are cultivated in crocus beds: C. versicolor, or party-colour crocus, a kind which requires a light loam, while most of the others grow best in sand; biflorus, or yellow bottomed; mæsianus, or common yellow; susianus, or cloth of gold; and aureus, or true gold. The Scots crocus is a beautiful striped variety.

The bulbs may be planted in any light soil; but they succeed best in sand; and some cultivators to the westward of London have been at the pains to carry sea-sand fifty miles for this purpose. They should not be planted deep, not being covered more than an inch. In February the flowers begin to appear; in March they are in glory; and by the end of April the seeds begin to ripen. In good seasons these are produced plentifully, and by means of them new varieties may be procured. The leaves of most of the species grow chiefly after the flowering is over: these should not be cut, as is often done, the bulbs being thereby deprived of much of their nourishment; they may, however, very properly be tied up.

*Annual Flowers.*

519. Many of these are very beautiful; and, in fine flower-gardens, they not only appear in patches on the borders, but some of the elegant sorts are cultivated in beds in a separate compartment, called the Annual Flower-garden.

They are commonly divided into Hardy, Less Hardy, and Tender. The hardy are sown in the spring, in the natural ground where they are to remain; the less hardy are raised on a slight hot-bed, and planted out in April and May; and the tender require to be passed through two nursery beds before planting in the open border, and in the northern parts of Britain they are kept almost always under glass. In this place only a few of the most beautiful or curious of each of these divisions can be named. Pretty ample and correct tabular lists of them may be found in Abercrombie's *Practical Gardener*, under the head *Flower-garden.*

520. Of the *Hardy Annuals*, different species of *Adonis* are showy, none more so than the Pheasant's-eye, A. autumnalis: this, if not a native, has become completely naturalized in fields near London, and quantities of the flowers are every summer sold in the city by the name of Red Morocco. Several species of Snapdragon (*Antirrhinum*); white and purple Candytuft (*Iberis umbellata*); Lobel's Catchfly, red and white (*Silene armeria*;) Venus' Looking glass (*Campanula speculum*); with the purple and the red topped Clary (*Salvia horminum*), are very ornamental. Varieties of the Convolvulus major and minor, and of the Bluebottle (*Centaurea cyanus*), with the Sweet Sultan (*C. moschata*); the Fennel-flower (*Nigella damascena*), with many sorts of Scabious (*Scabiosa*), and the well known Stock Gillyflower (*Mathiola incana*), deserve cultivation. The Yellow Balsam (*Impatiens noli tangere*) is remarkable for its ripe capsules exploding the seeds upon being touched; it thus sows itself, and should therefore be placed in a by-corner. The yellow blossoms of the Bladder Ketmia or Flower of an hour, (*Hibiscus trionum*) are extremely perishable if the sun be bright, but they are produced in long succession. Many varieties of Larkspur (*Delphinium Ajacis*), single and double, branched or with simple stems; with several kinds of Lupine (*Lupinus*), and of Sweet Pea (*Lathyrus odoratus*) are well known, and very ornamental. The varieties of Carnation Poppy (*Papaver somniferum*) are very showy; they are generally allowed to sow themselves. Strawberry Blite (*Blitum capitatum*) is a curious plant, the fruit resembling strawberries only, however, in appearance. Belvedere (*Chenopodium Scoparia*) is a handsome plant, resembling in its close pyramidal shape a dwarfish cypress-tree; from which circumstance it is often called Summer cypress. The Caterpillar (*Scorpiurus vermiculata*), Hedgehog, and Snail plants (*Medicago intertexta* and *scutellata*) have no beauty, but are remarkable on account of their vermiform pods. The Eternal Flower (*Xeranthemum*) is excelled by none, and there are red, white, purple, and blue varieties of it. Mignonette (*Reseda odorata*) is universally liked; it is generally sown in large patches, or an entire border is filled with it, commonly in front of the conservatory or greenhouse.

Hardy annual plants are generally sown in circular patches, traced with a hand trowel, with which, at the same time, the earth is broken small. A bit of stick is placed as a mark in the centre of each patch. Usually two or three successive sowings are made, from the middle of March to the middle of May, the season of flowering being thus prolonged. The plants must afterwards be thinned, according to the nature of their growth, the belvedere, the sunflower, and some others standing quite detached. After thinning, a plentiful watering is proper, in order to settle the earth about those that remain; and in dry weather, frequent watering will ensure the production of much finer and stronger plants. Most of the kinds bear transplanting in dull and showery weather. The tall-growing plants should of course be placed in the back part of the border; the low-growing in front. When the flowering is nearly over, some of the earliest and strongest plants should be marked for affording a supply of seed, and should, if tall, be tied to stakes, to prevent their being broken, or falling down. It often happens that some of the kinds spring up in the borders from seeds sown naturally the former year; from these the best and ripest seed may be expected.

521. The list of *Less hardy* annual plants embraces many fine flowers, such as different varieties of the African Marigold (*Tagetes erecta*), and of the French Marigold (*T. patula*); the Amaranth or Love lies bleeding (*Amaranthus caudatus*), and Prince's Feather (*A. hypochondriacus*); the rich and elegant Balsams, many varieties, (*Impatiens balsamina*); different kinds of Chrysanthemum, particularly C. tricolor, and also of Zinnia; with the Indian corn (*Zea mays*), and Tobacco plant (*Nicotiana tabacum*), which are curious. For these and others a moderate hot-bed is necessary, on which they may be sown in March or April, so as to be ready for transplanting into the borders in May or June. It is better, however, instead of removing the seedlings at once to the open border, to prick them into a nursery border, covered with a canvas awning, or hooped over and protected by mats at night: here they may be allowed to establish themselves and get hardy, for some weeks. In dry weather, frequent watering is essential, especially at the times of transplanting.

522. The list of *Tender* annual plants is not numerous, unless the balsam and some others from the less hardy list be included, which in the northen part of the island is always the case. Many varieties of Cock's-comb (*Celosia cristata*), with scarlet, purple, and yellow heads, some of the plants dwarfish, others three or four feet high, are exceedingly ornamental. The Globe amaranth (*Gomphræna globosa*) of various sorts, with the Amaranthus tricolor, having each leaf composed of three colours, bright red, yellow and green, are likewise among the more showy of the tender annual flowers. The Egg-plant deserves the same character; not on account of its flower, but of its singular and elegant berry, which has much of the shape and appearance of a large egg, as already noticed (§ 403). The Ice-plant (*Mesembryanthemum crystallinum*), remarkable for its stalks and leaves being covered with crystalline globules like small icicles, and the well-known Humble plant (*Mimosa pudica*), may also be mentioned. These are raised, in March, in a small hot-bed that is in a pretty strong state of fermentation, and afterwards transferred to one that is larger and of more moderate warmth. In general, the plants are subsequently kept in flower-pots, and are placed near the green-house plants, or perhaps in the greenhouse, the shelves of which they may thus decorate, while the proper inhabitants are abroad. Here too, if properly attended to in regard to watering, they will ripen their seeds, which they seldom do in our climate without the protection of glass. A few cock's-combs, globe-amaranthts, and egg-plants, likewise make a fine appearsnce on the back shelves of a hot-house.

*Biennial Flowers.*

523. Some flowers which are, strictly speaking, *biennial*, are often cultivated among the annual kinds: Such are, the Indian pink, (*Dianthus Chinensis*); the Palma Christi, (*Ricinus palma Christi*); and the Sensitive plant, (*Mimosa sensitiva*). Others are always treated as biennial plants, being kept in nursery rows for the first season, and planted out the next. Some of the most common are, Honesty or satin-flower, (*Lunaria annua*,) white and purple flowered; French Honeysuckle, (*Hedysarum coronarium*,) red and white; Yellow Horned Poppy, (*Glaucium luteum*); tree-primrose, several species, (*Oenothera biennis*, &c.); and Mullein of different kinds, (*Verbascum*.) particularly the Moth-mullein, (*V. blattaria*,) yellow and white flowered.

*Rock-work.*

524. In forming a piece of rock-work, it is found very useful to have at least the two or three outward layers of stones composed of *moor-stones*, that is, of such as have long lain exposed to the action of the weather. At the bases of greenstone and basalt hills very suitable masses may generally be found: those should be selected which have cavities in them, or are unequal on the surface; keeping in view also that they must be of such shape as to be capable of being piled on each other in a sloping direction without cement. If such weather-worn stones be selected, and mossy earth be used in place of cement, many kinds of ferns, and various cryptogamous plants, will be found to thrive, which would not succeed on sandstone, or on masses of any kind of rock fresh dug from a quarry. Besides, some part of the stones being always seen, the appearance of these is to be considered. Masses covered with lichens, especially Lichen atro-flavus, geographicus, ventosus, perellus, and stellaris, are therefore desirable. Pieces of plum-pudding stone and of serpentine have likewise a very good effect; some joints of columnar basalt are in some places introduced, and large petrifactions, or casts in sandstone or limestone, of the trunks and branches of trees. Large shells, too, particularly valves of the Chama gigas, are occasionally placed in the rock-work; and among sand in these some plants will thrive, such as Cotyledon umbilicus. All plants which grow naturally in a dry soil may be accounted fit for the rock-work. Several species of Dianthus, particularly D. deltoides, armeria, and cæsius, are highly ornamental. Red Valerian, (*Valeriana rubra*,) and a white variety of it, grow very readily among stones. If peat-earth be used, Erinus alpinus is a desirable plant. It forms close tufts, and produces its pretty purple flowers from April to July; and when well established, it often ripens its seed, and sows itself. Different species of Madwort are suitable, particularly Alyssum saxatile and deltoideum. Cerastium repens grows freely, but is apt to overrun the other plants: indeed, if it be wished at any time entirely to hide a heap of rubbish with garden plants, this is one of those to be selected for the service. To those already mentioned may be added, Erigeron alpinum; Cyclamen Europæum and herderæfolium; the spring Gentian, Gentiana verna; Soldanella alpina; purple Saxifrage, (*Saxifraga oppositifolia*,) and double Sengreen, (*S. granulata*, fl. pl.); the borage-leaved Mullein, (*Verbascum Myconi*); alpine Lychnis, (*Lychnis alpina*); and different species of Primula, P. nivalis, integrifolia, helvetica, and marginata. The basil-leaved Soapwort (*Saponaria ocymoides*) is one of the most beautiful little plants that adorns the flower-garden, and it is peculiarly well suited for rock-work. All the smaller species of hardy Stone-crop deserve a place, in particular Sedum album, glaucum, rupestre, aizoon, and sexangulare; as well as several species of House-leek, especially the cobweb kind, (*Sempervivum arachnoideum*). In small flower gardens, the rock-work is often constructed on the margin of a little pond for hardy aquatic plants.

*Aquarium.*

525. The shape of the pond is generally either circular or oval. Its dimensions must be regulated by the size of the neighbouring parterre or lawn, and by the taste of the owner for the cultivation of aquatic plants. If it be wished

to have the white and yellow water-lily (*Nymphæa alba* and *Nuphar lutea*) in perfection, it must be at least three feet deep. If the ground be open, especially if the subsoil be sandy or gravelly, the bottom should be well laid with puddled clay, and the sides should also be lined with the same material, in order to prevent the escape of the water. On the margin a kind of small terrace or shelf is formed, immersed only a few inches under water, and commonly laid with channel; on this are placed pots containing various marsh plants, such as the Marsh Calla, (*Calla palustris*), a native of Lapland and other northern parts of Europe. In some gardens, (as formerly noticed, § 191.) the margin is occupied with the American cranberry.

Several of our native aquatic plants are very ornamental; particularly the yellow and the white fringed Bog-bean, Menyanthes nymphoides, and trifoliata; the Flowering-rush (*Butomus umbellatus*,) and the Water-violet, or Feather-foil, (*Hottonia palustris*,) which grows in deep ditches near London. The Cats-tail or Reed-mace (*Typha latifolia* and *angustifolia*) has a singular appearance, especially when in flower, but it is apt to overrun a small pond.

*Rosary.*

526. The rose has always been deservedly a favourite; and at no period was it ever more high in repute than at present. Every hardy species is now carefully cultivated, and many new varieties raised from seed have of late years been introduced. The catalogue of Lee and Kennedy, of Hammersmith, enumerates no fewer than 315 varieties; but the *species* are not distinguished. Many of the finest varieties have been beautifully figured by Miss Lawrence, in her splendid collection of Drawings of Roses. Most of the species throw out suckers. These should be annually removed in October, and in this way abundance of plants may soon be procured. Still better plants however may be prepared by laying down branches; and this is the chief way of propagating adopted by the dealers in roses. Few of the kinds need any other pruning than shortening some of the strongest shoots, to cause them to push new buds and bear more flowers.

The following are the species generally preferred, but a few only of the varieties can be enumerated.

Hundred-leaved rose. (*Rosa centifolia.*) Of this there are many varieties, as the Dutch, blush, velvet, and Burgundy, the latter an elegant little plant, sometimes not more than a foot in height.

Red rose, or Crimson rose, (*R. Gallica.*) This is the kind, the unexpanded petals of which are used for making conserve of roses. A sort with variegated flowers is called Rosa Mundi.

Damask rose, (*R. Damascena.*) Of this there are some pretty variations, as the blush damask, the York and Lancaster, and the red and the white monthly roses, these last continuing to flower in succession during most of the summer.

Provence rose, or Cabbage rose, (*R provincialis.*) is one of the most beautiful of the tribe, and perhaps the most fragrant of all the roses. Of it there are likewise some favourite varieties, as the scarlet, the blush, and the white Provence; the rose de Meaux, and the pompone or dwarfish rose de Meaux. It may be remarked, that if the new wood be in a great measure cut down every year, after the flowering is over, the plants throw out more vigorous shoots, and yield a greater profusion of flowers.

The Moss rose (*R. muscosa*) is well known in gardens in a double state; but it is curious, that the single moss rose is quite unknown to us. The double is often propagated by budding on other stocks; but better and more durable plants are procured by laying down the branches. A white moss rose has lately appeared in the London nurseries; but it is still scarce and high priced.

The common White rose, (*R. alba*,) both single and double, deserves a place; as well as the varieties called large, small, and cluster maiden blush.

Single yellow rose, (*R. lutea.*) The Austrian rose, with the petals orange or scarlet at the base, is considered as a variety of this. Both kinds grow better in upland places than in the richest and warmest situation.

The Double yellow rose (*R. sulphurea*) is remarkable for the flowers seldom opening fairly. It should be planted in a cool and rather shady situation, or at least it does not succeed against a south wall. It is quite a distinct species from the single yellow; the leaflets, for example, are simply serrated, not glandular, and they are glaucous underneath; while in the single yellow, they are doubly serrated, glandular, and of a shining green.

Of the Cinnamon rose, (*R. Cinnamomea*,) a variety with double flowers is usually cultivated. It is the smallest and the earliest of the double roses, often coming into flower in the beginning of May.

Scots rose, or Burnet rose, (*R. spinosissima.*) Of this species, which, as a native plant, is more common in Scotland than in England, several varieties have long been known, particularly the red, the semi-double white, and the semi-double red. Messrs Brown, of the Perth nurseries, have of late years raised several new and very beautiful varieties of this rose. The Rosa Ciphiana, celebrated in a Latin ode by Sir Robert Sibbald, the earliest illustrator of the natural history of Scotland, was a variety of this species. Professor Martin says, it was found on his "Ciphian farm;" but the fact is, that the name of Sir Robert's estate was the unpoetical one of *Kips*, from which, *euphoniæ gratiâ*, Ciphia, was formed.

Sweet-briar-rose, (*R. rubiginosa.*) Of this well known species, the Eglantine of the poets, there are several varieties,—the common double flowered, mossy double, marbled double, and red double. A single flowered yellowish variety is kept in some gardens, but it is very scarce.

The Musk rose (*R. moschata*) is a climbing kind, flowering late, and continuing till the end of October. It varies with double flowers.

The deep red China rose, (*R. semperflorens*,) if placed against a south wall, or in front of a green-house, flowers for the greater part of the year. There is a pale China rose, by some considered as only a variety of R. semperflorens.

The Indian rose, (*R. Indica*, already noticed, § 472 ) is a very great acquisition to our gardens, being perfectly hardy. Although but lately introduced, it has now become very common; and by means of it we possess, in the open air, or against a wall or paling, full blown red roses in March and April, and in November and December. The common sort has very little smell; but a fragrant variety has been raised, thus uniting all the excellent properties of the rose.

In order to have a continued succession of roses, for instance, of the common moss rose, the best plan is, to cut off in May the tops of shoots produced the same spring. In this way new shoots are elicited, which come into flower late in autumn.

Beds of roses, of different shapes, are now commonly formed in the lawn near the mansion-house, or by the sides of the approach to the pleasure garden; when of an oval form, they are often called *baskets* of roses. The surface of the circle or oval is made to rise in the middle; the shoots are layered, and kept down by means of pegs till they strike roots into the ground; the points only, with a few buds on them, appear above the earth. By this sort of management, in two or three seasons, the whole surface becomes covered with a close and beautiful mixture of flowers and leaves. Sometimes only the moss rose is employed for this purpose; but frequently several kinds are intermixed. Even a single plant, particularly of the moss rose, may, by continued attention, be made in this way to cover a large space, and to afford at once perhaps several hundred flowers. Plans for rosaries of different shapes, circular, oval, square, and octagonal, have been published by Lee and Kennedy, and circulated along with their list of roses.

*Climbing Plants.*

527. In many gardens a walk is arched over with trellis work, either of wood or wire, principally for the purpose of affording a proper opportunity of cultivating the finer kinds of climbing shrubs, and enjoying the beauty and fragrance of their flowers, which render such a berceau walk extremely delightful in the warm weather of July and August. The finest of them, however, flourish only in the milder counties of England, and are planted in vain to the northward of Yorkshire.

The Kidney-bean tree (*Glycine frutescens*) shews elegant clusters of purple flowers; and the Virginian silk-tree (*Periploca Græca*) produces bunches of flowers of the same colour. *Smilax aspera*, sometimes called Rough Bindweed, and *S. excelsa*, although their flowers are not showy, are desirable climbing plants, as they retain their verdure during winter. Of the honeysuckles, besides different varieties of the common Woodbine, (*Lonicera Periclymenum*,) the trumpet-honeysuckle (*L. sempervirens*) particularly deserves a place. The yellow and the white Jasmine (*Jasminum fruticans* and *officinale*) are well known plants. Three species of *Atragene* are now cultivated; the Austrian, (*A. Austriaca*.) the Siberian, (*A. Sibirica*,) and the American, (*A. Americana*): the two former were long confounded under the name of A. alpina; they resemble each other, but the Austrian comes into leaf and flower two months before the other; the American species is also early. Several kinds of *Clematis*, or virgin's-bower, are highly ornamental, particularly the purple, (*C. viticella*,) and the double-flowered variety of it, with red and blue varieties of the single; the Virginian, (*C. Virginiana*,) with white flowers; and the evergreen, (*C. cirrhosa*,) which produces its greenish flowers about mid-winter. The common Traveller's-joy (*C. vitalba*) is too rampant to be trusted near to delicate climbers. The common Passion-flower (*Passiflora cærulea*) succeeds in some sheltered places, but in general it flowers better when trained against a wall.

528. For covering walls, some other plants are well suited. If the exposure be good, *Bignonia radicans*, or ash-leaved Trumpet-flower, is highly ornamental, being covered with orange flowers in the autumn: this is a plant, however, which requires some management as to pruning; all small weak shoots must every year be removed, and when the plant has filled the space allotted to it, a quantity of new or young wood for flowering is procured, by annually shortening a number of strong shoots. Common Ivy (*Hedera helix*,) with the silver-striped and gold-striped varieties, and the large-leaved or Irish, are very desirable; as is likewise the Virginian Creeper or five-leaved ivy, (*Vitis hederacea*.) The double Pomegranate has been already mentioned (§ 180.) as admirably adapted for covering a wall, or the end of a house, especially if it have a south aspect.

529. It has been more than once noticed, that the most effectual way of *acclimating* the plants of warmer countries is, to endeavour to bring such plants to ripen their seeds in the open air in this climate with as little assistance as possible, and then to sow these seeds, from which a more hardy progeny is likely to spring. Some plants, however, seem gradually to become inured to our climate, even without being reproduced by seed; or perhaps these plants were at first accounted more delicate than they really are. Several Japan shrubs have of late years become common ornaments of our gardens, particularly the Loquat or Mespilus Japonica; the Japan apple, (*Pyrus Japonica*,) which requires a south wall; the Sophora Japonica; and the Corchorus Japonicus. This last was introduced only about 1804; yet it may now be seen growing like a willow in our borders; and, if kept near to an east or a west wall, to save the buds from severe frost, producing a profusion of its yellow blossoms early in the spring. Trained to the back of a hot-house at the Botanic Garden at Edinburgh, and of course with a northern exposure, it has for several years past stood remarkably well, and has been regularly clothed with flowers in March and April. The Tea-plants (*Thea bohea* and *viridis*,) which are natives of the north of China, stand in the open border in the southern counties of England; but in severe winters they require some degree of protection. Edwardsia grandiflora and microphylla are natives of New Zealand, which flower in February in our sheltered borders, or trained against a wall. Several natives of the south of Europe now inhabit our borders; such are, Jupiter's-beard, Anthyllis barba Jovis; Coronilla glauca; and Moon trefoil, Medicago arborea. Two species of Leptospermum or South Sea myrtle, L. junipermum and baccatum, succeed in the milder parts of England, if trained against a wall; and Metrosideros lanceolata, likewise from New South Walès, has already been noticed as trained on the open wall in the College Botanic Garden at Dublin, § 28. Rhamnus glandulosus, from Madeira, is an addition to our evergreens. Some perennial species of *Convolvulus*, formerly accounted tender, are now trained against the border walls; particularly C. bryoniæfolius from China, and C. althæoides from the Levant. Of the common myrtle (*Myrtus communis*) there are several varieties, some of which are more hardy than others: a single-flowered sort, resembling the double-flowered, but with narrower leaves than the Dutch broad-leaved, is the most hardy; and a variety of the narrow-leaved, called the bird's-nest myrtle, seems also to be more hardy than the Dutch broad-leaved kind.

*Framed Borders.*

530. They who are curious in flowers frequently have a border covered with glazed frames, which can be easily removed during the warm season of the year, from the middle of June to September. Many plants, particularly of the bulbous kind, grow much better when planted in a large border than when confined to flower-pots. Bulbs in general require a deep soil; for they commonly send their fibrous roots, by which they draw their nourishment, to a considerable depth in the earth. Some of the bulbous plants which succeed well in such covered borders are, several species of Ixia, of African Gladiolus, of Hæmanthus or blood flower; and the Tigridia pavonia, or Tiger-flower, equally remarkable for its gorgeous beauty and its transitory nature. Tuberoses (*Polyanthes tuberosa*,) after having been fostered on a slight hot-bed, may be sunk in pots in a framed border, in order to their flowering. Several species of the splendid genus *Amaryllis* might be added to the list, particularly the Belladonna lily (*A. belladonna*,) the Jacobea lily (*A. formosissima*,) and the Guernsey lily (*A. sarniensis*.) Concerning this last, it may be ob-

served, that a few plants only can be expected to flower every year; for, as noticed by Miller, the same plant does not flower in two successive years, nor probably till after the lapse of several years. Dr Macculloch (*Scottish Hort. Mem.* vol. ii. p. 60.) has given an account of the cultivation of this favourite lily in Guernsey. Even there, the Doctor informs us, "scarcely five flowers are produced among a hundred healthy roots." Boxes containing parcels of the bulbs, generally with the flower-stems formed, are annually sent from the Channel Islands to the nurserymen of London, and by them distributed through Britain. Miller has justly remarked, that this lily may more properly be cultivated in a bed on a south border than in pots; it is therefore peculiarly well adapted to the framed border. For the soil, he recommends a third part fresh earth from some light pasture ground; about an equal part of sea-sand; and the remaining third to be composed equally of rotten dung and sifted lime-rubbish.

The different species of Cyclamen or sow-bread are humble plants, likewise well adapted to the framed border, where they make a very beautiful appearance.

In many gardens, where fine bulbous plants are much attended to, as at the Botanic Garden at Liverpool, all the borders immediately in front of the various hot-houses are covered with moveable frames. In these framed borders, it may be added, many alpine plants may likewise be preserved during winter; for such plants being accustomed, in their native place of growth, to the protection of a thick covering of snow during that severe season, are impatient of intense cold.

*Green-house.*

531. The proper situation for the Green-house has been already pointed out (§ 55.) as being somewhere in the flower garden. Its aspect ought of course to be towards the south. In fixing on the plan and elevation of a green-house, there is great scope for fancy and taste; for the indulgence of these is quite consistent with the production of a house, which shall afford shelter during winter to plants which require little more than to be saved from the effects of frost. It is scarcely ever wished that the temperature should exceed 45° Fahrenheit; and when the weather is such that air can be given, it is enough if the thermometer indicate from 38° to 42°. To every part of the house, however, light ought to be freely admitted, else some of the plants will necessarily become *drawn up* and distorted: a great part of the front of the roof should therefore be of glass. Nicol observes, that a green-house may have two straight sides, but should have circular ends; he is better pleased, however, with an octagon, whose sides are not equal, but which has two opposite longer sides, forming as it were an "angular oval." In some gardens the green-house forms a complete circle; in others it is of an oval shape: in these cases, and indeed in general, it is now constructed of glazed frames on every side. The roof is not made nearly so lofty as formerly; indeed, it seldom exceeds in height ten or twelve feet from the paved walk. The furnace and stock-hole are of course as much concealed as possible; and if the house be circular or octagonal, the smoke is carried by a flue under ground to some distance, and then discharged by a small chimney, hid by shrubbery. The interior is fitted up with stages and shelves for holding the plants. These are arranged according to their sizes, the shape of the leaves, and the general tint of colour: the smaller plants are chiefly placed in front, and those that are likely to flower during winter have conspicuous stations allotted to them: the taller plants occupy principally the back shelves: in this way a symmetrical mass of varied foliage is presented to the eye, interrupted only by projecting clusters of variously coloured blossoms. Several of the sashes, or perhaps each alternate sash, should be made moveable, for the admission of air; and ventilators are also proper for promoting a circulation, when the state of the weather prevents the admitting of air by the roof. Very little water is given to the plants during winter; and they are cleared of dust rather by means of a bellows than by the application of the syringe.

The roots of green-house plants are generally examined twice in the year, by turning the plants gently out of the pots. Many kinds only need repotting once in the year; and this operation is commonly performed in August: but others require it twice in the year, and the other period is usually March. It is not always necessary that the plants should be shifted into larger pots; on the contrary, it is often better to retrench the matted roots, and keep to pots of the same size. It is always proper that some small gravel or shivers of broken flower-pots be put in the bottom of the pots, to drain off moisture. And here a very common error in the manufacture of that earthen-ware article may be pointed out: the hole in the bottom is frequently made so as to have a small unintended rim on the inside, which necessarily retains a portion of water; whereas the sides of the hole ought to have a slope from the interior, so as to allow every particle of water to escape.

532. In the course of this treatise, the different sizes of flower-pots have more than once been mentioned in the technical style employed by gardeners, such as "eights," "sixteens," &c., or "No. 1," "No. 3," &c. These terms it may be proper here to explain. The meaning of them will be rendered obvious by a tabular view; but it may first be observed, that potters usually make seven *sizes*, also called *numbers*, of pots; that the pots of each particular size are sold in what are called *casts*; and that the number of pots in a cast increases proportionally as the size of the pots decreases. Of No. 1., which is the largest kind of pot in common use, there are eight in the cast, and a pot of this class is called either a "No. 1," or an "eight."

| | | | |
|---|---|---|---|
| No. 1. | first size, | has 8 in the cast, called | Eights. |
| —— 2. | second size, | 12 . . . . . . . | Twelves. |
| —— 3. | third size, | 16 . . . . . . . | Sixteens. |
| —— 4. | fourth size, | 24 . . . . . . . | Twenty-fours. |
| —— 5. | fifth size, | 32 . . . . . . . | Thirty-twos. |
| —— 6. | sixth size, | 48 . . . . . . . | Forty-eights. |
| —— 7. | seventh size, | 60 . . . . . . . | Sixties. |

Pots larger than eights, or of extra size, such as 4 in the cast, are often made, for the accommodation of large plants; and, on the other hand, pots of a smaller size than sixties are sometimes manufactured, particularly for holding small seedling plants, or very young Cape heaths. These very small pots are among gardeners called *thumbs*.

533. Plants suited to the green-house are extremely numerous, and constantly on the increase: the selection of them must depend on the taste of the owner, and the size of the house. To give any enumeration seems unnecessary: it may be sufficient to refer to those excellent lists, the Epitome of Hortus Kewensis, and the Cambridge Catalogue; in these the plants suited to the green-house are marked G; and their duration or character are indicated by the marks usually employed by botanists and gardeners; ⊙ for annual; ♂ for biennial; ♃ for perennial; and ♄ signifying that the plant is shrubby or arbo-

reous. In the first mentioned catalogue, the plants which require a black heath mould, or peat soil, have an asterisk * prefixed to them. In the Botanical Magazine, edited by Sims, (formerly mentioned § 18.), all new and curious green-house plants are figured and described as they come into notice.

534. To keep up the show of plants actually in flower in the green-house, especially in the early spring months, a usual and very proper expedient is, to plant a number of the common ornamental bulbous plants, in pots, in the month of October; to forward these in the stove, and to place them, as the flowers appear, upon the shelves of the green-house. For this purpose some of the many varieties of hyacinth, with single and double jonquil, white and yellow polyanthus-narcissus, Persian iris, and the early sweet-scented tulips, are well adapted. The jonquil bulbs, it may be observed, must be two years in the pots before they can be expected to flower properly.

535. We may take this opportunity of noticing the mode of bringing these bulbous plants into flower by means of water alone. It was described by Miller in a communication published in the 37th vol. of the Philosophical Transactions, for 1731. November is the usual season for beginning this sort of chamber-forcing. The flower-glasses are filled up to the bottom of the bulb with fresh soft water; and it is kept up to this point by adding to it as often as necessary. The water should be entirely changed once in the week or ten days. The glasses should be situated in a light room, where a fire is kept, and, if possible, near to windows exposed to the forenoon sun. If they be placed in a hot-house for a few weeks, they are greatly forwarded, and appear in perfect flower in January. The numerous varieties of hyacinths, raised by the incredible industry of the Dutch florists, answer extremely well for this purpose; likewise the different sorts, white and yellow, of the polyanthus-narcissus. The jonquil, also, is pretty well adapted; but to many its fragrance is too powerful in a room. The small tulips, called Duc de Vanthol, Claremont, and Pottebakker, may be treated in this way; and the Persian iris is sometimes brought to flower, but is rather apt to fail. The common poetic narcissus, and the common daffodil, may be made to bloom in the same way.

### *Conservatory.*

536. The Conservatory is distinguished by its interior being laid out in beds and borders, in which exotic trees, shrubs and perennial plants are cultivated as in the natural soil. The sides and roof are of glass; and not unfrequently this last is so formed, that it can be removed during the summer months. The parapet wall should be arched, in order to allow the roots of plants in the border next to it to penetrate to the exterior border, in quest of food. In general the flue passes under the walk, and has cavities at each side, to let heated air escape through holes in the earthen tiles with which it is covered. The side borders are occupied with some of the smaller ornamental shrubs of New Holland, and with some others, which, though occasionally placed in the open border, are apt to perish during winter; such as the scarlet Fuchsia of Chili, and the fragrant Vervain of the same country (*Verbena triphylla*); the Dutch double-flowered myrtle, and the tea plants. To these may be added some of the showy species of Polygala, Hermannia, and Gnidia. The bed in the middle of the house should be formed of compost soil to the depth of at least two feet; the bottom being laid with some hard material, to prevent the roots from penetrating, particularly if the subsoil be indifferent. For the general soil, Nicol recommends a perfectly homogeneous compost of 3-4ths brown loam, being the sward of an old pasture, and 1-4th vegetable earth, preferring that resulting from decayed tree-leaves. The earth should not be screened; indeed it is the better for having small stones mixed with it. This middle bed is occupied by some lofty New Holland plants, such as different species of *Acacia*, particularly A. decurrens and longifolia; the dwarfish fan-palm, Chamærops humilis; Clethra arborea, one of the ornaments of Madeira; Olive-trees, and frequently one or two of the Citrus genus. The different varieties, red and white, single and double, of the Japan rose (*Camellia Japonica*) deserve a place; with Daphne odora; the red-flowered Anise-seed tree, Illicium Floridanum; the Malabar nut, (*Justicia Adhatoda*); the Camphor-tree (*Laurus camphora*); several of the elegant genus Protea, and one or two of the no less pleasing and curious genus Banksia. Where the house is of an oval or oblong square shape, and is composed of glass only on three sides, the back is covered with a trellis, to which several of the arborescent Cranes-bills, (such as *Pelargonium inquinans*, different varieties, *P. peltatum*, *cuculatum*, and *lateripes*) are trained; and these, when in flower, have a very brilliant appearance. In some conservatories, a small *aquarium* is formed, where several of the foreign species of Nymphæa and Menyanthes may be brought to flower.

537. Sometimes the characters of the green-house and the conservatory are to a certain extent combined in one house. In particular, some ornamental climbers are planted in the borders, trained against the rafters and pillars, and often led in festoons from place to place. Several species of Passiflora, such as cœrulea, aurantia, and incarnata, and of Glycine, become in this way very elegant, and the large bell flowers of Cobbea scandens make a fine appearance; with different species of Convolvulus, and the Maurandia semperflorens. The Caper-bush, already noticed, § 405. is at once showy and in some measure useful.

538. In a few fine gardens, where the cultivation of curious plants is much attended to, a separate *heath-house* is erected, and appropriated to the numerous Ericæ from the neighbourhood of the Cape of Good Hope. This tribe of plants, it is justly remarked by Professor Martyn, has within these few years "risen from neglect to splendour." Miller, in the edition of his Dictionary published in 1766, mentions only five sorts, four of which are indigenous to this country, and the fifth a native of the south of Europe. The stores of the Cape were then nearly unknown. In 1775, Mr Francis Masson, travelling botanist to the king, sent home many new species from Southern Africa; and the same botanist revisited that country in 1787, and was equally successful in his researches. More lately, Mr Niven of Edinburgh, by extending his travels, made a rich harvest among the same tribe of plants. The Cape ericæ are now about two hundred in number, and many of them both beautiful and fragrant. In construction, the heath-house differs in no respect from a small green-house with a low roof. The plants thrive best in a light rather poor soil; such as a mixture of bog-earth, light loam and sand. They are propagated chiefly by cuttings; the cuttings preferred are very small, inserted closely together in fine soil, sifted over with very pure and fine sand, and covered with small crystal glasses, so as to prevent evaporation; the pots are kept in a moderate heat, but shaded. Cuttings of E. retorta, articularis, and several others, do not grow without great difficulty: such species are therefore often layered. Several kinds ripen their seeds in this country; and by sowing these, great numbers of plants are frequently raised.

*Hot-houses.*

539. The hot-houses for exotic plants have already been mentioned, under the title of Dry Stove and Bark Stove, (§ 199, 200). It was there observed, that in the latter some of the more delicate kinds of grape vines are often trained along the rafters, and that pots with kidney-beans and strawberries are sometimes placed on the side shelves. In first rate gardens, where the stove is entirely appropriated to ornamental plants from tropical climates, the house is sometimes formed of glass on all sides, those plants which naturally grow in shady woods in their own country being placed on the north side of the house. It may here be mentioned, that a book, in folio, on the Construction of Hot-houses, Green-houses, &c. has been published by Mr George Tod, including plans and elevations of some of the fine stoves for exotics at Kew gardens, which were executed by Mr Tod, under the direction of the late distinguished Mr Aiton.

Many curious and beautiful plants might be mentioned as deserving a place in the bark stove, but only a very few can here be named. Among the curious may be noticed, the Date-palm tree (*Phœnix dactylifera*); the Sago-palm (*Cycas revoluta*); the Cyperus Papyrus of Egypt, which afforded the scrolls of bark on which the ancients wrote with the stylum; the Coccolobo pubescens, remarkable for producing the largest round-shaped leaves in the world; Hernandia sonora, or the whistling tree of the West Indies; Musa paradisiaca, the plantain tree, and M. sapientum, the banana; several of the larger species of Acacia, which yield gum arabic; with others which, in our Eastern or Western possessions, afford well known commodities, such as the sugar-cane, the coffee-tree, the pimento and the clove-tree, the indigo plants, and the Ficus elasticus, from which the substance called Indian rubber is procured.

The Papaw-tree (*Carica papaya*) deserves a place in every large hot-house, on account of its possessing a remarkable property, which has been long known to those who have resided in the West Indies, but which has only of late been particularly described in this country by Dr Holder,—that of intenerating butchers-meat or poultry. This singular property is not even hinted at in the last edition of Miller's Dictionary. The juice rubbed on beef or mutton has the effect of rendering the meat as tender as veal or lamb, without injuring its other qualities. Indeed it is affirmed, that if a fowl be hung against the trunk of a papaw-tree, it becomes intenerated in a short space of time by mere proximity; and that the oldest poultry may thus be rendered as tender as chickens. In stoves in England, the papaw-tree has been known to attain the height of twenty feet in three years, and to produce its flowers and fruit: it is not however a durable plant.

Among the more showy stove plants may be mentioned, the different species of Strelitzia, Limodorum Tankervilli, Plumbago rosea, Canarina campanula, and Lantana odorata. Along the rafters may be trained Passiflora quadrangularis, which in the West Indies affords the fruit called Granadilla, but which in this country requires the utmost heat of our stoves to induce it to shew its brilliant and fragrant flowers. P. alata is also highly deserving of a place.

## *Diseases of Plants.*

540. In treating of the different kinds of fruit-trees and esculent plants, several of the maladies to which they are subject have already been noticed, as well as the usual means adopted either for prevention or cure. The diseases of plants shall therefore be only very slightly touched in this place. Any extensive discussion of the subject, indeed, could not be attempted: our knowledge of it is yet in its infancy. Some authors have no doubt given us lists of diseases of the vegetable race, drawn up in the formal style of nosological nomenclature; but they are in general destitute of the requisite permanence and precision of type and character. We shall therefore continue to use the popular terms, such as *Canker*, confessing at the same time that they are sometimes much too indefinite.

541. *Canker* is by far the most prevalent and the most fatal disease incident to fruit-trees in this country. It may be described as a sort of gangrene, which usually begins at the extremities of the branches, and proceeds towards the trunk, killing the tree in two or three years. It seems, in different situations, to arise from different causes; very often from bad subsoil, trees planted over a ferruginous and retentive soil being observed to be very liable to it. Sometimes it appears to take its origin merely from some external injury, or from injudicious pruning, and leaving ragged wounds and snags. In other cases, it makes its first appearance after exudations of gum; and Mr Spence of Hull has remarked, that the foundation of canker in full grown trees is often laid by the attacks of insects, particularly the larvæ of Tortrix Wœberana. It frequently happens that cions for grafting have been taken from infected trees; and the young trees produced in this way are, as might be expected, peculiarly obnoxious to the disease. Among apple trees, those which come soonest into a bearing state, such as the Nonsuch and Hawthorndean, are observed to be most subject to canker. Trees trained as standards or against espalier rails are more liable to it than wall-trees; the more tender and finer sorts of fruits than those that are hardy,—the reasons of which seem to be, that the young wood, not being thoroughly ripened, is killed in the course of the winter, or the buds and early shoots are incurably injured from the same cause.

In order to guard against canker, if the subsoil be indifferent, the trees should be planted as much on the surface as possible. (See § 78. and 110.) If certain varieties of fruit seem peculiarly liable to the disease in any particular garden, other varieties should be introduced by means of grafting. The greatest care should be taken, in pruning, to make the cuts quite clean, and to cover with a plaster any accidental wound. Where the extremities of unripe shoots are nipped by the frost, they should be carefully removed with a sharp knife. Mr Forsyth, as is well known, was remarkably successful in overcoming the ravages of canker, in the Royal Gardens at Kensington, by means of heading down the trees, and thus procuring new branches; an example which may in similar cases be followed. Mr Knight seems to consider canker as principally affecting those varieties of fruit-trees which are in an advanced stage of existence, or which have long been propagated by means of grafts or buds; and the observation is probably well founded. Mr Sang of Kirkcaldy (*Scottish Hort. Mem.* i. 339.) very justly insists on the importance of grafting only on healthy *stocks*, and mentions a case which occurred in his own experience, where many stocks became diseased with canker, apparently from having been raised in an unpropitious soil. For further information regarding canker, the reader may be referred to a paper on that subject by Mr James Smith, gardener at Hopeton House, published in the first volume of *Scottish Horticultural Memoirs*, p. 221, *et seq.*

542. *Blight* commonly means the effects of cold winds, or of hoar-frosts, on the foliage and blossoms of trees. In

this country, easterly winds, accompanied with fogs, often produce blight; the buds are nipped, and the tender vessels burst; innumerable minute insects soon appear, feeding on the extravasated juices, and these are often erroneously supposed to have been wafted hither by the wind, or "engendered by the hazy" *east*. When some fine weather has induced the blossom to expand itself prematurely, and frost supervenes, blight very often ensues. It is not therefore desirable, especially in the northern parts of Britain, that fruit trees should come early into flower: on the contrary, it would be advantageous if the flowering were retarded. Various devices are resorted to for protecting early blossoms, some of which have already been described, § 84.

543. What is called *suffocation* is very commonly induced by the stems and branches being overgrown with lichens and mosses; an evil to which the trees in old orchards, where perhaps the bottom is naturally moist, and has not been drained, are peculiarly liable. The remedy is simple, consisting in rubbing off the parasitical plants, an operation which is much more easily and effectually performed in wet than in dry weather. A round-mouthed iron scraper is sometimes used for this purpose; but one of hard wood answers perfectly well. The trunk and larger branches are afterwards hard swept with a birchen rubber, and it is found very useful, even after both these operations, to wash the branches with old soap-suds or any penetrating liquid, or to apply a coating, of the consistence of paint, of a mixture of equal parts of quicklime, cow dung, and clay.

544. Sometimes *blotches* or dark spots appear, terminating in ulcers. If these occur on old branches, the best remedy is to cut off the diseased parts, if practicable, and to apply a plaster. This may be composed of horse-droppings and clay wrought together, these ingredients being found to answer every useful purpose. Many however prefer a mixture of cow dung and old lime; and where the wounds are small, this is more easily applied. This last, indeed, is very nearly Forsyth's "composition," the specification of which the reader may like to see. It is as follows: Take one bushel of fresh cow-dung, half a bushel of lime rubbish of old buildings, half a bushel of wood-ashes, and a sixteenth part of a bushel of pit or river sand; the three last articles to be sifted fine before they be mixed; then work them well together with the spade, and afterwards with a wooden beater, until the stuff is very smooth, like fine plaster used for the ceilings of rooms. Chamber-lye and soapsuds are to be added, till it be reduced to the consistence of a pretty thick paint, which may be applied to the trees with a painter's brush. The application of such plasters or paints, it may here be remarked, is proper wherever any accident has occurred to fruit trees, or where large branches are lopped off.

In some cases, especially in peach-trees, blotches appear on the young shoots, which must of course be entirely removed. Mr. Kinment, gardener at Murie in Scotland, has assigned some reasons for believing that such blotches on the young wood of the peach-tree, are induced by the gross feeding of the tree; in other words, he observed, that blotches always occurred on trees where the borders were manured with simple dungs, but that where fresh soil or well prepared compost only was added to the border, the trees continued in a healthy state.

545. When a tree becomes *hide bound*, or when the stem swells too fast for the bark, the usual remedy is, with a knife, to score or divide the outer bark longitudinally in various places.

546. In cases where the outer bark has become rough and full of chinks, so that small insects deposit their eggs and produce their larvæ below this bark, it is a good practice entirely to remove it. This sort of decortication is by no means a novelty in gardening; it is recommended by several of the authors mentioned in the introduction to this article. Thus, Le Gendre, (§ 10) writing about 1650, says, "Those trees which have their bark base, you must with a bill take away the old bark to the quick; for the trees being thus cleared and discharged, do shoot forth with new strength, bearing fairer and better nourished fruit." (Translation, p. 136) And Hitt (§ 14) who wrote in 1754, recommends for trees that have been neglected or ill dressed, "taking off the old rind, and cleansing cankered parts, thus destroying many insects, as also their eggs, concealed in these places." (*Treatise on Fruit Trees*, 3d edit. p. 271.) Of late years Mr Knight practised decortication on some old fruit trees, particularly red-streak apples, and found the new growth thus produced quite surprising, so that the growth of some trees deprived of their external bark in 1801, exceeded in the summer of 1802, the increase of the five preceding years taken together. (*Treatise on Apple and Pear*, 4th edition, p. 86)

547. More recently, a zealous horticulturist at Edinburgh, Mr P. Lyon, surgeon, has called the attention of the public to the advantages of decortication. At first Mr Lyon recommended the removal of the bark only in cases where it was cracked and rugged, and chiefly with the view of destroying the *ova* of insects; but of late he has inculcated the stripping off the outer bark even of young trees, and of the new shoots of full grown trees, even where the bark is sound and healthy. The beneficial effects of the former practice we have repeatedly witnessed; old trees which usually bore very little fruit, and produced little new wood, becoming, after the removal of the outer bark, fruitful, and rather exuberant in the production of shoots: the fruit, however, though plentiful, has in general been of smaller size than usual. The depriving young trees and new shoots of their bark is quite a different thing. We know that it is the earnest endeavour of many excellent practical gardeners to keep the bark *on*, provided they can preserve it in a clean and healthy state. We shall only, therefore, for an explanation of this part of Mr Lyon's doctrines, refer to his book, entitled "A Treatise on the Physiology and Pathology of Fruit-trees," 8vo. Edin. 1816,—warning the reader that he must make allowance for no small proportion of extraneous matter.

548. In order to clear trees, especially wall-trees, of insects and their eggs and larvæ, and to prevent the breeding of these, the trunk, branches, and even twigs, are, by careful horticulturists, regularly washed with some penetrating liquid every winter. Some of the most experienced practical gardeners in Scotland have followed this plan, tedious and laborious although it may seem, for a number of years past, and have found the greatest benefit result from it. They have very generally adopted a mixture recommended by Mr Nicol, and from his writings, therefore, the recipe shall be given: "Take of soft soap, 2lb; flower of sulphur 2lb.; leaf or roll tobacco 2lb.; nux vomica, 4 oz.; turpentine, a gill English measure. These ingredients are to be boiled in eight gallons English of soft or river water, down to six gallons." This mixture is applied by means of a house-painter's brush and a sponge, generally when in a milk-warm state. All the branches in succession are loosened from the wall, and completely rubbed or anointed on every side, particular attention being paid to the cleansing of angles or cavities. If the trees have been much overrun with insects, even the wall should be anointed, or

the trellis in the case of espalier trees. This operation may be performed any time from the beginning of November till the middle of February.

549. Sir George Mackenzie has lately communicated to the Caledonian Horticultural Society, the result of an extensive experiment of anointing the stems and branches of trees with oil, or oily matter, for the purpose of destroying the eggs and pupæ of insects. The experiment has succeeded beyond expectation; but care must be taken not to touch the buds, particularly those which are to produce blossoms. Apricot and cherry trees are the only kinds which seemed to suffer injury from oil, every other kind having made vigorous shoots, and the bark of those which had a diseased appearance having sloughed, and shown the advance of new healthy bark; and aphides, &c. seeming to have been banished.

The same gentleman has discovered a nocturnal enemy in a Curculio, supposed to be C. vastator, whose ravages have been attributed to caterpillars. This kind of weevil conceals itself during the day about the foot of the stems of trees in the earth, from which, owing to its brownish-grey colour, it is difficult to distinguish it; and at night it crawls up, and attacks the young shoots and blossoms. It is very destructive to young grafts. The method which Sir George Mackenzie took to destroy them was, to tread the earth about the foot of the stems of the trees, at night when the weevils were on the trees, and putting small flat stones, pieces of slate, or the like, on the trodden space. In the morning the enemy having retreated under these, were destroyed. The trees and grafts should, however, occasionally be examined by candle light, and the insects picked off. They have been found sometimes to harbour also in the clefts of branches, and about portions of dead or decayed and rugged bark.

550. *Mildew* consists in a thin whitish coating, investing the leaves especially of peach-trees and the finer kinds of fruits. It is observed that it commonly appears in the warm months, when the ground is dry, the weather calm, and when hazy vapours or slight fogs appear in the evenings. It is a remark of experienced gardeners, that trees washed during winter with such a liquid as that above described, are scarcely ever known to be affected with mildew, probably owing to the leaves being perfectly healthy and able to withstand the immediate cause of the evil, whether it be minute fungi or the slime of aphides. Washing the foliage with the garden-engine is found very useful in removing the mildew or in stopping its progress.

551. What is called the *scale* seems to be the nidus of an insect, or a collection of its minute eggs, covered with a thin pellicle. It very much resembles a drop from a spermaceti candle. The hatching of the eggs and consequent bursting of the pellicle, have been observed and described by Mr Thomas Thomson, an excellent Scottish gardener. It generally appears in August, and it continues in the state of a scale during the winter. The larvæ usually emerge about the time when the trees are in blossom, and they immediately begin to devour the tender parts of the flower. Afterwards, as they acquire strength, they attack the young leaves and even the new shoots of the trees. When about to undergo their transformation, they involve themselves in leaves drawn together with fine silky threads: from this retreat they come forth in the form of small moths, but the species has not been ascertained. The most effectual method of destroying these scales consists in removing them with the nail of the finger at the time of winter dressing. In rainy weather they are most discernible, being of a lighter colour than the wet bark. Another simple method of overcoming them is, to make a paste of fine clay of the consistence of thick paint, and with a coarse brush completely to anoint the branches of the tree. This should be done in March; and if heavy rains do not immediately wash away the coating of paint, the breeding of the insects at the proper season is prevented, and their destruction thus ensured.

Several of the diseases of plants, we have thus seen, arise from the attacks of insect assailants. Some more of these remain to be mentioned, and also a few enemies of larger size.

*Enemies to Garden productions.*

552. *Aphides* or green-flies, of many species, very much annoy wall-trees in the spring and early part of summer, attacking the leaves while just expanding, and preying much about the points of the young shoots. A fumigation with tobacco is the common cure, and it very generally proves effectual. In the case of wall-trees, a large cloth, preferring one that is waxed or oiled, is placed over the tree, and the tobacco smoke applied under it with bellows; the wall and the tree are previously wetted with the garden engine, the moisture having a tendency to detain the smoke. The tree is then briskly washed with the force-pump, and the border is delved over, so as to bury the stunned aphides. In the same way gooseberry or currant bushes may be freed from them. In hot-houses the fumigation is easily performed, while the doors and sashes are kept close. It is likewise very readily accomplished in melon or cucumber frames, the crops in which are sometimes infested. In the kitchen-garden, kidney-beans are subject to the attacks of aphides; and in the flower-garden, rose-bushes are peculiarly obnoxious to them.

The Apple-aphis (*A. lanigera*), sometimes called American blight, which has of late proved exceedingly destructive to young apple-trees, first appeared in the neighbourhood of London only about the year 1795. It is a minute insect covered with a long cotton-like wool; it breeds in chinks and rugosities of the bark, and at length almost covers the infected tree. It is said that the application of the spirit of turpentine to the bark proves an effectual remedy; and we know that it has been wholly banished from a garden where it had spread, by merely smearing the infested branches with oil, as recommended by Sir George Mackenzie. Sir Joseph Banks extirpated it from his own apple-trees, by the simple means of removing all the rugged old bark, and then scrubbing the trunk and branches with a hard brush. Mr William Salisbury, in his "Hints to the Proprietors of Orchards," published in 1816, gives it as his opinion, that this is the same insect which has of late infested larch-trees. He supposes it to have been brought to this country by the Protestant refugees in the reign of Louis XIV.; but he has assigned no reason for this extraordinary opinion, nor has he attempted to explain why so destructive an insect had lain dormant for so many years, and at length suddenly extended its ravages in so striking a manner. He observes, that some of the insects descend during winter to the upper roots, and lodge there; in cleansing the trees, therefore, these should be examined, as well as the trunk and branches.

553. There are several distinct kinds of *gooseberry-caterpillar*. One species, of a whitish colour, becomes a longish fly, with golden-tinged wings, a yellow body, and yellow thighs; probably the Tenthredo capreæ. Another, of a greenish hue, which becomes T. flava, often proves quite destructive to the foliage of the plant, and consequently to the fruit. A third, of a larger size, and sometimes very common, is the larva of the magpie-moth (*Phalæna grossulariata*, Lin. *Abraxas* of Leach. (The young of this last haunt during winter about the crevices of the bark; and

this is considered as the best time for destroying them. Their destruction may be effected merely by hard rubbing of the stems and branches, or by pouring boiling hot water over these parts, which at this season does not injure the bushes. The larvæ of the saw-flies or tenthredines penetrate about an inch under ground in July, and, passing into the chrysalis state, remain there till the following spring, when they come forth in the form of flies. For destroying these, one of the most effectual means consists in delving the ground about the bushes very deep during winter, taking care to bury the surface-soil in the bottom. In this way the chrysalids are placed beyond the genial influence of the atmosphere, or, if the transformation be accomplished, the fly is unable to gain the surface.

Different species of *Coccus*, particularly C. hesperidum, often called *scaly insects*, infest the plants of the greenhouse and the conservatory, particularly the myrtle, the orange, and the olive. A thorough washing with soap and water, rubbing the leaves with a woollen rag or bit of sponge tied on a small stick, is the remedy usually resorted to, the plants being afterwards well syringed with pure water. Coccus vitis infests vines placed in stoves, and is often very injurious, covering their stems, as it were, with little tufts of white cotton. The means of freeing pineapple plants from the coccus have already been adverted to, § 223.

554. The *red spider* (*Acarus telarius*) infests not only the pine-stove, vinery, and melon frames, but often proves very injurious to ornamental stove plants. Water applied with the syringe is destructive to it. Some persons recommend the use of lime-water; but it is not commonly employed, being found hurtful to the foliage; nor does any addition to the water seem necessary.

555. The finer kinds of fruits, as they approach ripeness, are subject to the attacks of different insects. Among these *wasps* (*Vespa vulgaris*) may be first mentioned. Various expedients are resorted to for destroying them. In some places, phials half filled with honey and water, or any sweet liquid, are hung in different parts of the tree; and great numbers are thus ensnared. The most effectual means, however, of keeping down the numbers of this formidable enemy is, to destroy the females in the early part of the season, and the nests in the autumn. From hot-houses they are, in some places, excluded, by employing temporary doors and temporary frames below the sashes, covered with thin muslin or gauze: both kinds of doors are never allowed to be open at the same time, and the gauze or muslin does not prevent the access of sufficient light and air. Where their exclusion is not thus effected, it is found very useful to have a plant of Hoya carnosa established. This is an ornamental climber (named in honour of Mr Thomas Hoy, a distinguished botanist, who has for about half a century been head-gardener to the Duke of Northumberland at Syon House), and may be trained along any spare parts of the house. It flowers freely; and as long as the blossoms continue, which they do for several weeks, the wasps give a decided preference to the sweet exudation they afford, leaving grapes and peaches untouched.

556. *Earwigs* (*Forficula auricularia*) attack all sorts of ripe fruit. No remedy is known but ensnaring and killing them. Short cuts of reeds, or of strong wheat-straw, or hollow stalks of any kind, are placed here and there among the branches, and also at the roots of the trees. Into these the earwigs take refuge in great numbers; and from the tubes they are blown into a bottle containing water.

557. The *woodlouse*, called *sclater* in Scotland (under which name are included the Oniscus asellus and Porcellio scaber of naturalists) is often entrapped along with the earwig. It is almost equally injurious to ripe fruit as that insect.

558. *Flies* of many different species, and belonging to various genera, may be numbered among the enemies of ripe fruit. The wasp, the earwig, and the woodlouse, commence the attack, and "sap the blushing rind;" the flies enter the openings made by these more powerful insects, and extend the devastation. Several *muscæ* are very frequently to be observed, particularly M. tenax, Cæsar, and canicularis. Wherever the juices begin to corrupt, the large blow-fly (*M. vomitoria*) is to be found in every hollow.

559. The *caterpillars*, which devour the leaves of cabbages, savoys, and broccoli, are principally the larvæ of Noctua brassicæ, and N. oleracea. The completely green caterpillar, which frequently preys on cauliflower and broccoli plants, is the larva of *Papilio rapæ*, Lin. (*Pontia*, Fabr.) The cabbage tribe is observed to be most subject to the attack of caterpillars in the neighbourhood of towns and in long cultivated soils, where much crude manure has been applied. The best and simplest remedy consists in turning up the soil in ridges in the autumn, and leaving it exposed to the action of the winter's frost; but the application of quicklime is also useful.

560. The *wire-worm* is an indefinite sort of name for any small thread-like grub, which lodges in the roots of culinary plants, particularly such as are of a bulbous or tuberous nature. These grubs appear to be principally the larvæ of different species of Elater. They sometimes attack also the roots of ornamental plants kept in pots: The remedy, in this case, consists in repotting, shaking the roots clear of the old earth, and using fresh soil brought from some old pasture at a distance.

The *maggot* which infests onions and shallots (§ 335 and 344), is a small larva, the transformations of which have not yet been traced by naturalists.

For further information concerning the natural history of the insect enemies of fruits and culinary vegetables, we may refer to the first volume of a very entertaining and instructive work, entitled "An Introduction to Entomology," by Messrs Kirby and Spence, 8vo. London, 1815; and to the article ENTOMOLOGY in this work.

561. The other enemies of garden productions can only be very slightly noticed here.

*Slugs*, meaning principally Limax cinerarius and L. flavus, are often very mischievous to wall-trees, which they ascend in the spring months, cutting off the fruit at the time of setting. Inverted flower-pots are sometimes placed as decoys at the bottom of the trees, the slugs being induced to take shelter within them. Ducks are very good destroyers of slugs; and a few are often turned into gardens for this purpose; they must be kept in it for two or three days, and get no food but what they cull for themselves.

*Snails* (meaning chiefly *Helix aspersa* of Montagu, or *H. hortensis* of Pennant) often abound, especially where the garden-walls are old or rugged. In well kept gardens they are looked for in the mornings, particularly after showers, when they never fail to appear, and are destroyed.

*Moles* (*Talpa Europæa*) are sometimes very injurious in gardens, and must be extirpated wherever they appear. Traps are set for them by persons who have studied their habits: and the expertness of some of these in taking them is wonderful. The moles seem to be social animals, keeping together in families or societies. The great art in catching them depends on ascertaining their recent and frequented galleries or subterraneous roads, and in placing the traps neatly in these.

*Mice* (principally the field-mouse, *Mus sylvaticus*) frequently devour newly sown peas and beans, if these have not been duly covered with soil; and they sometimes likewise attack the beds of tulips, ranunculuses, and crocuses. They may soon be subdued by placing a number of *fourth-figure* traps (as they are called, from resembling in shape the Arabic 4) in the garden: this kind of simple but effectual trap is figured and described both in Nicol's "Calendar," and in Abercrombie's "Practical Gardener."

Many kinds of *birds* may be numbered among the enemies of gardens. Even the beautiful bulfinch (*Loxia pyrrhula*) destroys many blossoms of fruit-trees, scooping them clean out; but whether the bird feeds on the blossom, or only nips it off for the sake of caterpillars contained within it, is not known. The jay (*Corvus glandarius*,) the black-bird (*Turdus merula*), and the mavis (*T. musicus*,) make great havock among the best kinds of cherries, where means are not resorted to for saving them. Rooks (*Corvus frugilegus*) often attack pear-trees, and destroy vast quantities of the fruit; and jack-daws (*C. monedula*) are sometimes also guilty of this sort of trespass. The common sparrow (*Fringilla domestica*,) and the chaffinch (*F. cœlebs*), likewise commit great depredations. For the protection of large standard trees, dead birds are occasionally hung up, so as to wave with the wind; and such scares are of considerable service in deterring depredators. In the case of espalier and wall-trees, nets are generally employed, being hung over them, and fixed close to the ground. It may be remarked, that different species of titmouse (*Parus cæruleus* and *ater*) with the common creeper (*Certhia familiaris*), and all the Motacillæ or warblers, may be considered as useful in destroying insects or their larvæ, which are their principal food, and should therefore be winked at in gardens, although they may possibly destroy a certain quantity of the blossom.

### *Implements of Gardening.*

562. The principal tools employed in horticultural operations have already been mentioned incidentally; but it may be proper in this place to enumerate them together.

The spade may be first named, as the oldest and most indispensable garden tool. Besides common sized spades for delving, small spades are required for working in the flower-borders. The manufacture of spades is carried on to a great extent at Dalston near Carlisle; at Gateshead, Newcastle; Bedburn, near Durham; Burton upon Trent; and Ulverstone in Lancashire; and of late years, some Scots forges, particularly those at Cramond, near Edinburgh, and Dalnottar, near Glasgow, have disputed, with those mentioned, the palm of excellence in this useful and important article of our iron manufacture. Shovels of different sorts are made at the same manufactories. Forks are necessary for pointing over ground where it is improper to use the spade: They are of different sizes, and some have flat and others rounded tines: asparagus-forks have been already mentioned (§ 353.) Hoes of different sizes are indispensable, with small weeding and thinning hoes, and also the sort called the Dutch hoe. Rakes of different sizes are necessary: for large ones, those in which the teeth are of iron, and the head of well-seasoned ash, are best; and for small ones, those in which the teeth and head are formed of one solid piece of iron are to be preferred. Shears for clipping hedges, and a kind with bent handles for dressing grass verges, are not to be forgotten. A flat faced hammer, with large headed nails, both of wrought iron and of cast iron, and a stock of lists or *roonds* are requisite for the nailing of wall-trees: as well as a proper wall-ladder, such as is described, § 245. Pruning, grafting, and budding knives, with hand-bills, chisels, and small saws, are indispensable. Some recently invented pruning instruments might here be noticed. One called the Averuncator has a handle from 5 to 8 feet in length; by means of a cord and pulley, a lever connected with a cutting blade is acted upon; so that a person standing on the ground may prune the greater part of ordinary sized trees. The Pruning-shears are more easily managed, and are found very useful on many occasions, making the cuts more clean and neat than can be done with any kind of knife. Both instruments take off branches an inch and a half in diameter with great ease. The form of the averuncator is given at Fig. 6. of Plate CCCXII., and of the pruning-shears at Fig. 7. of the same Plate. Trowels of different sizes and shapes, with planting irons and dibbles, are all very useful implements. These, with scythes and paring-irons, and similar instruments, are manufactured to a great extent at Sheffield; and from the subdivision of labour there established, they are furnished at rates so cheap as cannot fail in a great measure to command the market: but it is not to be disputed, regarding hoes and rakes in particular, that the blacksmiths of some towns not distinguished as manufacturing places, such as Edinburgh, produce these instruments of better materials, if not of neater workmanship. A garden reel and line is constantly needed. Sieves of iron or of brass wire of different degrees of closeness are required, wherever attention is paid to the raising of exotic seedlings. Fumigating bellows are useful for green-houses, vineries, and melon-frames. Where forcing is practised, or where a collection of stove-plants is kept, thermometers are necessary: those graduated to the scale of Fahrenheit are universally in use: what is called the botanical thermometer differs in no respect from another, excepting that some terms, such as "Ananas," are inscribed at the proper degrees on the sides of the scale. One thermometer is placed in the open air; and in the centre of each of the hot-houses there is another: by comparing these, the propriety of increasing or diminishing the fire-heat, or the quantity of fuel, is regulated. Watering-pots are made by tinsmiths, with pipes of different lengths, and with roses more or less closely perforated: for watering delicate seedlings, pots with brass nozles finely perforated are used, producing an extremely light or minutely divided shower.

563. The *garden engine* has been repeatedly mentioned, and its use recommended, (§ 92, 205, &c.) Considerable improvements having been made on this instrument at Edinburgh, a few words additional concerning it may be excused. The engine consists of a force pump or barrel, commonly two inches and a quarter in diameter, to the bottom of which, above the valve, is connected an air-vessel: into this the water is forced; and it is emitted from it, by the action of the compressed air, through the directing pipe in a continued stream. This pipe is attached to the top of the air-vessel by means of a swan-neck swivel joint, with double screws, which are water tight: in this way the pipe can be moved in any direction. Formerly, leathern valves and a leathern flexible director-pipe were in use; but from occasional exposure to drought, the seams of the leather were very apt to open, and allow water to escape; well executed brass work, on the other hand, is of all others least liable to derangement. The pump and air-vessel are fixed in a copper cistern, sixteen inches deep, and capable of containing about twenty-two gallons of water, wine measure. The cistern has likewise a strong

wooden bottom, to which are attached two rollers, an improvement of Mr John Hay's, which greatly facilitate the moving of it when taken into hot-houses or vineries. The engine is, at the same time, fitted to a barrow with wheels, for the conveniency of wheeling it through the garden; and to this the rollers form no obstacle, as they pass between the *steels* of the barrow. The pump is worked by a lever, and requires very little exertion. The water can be projected about fifty feet; so that wall-trees of any height may be washed, while the engine remains on the gravel walk.

The best writers on the various branches of horticulture, particularly British authors, have been mentioned, either in the introduction to this article, or in the course of treating the different parts of the subject; but it may be useful to recapitulate them here in alphabetical order. (P. N.)

HOSPITAL. See Infirmary.

HOT-BATH. See Bathing.

HOT-BED. The common hot-beds in use in this country are composed of new or fresh stable dung in the following manner. The dung is collected in a heap, under cover, if possible, and kept for about a week in this situation, when the heat arising from fermentation becomes considerable. It is then turned over, well mixed, and again formed into a heap, to remain for five or six days more, in order that the heat may be equally distributed. It is now transferred to the site of the intended hot-bed. Here it is again very completely intermixed by means of the dung-fork, in the course of making up the bed; at the same time every layer is settled compactly, and beat smooth. The bed is usually five or six feet in breadth, according to the size of the glazed frames, beyond which it ought to extend on every side about eight or nine inches; and it is from four feet to two feet and a half thick or deep,—the thickest beds being used in winter, and the thinner in the spring months. The part of the dung which is *shortest*, or freest from litter, is placed on the top, forming a close covering, through which steam or vapour may not readily pass; sometimes a layer of cow-dung is placed on the surface, with the same view. After the bed is made up, it is allowed to remain for a few days, during which it sends off a good deal of vapour, and acquires an equal temperature throughout. When the heat declines, it is revived by adding *linings* on the outside; but for information respecting these, as well as concerning the use of tanner's bark and decayed tree leaves in forming hot-beds, see Horticulture, § 257, 355, &c.

HOT-HOUSE See Horticulture, *Index*.

HOTTENTOTS, an extraordinary people in the southern extremity of Africa, originally occupying the territories around the Cape of Good Hope. They are altogether an insulated tribe, confined to a small corner of the African Continent, and bearing no resemblance either to the Negro race along the western coast, or to the Caffre nation to the eastward. Various conjectures have been proposed, but nothing very satisfactory has yet been established, respecting their origin, or affinity. Kolben, in full consistency with his multitude of marvelious stories on the subject, affirms, that they have a tradition among themselves, of having been thrust upon the promontory of the Cape out of some narrow passage; and, as a narrow passage might signify a door-way or window, he forthwith concludes, that it could be nothing else than the window of Noah's ark, out of which they crept. Mr Barrow considers them as approaching nearest in colour, and in the construction of the features, especially in the shape of the eye, to the Chinese or Tartar race; and accounts for this relation, by supposing them to have proceeded from the Egyptians, who have been not improbably represented as originally the same people with the Chinese. In support of this opinion, he adduces the strong resemblance between the physical character of the Bosjesmans, or real Hottentots, and the descriptions given by ancient writers, particularly by Diodorus Siculus, of the Egyptians and Ethiopians, especially of the Pigmies and Troglodytes, who are said to have dwelt in the neighbourhood of the Nile. The early Portuguese writers, also, mention a colony of Chinese in the vicinity of Soffala; and the natives in the interior of Madagascar are described as a small race of Tartars, resembling the Hottentots in stature, colour, and countenance. The name Hottentot, though frequently represented as their native appellation, is now ascertained to be of modern fabrication, and has no place or meaning in their own language. They take it to themselves, under the idea of its being a Dutch word; and it is conceived to have been applied at first as a term in some degree imitative of the remarkable clacking made by them in speaking, which is said to sound like *hot* or *tot*. Each horde had formerly its particular name, as the Attaquas, Hessaquas, Houtiniquas, Namaquas, and Coranas; but the designation by which the whole nation was distinguished, and which they still bear among themselves in every part of the country, is Quaïquæ.

The whole of the Hottentot country, comprehending all the different tribes of the race, extends along the east coast to the 32° of S. Latitude, and to the 25° on the West. None of the first discoverers of the Cape of Good Hope, nor of the early Portuguese navigators, had much communication with the natives; and the Hottentots were scarcely known to Europeans till about the year 1509; when Francisco D'Almeyda, Viceroy of India, returning home after his quarrel with Albuquerque, landed at Table Bay, and was killed, along with seventy of his people, in a scuffle with the natives. A Portuguese captain, having touched on the coast, about three years afterwards, planned the following cowardly scheme of avenging his countrymen. He landed a piece of ordnance loaded with grape shot as a pretended present to the Hottentots; and while the unsuspecting natives were crowding around the engine, the brutal Portuguese fired off the piece by means of a rope which was attached to it, and viewed with savage delight the mangled carcases of the deluded creatures, who had trusted their professions of friendship. They were occasionally visited for refreshments by the English, Portuguese, and Dutch traders, in their voyages to the East Indies, till the establishment of a colony among them by the last mentioned nation, in the year 1650. They made little opposition to the new settlers; and were soon induced, by their passion for brandy and tobacco, first to sell their country and cattle, and next to become themselves the servants of the purchasers, for the purpose of guarding those flocks and herds, which had so recently been their own property. These wretched people, duped out of their possessions and their liberty, have entailed upon themselves and their offspring a state of subjection, which is comparatively worse than slavery; inasmuch as, in consequence of their not being transferable property, their immediate value is diminished, and their treatment less tempered by the self-interest of their oppressors. In the remoter parts of the colony, especially, they are subjected to cruelties, which have not been surpassed in the worst of the West India islands. Instant death is not unfrequently the consequence of that brutal rage to which they are exposed. To fire small shot into their legs or thighs is no unusual punishment. One of the gentler chastisements which they endure is, to be lashed or rather bruised with thongs, cut from the hide of the sea-cow or rhinoceros, which are nearly as hard and heavy as lead. With these horrid instruments they are flogged at leisure, not by a number of blows, but by a period of torture; and the savage master makes it one of his favourite recreations to regulate the time of their suffering, by smoking as many pipes of tobacco as he deems proportionate to the offence.* These boors or Dutch farmers are authorised by an old law of the colony to claim as their property all the children of the Hottentots in their service, to whom they may have given in their infancy a morsel of meat; and, though the same regulation directs their emancipation at the age of twenty-five, this is a privilege which they are generally too ignorant to claim, or too feeble to enforce. At most, the poor wretches, after spending the prime of their strength in an unprofitable servitude, are turned adrift at last, with no other earthly property except the sheep skin upon their back. Those who are apparently free, and engage themselves from year to year, are not much better provided for. If they have families when they enter the service, their children are encouraged to run about the farm house, where they receive their morsel of food; and upon this ground, are often claimed as the property of the farmer, when their parents are desirous to remove, or perhaps forcibly turned away. Those who are unmarried, as well as free, are doubtless the least wretched; but even their personal service is easily converted into the hardest bondage. Their paltry wages are stopped upon every frivolous pretext; and should any of the cattle entrusted to their care be missing, they must prolong their service, without pay, till they have earned the value of what was lost. Or, should no damage of this nature be imputable to their negligence during the year, they may still have nothing to receive at the end of it, in consequence of a bill for brandy or tobacco, brought against them, to the full amount of their wages. In such circumstances, they have little inducement to en-

* Among many instances of the cruel treatment to which the helpless Hottentots are daily exposed, the following are recorded by Mr Barrow as peculiarly striking: "We had scarcely parted from these people, when, stopping at a house to feed our horses, we by accident observed a young Hottentot woman, with a child in her arms, lying stretched on the ground in a most deplorable condition. She had been cut from head to foot with one of those infernal whips, made from the hide of a rhinoceros or sea-cow, known by the name of Sambocs, in such a barbarous and unmerciful manner, that there was scarcely a spot on her whole body free from stripes; nor had the sides of the little infant, in clinging to its mother, escaped the strokes of the brutal monster." "The only crime alleged against her was the attempt to follow her husband, who was among the number of those of his countrymen that had determined to throw themselves upon the protection of the English." "The next house we halted at upon the road presented us with a still more horrid instance of brutality. We observed a fine Hottentot boy, about eight years of age, sitting at the corner of the house, with a pair of iron rings clenched upon his legs, of the weight of ten or twelve pounds; and they had remained in one situation for such a length of time, that they appeared to be sunk into the leg, the muscle being tumified both above and below the rings. The poor creature was so benumbed and oppressed with the weight, that, being unable to walk with ease, he crawled on the ground. It appeared, upon inquiry, that they had been rivetted to his legs more than ten months ago." "The fellow shrunk from the inquiries of the indignant general; he had nothing to allege against him, but that he had always been a worthless boy; he had lost him so many sheep, he had slept when he ought to watch the cattle, and such like frivolous charges of a negative kind," &c.

gage in marriage; and when they do enter into that state, they are frequently without any offspring, or at most have seldom more than two or three children. Their extreme poverty, scanty food, and constant dejection of mind, appear to exhaust the prolific powers of nature; and their practice of marrying only among their own limited horde is considered as an additional hindrance to their increase. Multitudes of the more independent tribes, also, have perished by the hostilities of the Caffres, and the ferocity of the wild beasts, as they receded towards the interior of the country.* From all these causes combined, the Hottentot race is rapidly diminishing, and in all probability will soon become wholly extinct. Many of their tribes, mentioned by the earlier travellers, have entirely disappeared; and, at the commencement of the present century, not a kraal or village was to be found about Camtoos river, where, only 20 years before, hundreds of the natives were met in groupes. In the whole extensive district of Graaff Reynet, there is not a single horde of independent Hottentots; and the whole number within the limits of the colony does not amount to fifteen thousand. Much has been done since the colony came last into the possession of Great Britain, especially by the measures of Sir John Craddock, and the progress of missionary settlements, to protect and preserve this oppressed race of beings; but, though a little remnant may thus be collected, the nation, it is to be feared, is almost already extinguished. A mixed breed, called Bastaards, produced from Hottentot women and European fathers, or the slaves from other countries, are likely to supplant the original inhabitants. They are already a numerous race in the colony; and are a tall, stout, and active people.

The ancient manners and primitive character of the Hottentots are acknowledged to have been greatly changed during their connection with the colonists of the Cape; and it may not, therefore, be a sufficient proof of the inaccuracy of the former accounts, that they do not correspond with the observations of recent travellers. At the same time, so many of the strange and ridiculous stories, published on the subject, have been discovered to have originated in ignorance, credulity, or deliberate fiction, that little dependence can be placed upon any of the narratives which preceded the enlightened enquiries and personal observations of Barrow, Truter, Somerville, &c. The Hottentots of one district differ considerably, in the present day, from those of another, in consequence of their living together in particular clans, and mixing with different kinds of people; but from observing their manners in those parts of the colony which have been most recently occupied, some approach may be made to a sketch of their original native character. The personal appearance of the Hottentots, though by no means prepossessing, is not nearly so revolting as has been often represented. Their countenance, indeed, is in general extremely ugly. Prominent cheek bones, and a narrow pointed chin, give to the face the form nearly of a triangle. The nose, in most of them, is remarkably flat, and rather broad between the eyes. The eyes are of a deep chestnut colour, long and narrow in their shape, and the eye-lids, at the extremity next the nose, instead of forming an angle, as in Europeans, are rounded into each other, exactly like those of the Chinese. Their mouth is of the ordinary size, the lips thinner than those of the Negroes and Caffres, and the teeth beautifully white. The hair of their heads is of a singular nature, growing in small tufts at certain distances from each other, and extremely hard and frizzled, resembling, when short, the bristles of a shoe-brush twisted into round lumps about the size of a large pea, and, when suffered to grow, hanging about the neck in strong tassels like fringe. The colour of their skin is that of a yellowish brown or faded leaf. Their figure, especially when young, is not devoid of symmetry. They are erect, clean-limbed, and well proportioned; their hands, feet, and all their joints, remarkably small; and the muscular parts of their body delicately formed, so as to indicate rather feminine inactivity, than masculine exertion. Some of the women, in their youth, and before child-bearing, are described as models of perfection in the human figure; every joint and limb being well shaped and turned; their breasts round, firm, and distant; their hands and feet small and delicately formed; and their gait not altogether deficient in grace. But, at an early period of life, and immediately after the birth of their first child, their beauty vanishes; their breasts begin to grow loose and flaccid, and at length become enormously distended; their bellies protrude, and their posteriors acquire immense masses of fat, so as to give to the spine an appearance of extraordinary curvature inwards. It is very rarely that a cripple or deformed person is seen among the Hottentots of either sex; and they are not subject to any particular diseases. Their health is generally sound; and their life, if not cut short by accident or violence, is usually terminated by a gradual decay. But they are not so long-lived as the natives of most other countries, which resemble their own in point of temperature; and it is a rare occurrence when any of them attains the age of sixty years.

The dress of a Hottentot is very simple; and in summer is so trifling, as not to deserve the name of covering. It consists of a belt cut from the hide of some animal, and fastened round their body. From this strap is suspended in front a kind of case or bag made of the skin of a jackal with the hair outwards; and which is intended to receive those parts, which modesty requires to be concealed. From the back part of the girdle hangs a piece of stiff dried skin, shaped like an isosceles triangle, with the point uppermost, and reaching nearly to the middle of the thigh. Sometimes two of these pieces are used; but these straps, especially when the wearer is walking or running, entirely fail to answer the purpose of concealment; and are conjectured to have been originally intended rather as a kind of artificial tail, to fan the body by its motion, and to lash away troublesome insects. In the winter months, they wear cloaks made of skins, generally of sheep, which are worn, as the weather requires, either with the wool inwards or outwards; and which serve as blankets and bedding through the night, as well as for a garment through the day. The women suspend from their belt in front a kind of apron made of skin, but cut into threads, which hang in a bunch between the thighs, and reach about half way to the knee; or they wear a smaller apron about seven or eight inches wide, not divided into threads, but ornamented with shells, metal buttons, and any of their most showy trinkets. In place of the tail worn by the men, they have a sheep's skin, which entirely covers the posterior part of the body from the waist to the calf of the leg, and makes a rattling noise as they walk. Instead of the thongs of dried skin, which formerly covered their legs from the ankle to the knee, as a protection against the bite of poisonous animals, they have substituted strings of glass beads and shells. These they wear also in great abundance around their necks and arms. Some of them have skin caps on their heads, differently shaped and adorned, according to the fancy of the wearer; and they have sheep skin cloaks resembling those of the men. When these cloaks are laid aside, which is commonly the case in the warmer weather, both sexes may be said to be nearly naked; but their bo-

* One woman mentioned to Mr Campbell that she had born ten children, who had all been destroyed by lions, tygers, and serpents.

dies are in some measure protected from the influence of the sun or air by the unctuous matter which they rub over the whole of their persons; and which, however filthy in itself, is a very natural and useful resource in hot climates, to prevent the skin from being parched and shrivelled by the scorching heat. It is supposed that a similar practice in parallel latitudes would prevent that disgusting and dreadful disorder, the elephantiasis, which is so common in many hot countries, but which, with most other cutaneous diseases, is wholly unknown among the Hottentots.* This greasy covering, applied from time to time, and accumulating perhaps for a whole year, sometimes softening in the sun, or melting before a fire, catches up the dust and dirt, and gradually covers the surface of the body with a thick black coating, which entirely conceals the natural colour of the skin. This native hue is perceivable only on the face and hands, which are kept rather cleaner than the other parts of the body, not by washing them in water, which would have no effect upon the grease, but by rubbing them with the dung of cattle.

The Hottentots are often reduced, especially in their native state, to live upon gums, roots, and the larvæ of insects, and at times make a kind of bread from the pith of the palm tree; but their universal delight is to indulge in animal food. They are remarkably patient of hunger, and are able to fast a very long time; but are equally voracious when supplied with their favourite diet, and are described as the greatest gluttons on the face of the earth. Their manner of eating sufficiently indicates the voracity of their appetite. They cut a large steak from the carcase upon which they feed, and, passing the knife in a spiral manner from one edge till they reach the middle, form it into a string of flesh two or three yards in length. This they coil round and lay upon the hot ashes; and, when the meat is just warmed through, they grasp it in both hands, and, applying one end of the string to their mouth, proceed without intermission, and with considerable expedition, to the other extremity. They do not think of cleaning the meat from the ashes of the green wood, which serve as a substitute for salt; and they wipe their hands, when done with eating, merely by rubbing them on different parts of their body. They are passionately fond of ardent spirits and tobacco; and, to make as much as possible of the flavour of the latter luxury, they purposely employ a very short pipe.

The Hottentot families, who engage in the service of the colonists, live in small straw huts around the farm house. In a more independent state, they horde together in kraals or villages, where the houses are commonly ranged in a circle, with the doors opening towards the centre, and thus forming a kind of court, into which their cattle are collected at night, to preserve them from the beasts of prey. The huts are generally circular in their form, resembling a beehive, covering a space about twenty feet in diameter, but commonly so low in the roof, that, even in the centre, it is rarely possible for a man of middle size to stand upright. The fire place is situated in the middle of the apartment, around which the family sit or sleep in a circle; and the door, which is seldom higher than three feet, is the only aperture for admitting the light, or letting out the smoke. The frame of these arched habitations is composed of slender rods, capable of being bent in the desired form, some parallel with each other, some crossing the rest, and others bound round the whole in a circular direction. Over this lattice work are spread large mats, made of reeds or rushes, which are about six or ten feet long, and sewed together with a kind of thread, or rather catgut, made from the dorsal sinews of different animals. These materials are easily taken down, and removed on the backs of the oxen, when there is occasion to change the place of residence.

These free Hottentots depend for subsistence upon the milk and flesh of their cattle, and the produce of their skill in the chace. They are excellent marksmen with the musket, but still make use occasionally of their ancient weapons, the Hassagai or javelin, and bow with poisoned arrows. The Hassagai is an iron spear about a foot in length, fastened to the end of a tapering shaft about four feet long, which is thrown from the hand by grasping it in the middle, raising it above the head, and delivering it with the fore-finger and thumb. The bow is a plain piece of wood, seldom much more than a yard long, and sometimes tapering to a point at each extremity. It is furnished with a string composed of hemp, or the fibres of animal-tendons twisted into a cord. The arrows are short, and consist of a reed about a foot in length, with a piece of solid polished bone at one end, about five inches long, the top of which is sometimes pointed to serve as the head, but generally cut square, and provided with a small sharp piece of iron in the shape of an equilateral triangle. This is bound tight to the bone with threads, along with a bit of pointed quill, turning to the opposite end of the arrow by way of barb, and intended at once to increase the difficulty of extracting the weapon from the wound, and by tearing the flesh to make the poison mix more readily with the blood. The poison is frequently taken from bulbous roots, or the most venomous serpents; but is also prepared by macerating the leaves or branches of poisonous plants, and thickening the juices, by boiling on the fire or evaporation under the heat of the sun. This preparation, in the consistence of varnish, is laid with a brush over the thread which binds on the tip of the arrow. Whenever an animal is killed with these arrows in hunting, the flesh around the wound is instantly cut away, and the blood squeezed out of the flesh. The quiver is made of a piece of wood hollowed out, frequently of the stem of an aloe, with a lid of skin or leather; and generally contains a dozen arrows, a brush for laying on the poison, and a sand stone to whet the points of the weapons.

The Hottentots may be said to be entirely ignorant of arts and manufactures, except the formation of coarse earthen ware, the sewing of sheep skins for their winter garments, the preparation of poisons, and the making of bows and arrows.

They discover very little taste for music; but a few instruments of sound have been observed among them. One is a kind of guitar with three strings stretched upon a piece of hollow wood, which has a long handle, and is called in their language *gabowie*. Another consists of a piece of sinew or intestine, twisted into a small cord and fastened upon a hollow stick about three feet long, by a piece of quill at one end fixed into the stick, and by a small peg at the other, which is made to turn for the purpose of stretching the string to the degree required. This instrument is called the *gowra*, and is played by applying the mouth to the quill, and producing faint murmuring notes, by giving a vibratory motion to the string. A sort of flute made of the bark of trees is also used among them.

The physical knowledge of the Hottentots is extremely limited. All their astronomy consists in having a name for

* A similar practice prevails among the inhabitants of Tombuctoo, as observed by the American sailor Adams. "It is the universal practice of both sexes," says his Narrative, "to grease themselves all over with butter produced from goats' milk, which makes the skin smooth, and gives it a shining appearance. This is usually renewed every day; and, when neglected, the skin becomes rough, greyish, and extremely ugly."

the sun, another for the moon, and a third for the stars. Their reckoning of time scarcely extends beyond the period of a day, and expresses events past only by saying, that they were before or after some memorable occurrence. They indicate the time of the day when any thing happened, by pointing to the place in the heavens where the sun then was; and the seasons of the year, by the number of moons before or after the time when the roots of the *iris edulis* (once a considerable article of their sustenance) are ready for use. None of those whom Mr Barrow saw in the more distant parts of the colony could reckon beyond the number five, or put two numbers together without the help of their fingers.

The language of the Hottentots is perhaps one of the most extraordinary forms of speech in use among human beings. Its principal peculiarity is, a strong clacking of the tongue, in uttering every monosyllable, and every leading syllable of larger words. This sound is formed by suddenly retracting the tongue from the teeth or palate, according to the signification of the word to be uttered, and in some measure answering the part of inflexions, &c. The sound of the dental clack is said to be exactly the same as that which is sometimes used to express impatience; and that of the palatial stroke is more full and sonorous, not unlike the clucking of a hen to her chickens. These sounds are thrown out at the same moment with the syllable, so that they cannot be said to precede or follow, but rather to accompany it. Though the difficulty of uttering and appropriating these sounds appear to Europeans extreme, yet it is not insurmountable; and most of the Dutch colonists are able to speak the Hottentot language with great fluency. Many vocables in the language seem to have been originally exact imitations of nature, and many of the names of animals, especially, are obviously suggested by their distinguishing cry; such as, *kraak*, a frog; *mnoo*, an ox; *meau*, a cat; *hahæ*, a horse; *hurroo*, the sea; *kaboo*, a gun. This last word particularly is so pronounced as to imitate the report of a musket. The syllable *ka* is thrown out with a strong palatial stroke of the tongue, expressing the stroke of the flint; while the last syllable *boo* is uttered with a full mouth, outstretched lips, and prolonged sound, descriptive of the report. We add a few of the common vocables; and a Hottentot version of the Lord's prayer, as a slight specimen of the language.

Few ancient usages are retained among the scattered tribes of the Hottentots; and all traces even of their religion, if they ever had any knowledge or observances on the subject, are now lost. No particular ceremonies are observed either at their marriages or funerals; and they are more like a people who have never been formed into any kind of communities, than the remains of a tribe or nation who had once possessed any laws or customs common to them all. The truest specimens of the unmixed Hottentot people and practices are probably to be found among the Bosjesmans, (see BOSJESMANS;) but, whether that wretched race existed in their present condition before the dispersion of the Hottentots, or in consequence of that event, must remain a subject of mere conjecture. A few detached customs and practices of the Hottentots may be briefly stated. One of the customs still generally prevalent is, to shave the heads of young girls as soon as the first symptoms of maturity appear, to remove all their ornaments, and wash the whole body thoroughly; and to restrict them to a milk diet, and seclude them from the company of men during the continuance of the periodical symptoms. Though they inter their dead without any ceremony, it is a common practice to pile a heap of stones over the grave; and it is firmly believed among them, that some misfortune would soon befal the individual who should pass the place without adding a stone to the heap. This custom is supposed to have originated in a wish to secure the bodies of the deceased from being dug up and devoured by wild beasts. The Hottentots, in drinking from a pool or stream, throw the water in their mouths with their right hand in a very expert and expeditious manner, seldom bringing the hand nearer the mouth than the distance of a foot. They generally wash their poisoned wounds with a mixture of urine and gun-powder, besides frequently using the actual cautery; and, for the most part recover easily, unless wounded severely. They kill their cattle, by thrusting a sharp-pointed instrument into the spinal marrow immediately behind the horns; and the animal being thus instantaneously deprived of life, the throat is cut to let out the blood. Among the Hottentots who reside at the mouth of the Orange river, a superstitious practice prevails, similar to what has been observed among the South Sea islanders, of cutting off the first joint of their little finger, as a remedy for a particular disease, to which they are subject when young.

The most prominent point in the habits and dispositions of the Hottentots is their extreme indolence, which even the urgent calls of hunger are scarcely able to overcome. Provided they are allowed to sleep, they would willingly fast the whole day, rather than undergo the trouble of digging the ground for roots, or procuring food by the chace; and Mr Barrow particularly relates, that in the course of his journies, the Hottentot servants frequently passed the day without a morsel of food, rather than walk half a mile for a sheep. They are habituated from their infancy to a life of sloth; and having obtained what is barely sufficient to support nature, contentedly spend the day as well as night in sleeping under a bush upon their sheep-skin. Even in the service of the Dutch colonists, they are rather confirmed in their laziness, than cured of it; as, in every farm-house there is so great a multitude of servants, that little work falls to the share of each individual. It is not uncommon to see twenty or thirty, where there is not employment for more than four or five; so that one of the domestics, during the space of a whole day, may have only to bring his master's whip from the next apartment; another to fetch his mistress's fire-box and place it under her feet; and a third to supply some of the family, three or four times in the day, with lighted wood, to kindle their tobacco pipes. They are by no means, however, a stupid people. They are uncommonly expert in finding out a passage over a desert uninhabited country. They are remarkably quick-sighted, and can discover the game in the chace at a very great distance. They will follow with the eye the flight even of a bee to an incredible distance, watching its motions, and tracing out its nest. They are able to distinguish the prints of the feet of whatever animal they chance to pursue, if they be at all acquainted with it; and would single out among a thousand foot-marks those of their companions. They learn the Dutch language with great facility; and though seldom employed as domestic servants by the colonists at the Cape, they can be taught to do every kind of work with as much propriety as Europeans. They are a mild, quiet, and rather timid people; but endure pain with extraordinary patience, and when led on by superiors, will encounter danger with sufficient alacrity. They are honest and faithful, and have little of that cunning which savages generally possess; but are ready to divulge the truth, when charged with crimes of which they have been guilty. They seldom quarrel among themselves, or make use of provoking language; but are kind and affectionate to one another, and ready to share the last morsel with their companions. Though extremely phlegmatic, they are not incapable of strong attachments, and are particularly sensible to any act of kindness. These are sensations, however, which they have, unhappily, few opportunities of indulging. In the state of hard bondage and cruel oppression under which they spend their miserable existence, the muscles of their countenance are rarely seen to relax into a smile, but are constantly overspread with the deepest melancholy. It has been sufficiently proved, that under humane treatment they are capable of being rendered active, industrious, and useful members of society. About 500 of them had been embodied by the Dutch in a corps called the Cape Regiment; and, though unsupported, had acted with considerable spirit in opposing the British troops at the capture of the colony in 1795. General Sir James Craig found it expedient to take them into the British service, and to increase their numbers. They became excellent soldiers, orderly, tractable, and faithful, ready on all occasions to obey the commands of their officers with cheerfulness and alacrity. "Never," says the above-mentioned officer, "were people more contented, or more grateful for the treatment they now receive. It is with the opportunity of knowing them well, that I venture to pronounce them an intelligent race of men. All who bear arms exercise well, and understand immediately and perfectly whatever they are taught to perform. Many of them speak English tolerably well. We are told, that so great was their propensity to drunkenness, we should never be able to reduce them to order or discipline; and that the habit of roving was so rooted in their disposition, we must expect the whole corps would desert the moment they had received their clothing. With respect to the first, I do not find they are more given to the vice of drinking than our own people; and as to their pretended propensity to roving, that charge is fully confuted by the circumstance of only one man having left us since I first adopted the measure of assembling them, and he was urged to this step from having accidentally lost his firelock."—"Of all the qualities, it will little be expected I should expatiate upon their cleanliness; and yet it is certain, that at this moment our Hottentot parade would not suffer in a comparison with that of some of our regular regiments. Their clothing may perhaps have suffered more than it ought to have done in the time since it was issued to them, from their ignorance of the means of preserving it; but those articles which are capable of being kept clean by washing, together with their arms and accoutrements, which they have been taught to keep bright, are always in good order. They are now likewise cleanly in their persons; the practice of smearing themselves with grease being entirely left off. I have frequently observed them washing themselves in a rivulet, where they could have in view no other object but cleanliness." These men shewed themselves highly deserving of this favourable testimony, during three years service in the distant district of Graaff Reynet, where they were required, by an unfortunate train of events, to act against their own countrymen and comrades; yet, during all that time, according to the testimony of Mr Barrow, they never shrunk from their duty, and only one man deserted in the whole corps. They became so attached to the British government, that, after the evacuation of the colony, they refused to enter again into the service of the Dutch; and most of them, upon being disbanded, fled into the interior to join their oppressed countrymen.

The labours of Christian missionaries, particularly of the Moravian Brethren, have not been less successful in forming the Hottentot race to live under the influence of religious principle, and to fulfil the duties of civilized society. The progress of their disciples at Bavian's Kloof, so far back as the year 1798, is thus described by Mr Barrow:—"Early in the morning I was awakened by the noise of some of the finest voices I had ever heard; and, on looking out, saw a group of female Hottentots sitting on the ground. It was Sunday; and they had assembled thus early to chaunt the morning hymn. They were all neatly dressed in printed cotton gowns. A sight so very different from what we had hitherto been in the habit of observing, with regard to this unhappy class of beings, could not fail of being grateful; and at the same time, it excited a degree of curiosity as to the nature of the establishment."—"These missionaries have succeeded in bringing together into one society more than six hundred Hottentots, and their numbers are daily increasing. These live in small huts dispersed over the valley, to each of which was assigned a patch of ground for raising vegetables. Those, who had first joined the society, had the choicest situations at the upper end of the valley near the church; and their houses and gardens were very neat and comfortable; numbers of the poor in England not so good, and few better. Those Hottentots, who chose to learn their respective trades, were paid for their labour as soon as they could earn wages. Some hired themselves out by the week, month, or year, to the neighbouring peasantry; others made mats and brooms for sale. Some bred poultry; and others found means to subsist by their cattle, sheep, and horses."—"On Sundays, they all regularly attend the performance of divine service; and it is astonishing how ambitious they are to appear at church neat and clean. Of the three hundred, or thereabouts, that composed the congregation, about half were dressed in coarse printed cottons, and the other half in the ancient sheep skin dresses; and it appeared, on inquiry, that the former were the first who had been brought within the pale of the church; a proof that their circumstances at least had suffered nothing from their change of life."—"The deportment of the Hottentot congregation during divine service was truly devout. The discourse, delivered by one of the fathers, was short, but replete with good sense, pathetic, and well suited to the occasion: tears flowed abundantly from the eyes of those, to whom it was particularly addressed. The females sung in a style that was plaintive and affecting; and their voices were in general sweet and harmonious." This establishment is described by Lichtenstein, little more than six years afterwards, as containing two hundred houses and huts, built in regular streets, and occupied by nearly 1100 Hottentots; several of whom had become very expert in various kinds of iron work, particularly in the manufacture of knives. "The men are clothed in linen jackets and leather small clothes, and wear hats; and the women have woollen petticoats, cotton jackets with long sleeves, and caps. Other missionaries have collected the wilder Hottentots in the more distant parts of the colony; and have succeeded in instructing and civilizing them in various degrees, proportioned to the duration and circumstances of the different establishments. Even the Bosjesman Hottentots have been found, in places beyond the limits of the colony, to be a docile and tractable people, inoffensive in their manners, and extremely grateful to their benefactors. The recovery of the colony by the British has at least secured to these defenceless tribes a protection from cruel oppression, and an encouragement to every benevolent exertion for their benefit, which they never enjoyed under the Dutch government. See Sparrman's *Voyage to the Cape of Good Hope*. Paterson's *Journies into the Country of the Hottentots*. Barrow's *Travels into the Interior of Southern Africa*. Campbell's *Travels in Africa*. HOURS. See Chronology.

HOUSSA, or Haoussa, the capital of a kingdom of the same name in Africa, is supposed to be situated two days journey south from the Niger, and about 200 miles south east from Tombuctoo. As it appears to have been unknown to the African geographer Leo, it is suspected to be of modern date; and, as Park could hear nothing of Tokrur or Tekrur, mentioned by Edrissi and Abulfeda as the metropolis of a great central empire of Africa, it is conjectured that Houssa must have superseded that ancient capital as the seat of government. Former accounts represented it as almost equal to London or Cairo in population, and its inhabitants as acquainted with the art of writing, and other civilized attainments. The country along the banks of the Niger, between Houssa and Tombuctoo, was also described as fertile, and well inhabited. All the native travellers, with whom Park conversed, assured him that Houssa was larger and more populous than Tombuctoo; and that the state of trade, police, and government, were nearly the same in both places. The recent Narrative of Adams, the American sailor, enables us to estimate the amount of this comparison, and to form some idea of Houssa, when he tells us, that Tombuctoo, to which it bears so near a resemblance, covers about as much ground as Lisbon with houses irregularly scattered; that it contains no shops for its boasted commerce, but that the imported goods are deposited in the king's palace, till they are disposed of; that this royal residence and warehouse is constructed of mud, and altogether mean in its appearance; and that the principal food of the king and queen consists, like that of the people, of Guinea corn, boiled like burgoo, and eaten with goat's milk, to which, in the case of their majesties, is added the luxury of a little butter. See Park's *Travels* and *Appendix*; Adams' *Narrative*; and Tombuctoo. (*q*)

HOWARD, John, the celebrated philanthropist, was born at Enfield, about the year 1727. His father was originally an upholsterer in Long-lane, Smithfield; but, having acquired a handsome fortune, had retired from business several years before his death. He was a strict Protestant dissenter; and, wishing that his son should be educated in the same principles, placed him under a preceptor at some distance from London, who seems to have been more distinguished by his religious character than literary qualifications. Under the tuition of this person, young Howard continued for the space of seven years, without being thoroughly instructed in any one branch of knowledge; and, though he was afterwards removed to the academy of Mr Eames, he never surmounted the deficiencies of his early education. He was not able to write his native language with grammatical correctness; and, excepting the French, his acquaintance with other languages was very superficial. His father died when he was young, and directed, in his will, that his son should not come to the possession of his property till the twenty-fifth year of his age. In conformity, also, it is supposed, to the wishes of his parent, he was bound apprentice to a wholesale grocer in the city; but he found this employment extremely irksome; and, as soon as he came of age, bought up the remainder of his time, and set out on his travels to France and Italy. Upon his return to England, he lived in the style of other young men of fortune; but had acquired a taste for the arts, and an attachment to the study of nature. The delicacy of his bodily health required him to take lodgings in the country, and to follow a rigorous regimen of diet, which laid the foundation of his future extraordinary abstemiousness. About the 25th year of his age, he married Mrs Sarah Lardeau, as a return of gratitude for her kind attention during his invalid state while he lodged in her house at Stoke-Newington; but she was twice as old as himself, as well as of a sickly habit, and died at the end of three years after their marriage, in the year 1756. After the death of his wife, he set out upon another tour, which he designed to have commenced with a visit to Lisbon, which had been recently overthrown by an earthquake; but the packet, in which he sailed, was taken by a French privateer, and he endured for some time all the hardships of a prisoner of war in France. The sufferings of his countrymen in the same situation made a strong impression on his mind, and first directed his attention to the condition of those unhappy persons who are doomed to inhabit the cells of a prison. Having remained abroad only a few months, he fixed his residence, after his return, on his estate at Cardington, near Bedford; and, in 1758, was united in marriage to the eldest daughter of Edward Leeds, Esq. of Croxton in Cambridgeshire. In this connexion and situation he spent the most tranquil and happy years of his life, occupying his leisure and his wealth in executing plans of beneficence for the more indigent part of mankind. But his domestic felicity was fatally interrupted by the death of his wife in the year 1765, soon after the birth of her only child; and, for many years afterwards, he cherished her memory with the most affectionate sorrow. For some time he was attached to his home, by an anxious attention to the education of his son; but the child was sent to school at an early age, and Mr Howard began to assume a more public character. In 1773 he was nominated High-Sheriff of the county of Bedford; and entered upon his office with a resolution to perform its duties with his accustomed punctuality. In the inspection of the prisons within his jurisdiction, his humanity became deeply engaged by the distresses which he witnessed; and, in the progress of his enquiries, he was led to extend his investigation to all the places of confinement and houses of correction throughout the kingdom. He pursued his object with so much assiduity, that, in the beginning of 1774, he was desired to communicate his information to the House of Commons; and, in consequence of his representations, two bills were brought forward for the relief and health of prisoners. Being desirous, before he should publish his account of English prisons, to suggest remedies, as well as to point out defects, he resolved to examine personally the practice of the continental kingdoms in this branch of police. For this purpose, in 1775, he visited France, Flanders, Holland, and Germany; repeated his visit in 1776, extending his tour to Switzerland; and, during the intervals of these travels, made a journey to Scotland and Ireland, and most of the counties of England. In 1777, he published the information which he had collected with so much risk, toil, and expence, and dedicated his work to the House of Commons. Anxious to diffuse the knowledge of facts so interesting to humanity, and, at the same time, desirous to obviate any suspicion of his wishing to repay his benevolent labours by the profits of bookmaking, he not only presented copies of his work to the principal persons in the kingdom, and his particular friends, but insisted upon fixing the price of the volume at a lower rate than the original expence of publication. In the conclusion of the work, he pledged himself, if a thorough parliamentary enquiry were instituted for the improvement of prisons, to undertake a more extensive journey into foreign countries, for the purpose of obtaining additional information. The House of Commons having zealously entered upon the business of regulating places of confinement, Mr Howard, agreeably to his promise, which he was well inclined to fulfil, began a new tour in 1778. In his progress, he revisited the establishments of a penitentiary kind in Holland; directed his course through Hanover and Berlin to Vienna; went to Italy by way of Venice; proceeded as far south as Naples, returning by the western coast to Switzerland; pursued the course of the Rhine through Germany; and, crossing the Low Countries, returned to England in the beginning of the year 1779. During the spring and summer of the same year, he made another complete tour of England and Wales, besides taking a journey through Scotland and Ireland. In the year 1780, he published the results of this extensive research, as an appendix to his former work; and also a new edition of that publication, in which all this additional matter was incorporated. Still intent upon the farther improvement of his plans, he resolved to explore those countries of Europe which he had not yet visited; and, in 1781, he set out on a tour to Denmark, Sweden, Russia, and Poland, from which he returned about the end of the year. In the year following, he made another complete survey of the prisons in England, and another journey into Scotland and Ireland. In 1783, he examined the prisons of Spain and Portugal, and returned through France, Flanders, and Holland. In the summer of the same year, he again travelled into Scotland and Ireland, and visited many of the English prisons. In 1784, he communicated to the public the fruits of the preceding three years investigations, in the form of another appendix, with a new edition of the main work, comprising all the additions. With the view of acquiring information respecting the means of preventing contagion in general, and the formation of establishments for guarding against pestilential infection, he resolved to visit the principal Lazarettos in Europe, and to extend his researches to those countries which are most subject to the ravages of the plague. Aware of the hazards which he should have to encounter in this most perilous of all his journeys, he would not permit any of his servants to partake of these dangers, but determined to travel without attendants. About the end of the year 1785, he entered upon this tour, taking his way through Holland and Flanders to the south of France. His former visits, however, had so much alarmed the jealousy and excited the displeasure of the government in the last mentioned country, that he was apprehensive of his personal safety; and travelled with the greatest secrecy under the character of an English physician. From Nice, he went to Genoa, Leghorn, and Naples; thence to the islands of Malta and Zante; and next to Smyrna and Constantinople. Determined to obtain, by personal experience, the fullest information of the mode of performing quarantine, he returned to Smyrna, where the plague then was, for the purpose of going to Venice in a vessel with a foul bill of health, which would necessarily subject him to the utmost rigour of the process. In the course of his voyage, the ship in which he was a passenger was attacked by a corsair from Tunis, which was beaten off after a smart skirmish, in which he rendered essential service, by pointing some of the guns. After leaving his quarters in the Lazaretto of Venice, in which his health and spirits suffered considerably, he proceeded, at the close of the year 1786, to Vienna, where he had a private conference with the Emperor Joseph II.; and, returning through Germany and Holland, arrived safe in England, in the beginning of the year 1787. During his absence on this journey, he received the afflicting intelligence of his son having fallen into a state of decided insanity; his only child, of whom he used to speak with all the pride and affection of a parent, and whose hopeless calamity it required all the fortitude of his mind, aided by the consolations of religion, to sustain. At the same time he was informed of a public subscription having taken place among his countrymen, to express their esteem and veneration for his character, by erecting a statue or monument to his honour. This design, instead of tending to console his wounded spirit, only added to his distress; and he instantly exerted himself to prevent its being carried into execution. In corresponding with his friends, he expressed, in the strongest terms, his aversion to the proposed honour; and, in a letter to the subscribers, while he acknowledged his grateful sense of their approbation, he displayed so determined a repugnance to the measure, that the matter was dropped during his life. In 1787 and 1788, he made several visits to the prisons, bridewells, infirmaries, &c. of England, Ireland, and Scotland, and, in 1789, he put to the press an account of his observations in these various journeys, abroad and at home; containing an account of the various Lazarettos in Europe, papers relative to the plague, with additional remarks on prisons and hospitals. After the printing of this work, he remained but a short time at home; and prepared to revisit Russia and Turkey, and to extend his tour to Asia Minor, Egypt, and the coast of Barbary. In this new journey, he is understood to have had no peculiar object in view; and to have been actuated chiefly by a conviction, that, in such researches, he was pursuing the path of his duty; that, in those countries where he had formerly travelled, he might be still farther instrumental in relieving human suffering; and that, in exploring new regions, he might discover farther subjects of observation connected with his main pursuit. He had resolved to undertake this journey also without an attendant; and it was only in consequence of most urgent entreaties, that a faithful servant obtained permission to accompany him. Arriving in Holland, in the beginning of July 1789, he proceeded through the north of Germany, Prussia, Courland, and Livonia, to Petersburgh; thence to Moscow, and finally to the extremity of European Russia, on the shores of the Black Sea, where he fell a lamented victim to one of those infectious diseases, the ravages of which he was exerting every effort to restrain. While residing at Cherson, he was earnestly requested to visit a young lady, about sixteen miles from that place, who had caught a contagious fever; and it was his own opinion, that from her he received the disease. During his illness, which from its commencement he considered as likely to prove fatal, he received a letter from a friend in England, containing favourable accounts of his son. He was greatly affected by the intelligence; and often desired his servant, if ever his son should be restored to reason, to tell him how much he had prayed for his happiness. Except during the fits, with which he was occasionally seized in the course of the distemper, he retained his faculties till within a few hours of his death, which took place on the 20th January 1790. He was buried, according to his own request, at the villa of M. Dauphine, about eight miles from Cherson; where, instead of a sun-dial, which he had desired to be erected over his grave without any inscription,* a rude pyramid surrounded by posts and chains, was raised by the inhabitants of the neighbourhood.

Mr Howard, though frequently requested, would never consent to sit for his picture; and the various portraits, which have been given of him, are said by his intimate friends to be totally unlike. The nearest resemblance, is said to be a head sketched by an artist in London, and copied for Dr Aikin's *View of his Character;* which, though considered as somewhat of a caricature, is said to have exactly the expression of his countenance, when in a very serious and attentive mood. His eye was lively and penetrating, and his features strong and prominent; his gait quick, and his gestures animated. In his youth, his constitution was delicate, and his habit supposed to be consumptive; but he afterwards attained (probably in consequence of his abstemiousness in diet and application to exercise) a power of enduring, without inconvenience, the greatest corporeal privations and fatigues. The strict regimen in point of food, which he had originally adopted from a regard to health, he afterwards continued from choice. He made no use of animal food, or of fermented and spirituous drinks. Water and the plainest vegetables sufficed for his ordinary diet, and milk, tea, butter and fruit, were his luxuries. He was sparing in the quantity of his food, and indifferent as to the stated times of taking his meals. He was equally tolerant of heat, cold, and all the vicissitudes of climate; and could without difficulty dispense with the ordinary seasons and proportions of sleep. When he travelled in England or Ireland, it was generally on horseback, and he rode regularly about forty English miles a day. He was never at a loss for an inn; but, in Ireland or the Highlands of Scotland, could accommodate himself with a little milk at any of the poor cabins in his way. When he came to the town where he was to sleep, he bespoke a supper like other travellers, but made his servant remove it, while he was preparing his bread and milk. When he travelled on the continent, he usually went post in his own chaise, in which he slept as occasion required; and has been known to travel twenty days and twenty nights without going to bed. He used to carry with him a small tea-kettle, some cups, a little pot of sweet-meats, and a few loaves. At the post-house he would get some water boiled, send out for milk, and make his repast, while his servant went to the inn. He was remarkably attentive to the perfect cleanliness of his whole person; and water was always an indispensable necessary for his ablutions. His peculiar habits of life, and his exclusive attention to a few important objects, made him appear more averse to society than he really was. He assiduously shunned all engagements, which would have involved him in the irregularities of general intercourse; but he received his select friends with the truest hospitality, and was often extremely communicative in conversation, enlivening a small circle with the most entertaining relations of his travels and adventures. He was never negligent of the received forms of polite life; and, however much he might be charged with singularities, no one could refuse his title to the character of a gentleman. He was distinguished especially by his respectful attention to the female sex; and nothing afforded him so much pleasure as the conversation of women of good education and cultivated manners. His own voice and demeanour were so gentle as to be almost denominated feminine; and furnished a striking contrast to the energy of his mind and the extent of his exertions. His language and manners were invariably pure and delicate; and it must have been no small triumph of duty over inclination, which brought him to submit, in the prosecution of his benevolent designs, to such frequent communications with the most abandoned of mankind. Yet the nature of his errand appears to have inspired the most profligate with respect; and he has himself recorded, that he never met with a single insult from the prisoners, in any of the jails which he visited. He possessed an elegant taste for neatness in his house and furniture; and employed much of his leisure time in the cultivation of useful and ornamental plants. In the course of his various travels, he brought home many curious vegetables; and his garden became an object of curiosity, both for the elegant manner in which it was planned, and for the excellent productions which it contained. He was elected a Fellow of the Royal Society in 1756; and contributed a few short papers which have been published in its Transactions.† His philosophical researches were chiefly directed to meteorological observations, and he seldom travelled without some instrument for that purpose. He applied himself, likewise, with considerable assiduity, to the prosecution of experiments on the effects of the union of the primary colours in different proportions. In his intellectual character, he discovered less of the faculty of extensive comprehension than of laborious accuracy. By his talent of minute examination and detail, he was peculiarly qualified for the patient investigations in which he engaged; and in his modest estimates of his own abilities, he was used to say of himself, "I am the plodder, who goes about to collect materials for men of genius to make use of." His liberality with respect to pecuniary concerns, was early and uniformly displayed; and he appears never to have considered money in any other light than as an instrument of procuring happiness to himself and others. Contented with the competence which he inherited, he never thought of increasing it; and made it a rule with himself to lay up no part of his annual income, but to expend in some useful or benevolent scheme the surplus of every year. Moderate in all his desires, and untainted by the lust of growing rich, he was elevated above every thing mean and sordid. He expended much in charities, and displayed in all his transactions

* He had a strong dislike of monumental honours, and had once given directions before he set out on a journey, that in case of his death his funeral expences should not exceed ten pounds; that his tomb should be a plain slip of marble placed under that of his wife in Cardington church, with this inscription, "John Howard died ——, aged ——. My hope is in Christ."

† See the *Phil. Trans.* vols. liv. lvii. lxi.

a spirit of the utmost honour and generosity. He imbibed from his earliest years a devout principle of religion, which continued steady and uniform through every period of his life. The body of Christians, to whom he particularly attached himself, were the Baptists; and the system of belief, to which he adhered, was what has generally been called moderate Calvinism. But he was always less solicitous about modes and opinions, than the internal spirit of piety and sincerity; and though always warmly attached to whatever interests he espoused, he possessed that true spirit of catholicism, which led him to honour virtue and religion wherever he found them. It was his constant practice to join in the service of the established church, when he had not the opportunity of attending a dissenting place of worship; and he often dwells in his works, with great complacency, on the pure zeal and genuine Christian charity, which he frequently discovered among the Roman Catholic clergy. But the peculiar feature of his character certainly consists in that decisive energy, and unshaken perseverance, with which he prosecuted the great work of benevolence, to which he seemed to have devoted his life. He was distinguished by decision and dispatch in all his proceedings; and this was rather the predominant habit of his mind, than the occasional result of any excited feeling. "At no time of his life," says his friend and biographer Dr Aikin, "was he without some object of warm pursuit; and, in every thing he pursued, he was indefatigable in aiming at perfection. Give him a hint of any thing he had left short, or any new acquisition to be made; and, while you might suppose he was deliberating about it, you were surprised with finding it *was done*." Nor was it during a short period of ardour, that his exertions were thus awakened. He had the still rarer quality of being able, for any length of time, to bend all the powers and faculties of his mind to one point, unseduced by every allurement, which curiosity or any other affection might throw in his way, and unsusceptible of that satiety and disgust, which are so apt to steal upon a protracted pursuit."—"Impressed with the idea of the importance of his designs, and the uncertainty of human life, he was impatient to get as much done as possible within the allotted limits. And in this disposition consisted that enthusiasm, by which the public supposed him actuated; for, otherwise, his cool and steady temper gave no idea of the character usually distinguished by that appellation. He followed his plans, indeed, with wonderful vigour and constancy, but by no means with that heat and eagerness, that inflamed and exalted imagination, which denote the enthusiast." Neither was he moved, as some supposed, by mere sternness of principle, or rigidity of habit, or insensibility of feeling. "I have equally," says the last quoted author, "seen the tear of sensibility start into his eyes on recalling some of the distressful scenes to which he had been witness, and the spirit of indignation flash from them, on relating instances of baseness and oppression. Still, however, his constancy of mind and self-collection never deserted him: He was never agitated, never off his guard." His coolness and intrepidity proceeded both from nature and principle; and when marching in the path of duty, he was fearless of consequences. This resolute temper neither originated in any idea of his being moved by an irresistible impulse, or a persuasion of his being secured from the natural consequences of the dangers which he encountered; but from a steady sense of religious obligation and pious confidence, which rendered him superior to mere worldly considerations. His own testimony sufficiently expresses the sentiments by which he was actuated. "My medical acquaintance," he says in a letter during his last journey, "give me but little hope of escaping the plague in Turkey. I do not look back, but would readily endure any hardships, and encounter any dangers, to be an honour to my Christian profession." So heroic a philanthrophist, (though not devoid of some singularities and foibles, which have sometimes drawn the sneer of contempt from trivial and selfish minds, unworthy and incapable to pronounce upon a character so far above their sphere of judgment,) could not fail to attract the admiration of every friend of humanity. The sublimest strains of poetry and eloquence have been frequently devoted to the celebration of his exertions; and his name is become indissolubly associated with every idea of pure and elevated benevolence. The following tribute to his fame, which burst, in all the enthusiasm of genius, from the lips of Mr Burke, though probably familiar to the reader, can bear to be reperused, and may suitably close our feeble sketch of this extraordinary character.* "I cannot name this gentleman without remarking, that his labours and writings have done much to open the eyes and hearts of mankind. He has visited all Europe,—not to survey the sumptuousness of palaces, or the stateliness of temples; not to make accurate measurements of the remains of ancient grandeur, nor to form a scale of the curiosity of modern art; nor to collect medals, or collate manuscripts;—but to dive into the depths of dungeons; to plunge into the infection of hospitals; to survey the mansions of sorrow and pain; to take the gauge and dimensions of misery, depression, and contempt; to remember the forgotten, to attend to the neglected, to visit the forsaken, to compare and collate the distresses of all men in all countries. His plan is original: it is as full of genius as it is of humanity. It was a voyage of discovery; a circumnavigation of charity." See *various lives and anecdotes of Howard;* and particularly Dr Aikin's *View of his Life and Character.* (*q*)

HOWDEN, or HOVEDEN, a town of England, in the east riding of Yorkshire, is situated upon an inlet of the Ouse, named Howden Dike, which may be considered as the harbour of the town. Howden consists principally of two considerable streets, extending in the direction of north-east and south-west, intersected by three or four lesser ones. The town has of late years undergone very considerable improvements; and, though the houses are ancient, yet they are neatly built and commodious. The principal public buildings are, the moot-hall, a large edifice in the market, where the courts, &c. are held; a work-house, built by subscription in 1791, which contains from 20 to 30 paupers, who are maintained at an annual expence of 300*l.*; and the old Gothic church. This church is a large building in the form of a cross, and, excepting the chancel, which is of more recent date, it appears to have been built during the first period of the pointed arch style. The tower, which is quadrangular and well proportioned, is 135 feet high, and is said to have been built in 1390, by Walter Skirlaw, Bishop of Durham, as a place of refuge from the inundations of the Ouse and the Derwent, which were formerly very frequent. The chapter-house, which is now unfortunately in ruins, is reckoned a most beautiful specimen of the pointed style. The chancel, particularly the east end of it, is greatly admired. A peal of eight bells was cast for this church in 1775. The ruins of the palace of the bishops of Durham are situated almost close to the church-yard, and are now converted into a farm-house. One of the greatest horse fairs in the kingdom is held here on the 25th of September, and continues till the 3d of October. Besides the church and its two chapels of ease, there is an Independent and Methodist meeting-house.

HUDDERSFIELD, or HUTHERSFIELD, a town of England, in the west riding of Yorkshire, is situated on the river Colne, and on the Huddersfield canal. This town is chiefly celebrated for its woollen manufactures, which consist of narrow and broad cloths, serges, kerseymeres, frize, &c. The buyers and sellers of these goods formerly met in an open square; but in the year 1765, Sir John Ramsden, who possesses all the land which the town covers, and also a great many of the houses, built a commodious cloth-hall. It is a circular building of two stories, and is divided by a diametrical range into two semicircular courts, into which all the windows open. It is subdivided into ranges like streets; and the cloths are laid close together upon their edge on benches or stalls. Over the entrance, is a bell placed in a handsome cupola. The Huddersfield canal (see INLAND *Navigation*) extends 8 miles to the river Calder. Ruins, supposed to be the ancient city of *Cambodunum*, are to be seen on the castle hill, about two miles south of the town, and west of Almonsbury; but Mr Watson thinks they are of Saxon origin. The Roman road, however, passed near Almonsbury. There are several medicinal springs in the neighbourhood.

In 1811, the township of Huddersfield contained,

HUDSON'S BAY, lying between 55° and 65° of North Latitude, is about 250 leagues in length, and 200 at its greatest breadth. It is 140 fathoms deep in the middle, and is navigable during four months in summer, but is filled, all the rest of the year, with shoals of ice. Numerous rocks, sand-banks, and small islands, are dispersed through it, of which may be mentioned; Southampton island, in 64° north latitude, stretching about 100 leagues from north to south, but of very inconsiderable breadth; Marble island, in 62° north latitude, about 6 leagues long and two broad, composed of white marble, variegated with green, blue, and black patches; Carleton isle, in the south-east corner of the bay, covered with trees, moss, and shrubs. The entrance of the bay is a strait, of dangerous navigation, more than 200 leagues in length, and in some places of considerable breadth. It stretches from south-east to north-west, in 62½° north latitude, bounded on the north by the isle of Good Fortune, and on the south by Labradore. Its eastern extremity is formed by Cape Elizabeth on the north, and Cape Chudley on the south, between which is situated Resolution island, about 15 leagues in length, and a little westward Savage and Grass islands, almost uninhabited. In the north-west extremity, between Point Anne on the north, and cape Walsingham on the south, are several small islands, named Salisbury, Nottingham, Mill Diggs, and Mansfield. The principal bays of this inland sea are, James's Bay in the south-east corner, containing many islets; Button's Bay on the western coast; Chesterfield Inlet on the north-west coast, stretching far inland, and terminating in a large fresh water lake; Roe's Welcome, a deep inlet of the sea on the north coast; and Repulse Bay, still farther north. The most remarkable rivers which flow into it are, Great Whale river, East Main or Slude; Rupert's, which has its origin in lake Mistassins; Abbitibbe, flowing from a lake of the same name; Moose, and Albany, which all empty their streams into James's Bay; the Severn, which is supposed to proceed from lake Winipig; Nelson or Bourbon river, from a lake of the same name; and Missin-ni-pi,* or Churchhill river, which loses itself in the bottom of Button's Bay. The north coast of Hudson's Bay is yet imperfectly explored. The country on the east is part of Labradore, called East Main. The tract which stretches southwards below Button's Bay is called New South Wales, bounded on the south and east by Canada. The regions to the north-west are in like manner called New North Wales, and very little known; and on the west, is a vast tract of country, extending across the American continent to the Pacific Ocean, separated from the territories of Canada by a mountainous ridge in 49° north latitude, which covers the sources of the rivers flowing north and south.

Hudson's Bay was discovered in 1610 by Henry Hudson, who had been sent out, by the English Russia Company, in quest of a north-west passage round the American continent; but his crew having mutinied, left him, with his son and other seven persons, to perish in those seas, which now bear his name. It was afterwards more thoroughly explored by successive navigators employed by the same enterprising Company, particularly by Button in 1612; by Lucas Fox, and Thomas James, in 1631, the former equipped by government, and the latter by a company of Bristol merchants; and by Zacharias Gillam, in 1668, who was sent out by Charles II. at the solicitation of Prince Rupert, and was assisted by two French merchants of Canada, named de Grosseliers, who had previously made a voyage from Quebec to the scene of the present expedition. Gillam passed the winter in Rupert's river, where he built the first stone fort erected in the country, which he named Fort Charles, and provided it with a sufficient garrison. Before his return, the king had granted to Prince Rupert, and divers lords, knights, and merchants, associated with him, a charter, dated May 2d, 1669, in which he styled them "The Governor and Company of Adventurers trading from England to Hudson's Bay;" and, in consideration of their having, at their own costs and charges, 'undertaken an expedition to Hudson's Bay, in the north-west parts of America, for the discovery of a new passage into the South Sea, and for the finding of some trade for furs, minerals, and other considerable commodities, and of their having already made, by such their undertakings, such discoveries as did encourage them to proceed farther in pursuance of the said design; by means whereof, there might probably arise great advantages to the king and his kingdom,' absolutely ceded to the said undertakers, the whole trade and commerce of those seas, &c. in whatsoever latitude they might be, which are situated within the entrance of Hudson's Straits, together with all the countries upon the coasts

* A word signifying "Great Waters."

and confines of the said seas, straits, &c. so that they alone should have the right of trading thither; and whosoever should infringe this right, and be found selling or buying within the said boundaries, should be arrested, and all their merchandize be confiscated, so that one half should belong to the king, and the other half to the Hudson's Bay Company." Of this extensive grant the Company have enjoyed uninterrupted possession from the year 1669 to the present day, except during the space of 17 years, from 1697 to 1714, when the settlement was occupied by the French; but the charter, instead of promoting the progress of discoveries, is understood to have produced the opposite effect. The Company have been charged with having rather endeavoured to conceal, as much as possible, the situation of the coasts and seas connected with their territories; and even to influence those who had any knowledge of these quarters, to withhold it from the world. The few feeble attempts which they did make, to save appearances, between 1720 and 1730, rather excited the displeasure than satisfied the expectations of the public; and, by the exertions of Mr Dobbs, Capt. Middleton was sent out by government in 1741, and Capt. Moor in 1746, the former of whom discovered Repulse Bay, and the latter explored Wager's Strait and Chesterfield Inlet, so as to ascertain with sufficient certainty, that no passage existed in that direction.*

The Company's settlements around the whole extent of Hudson's Bay are only four, viz. Prince of Wales, or Churchhill Fort, the most northern of the factories, situated at the mouth of Churchhill river, in 59° N. Lat.; York Fort, formerly called Bourbon by the French, a square building, flanked with bastions, standing on an island between two branches of Nelson's river, in 57½° N. Lat.; Albany Fort, called by the French St Anne, or the river Albany, in 52° 18′ N. Lat.; and Moose Fort, or Monsipi, or St Louis, at the mouth of a small river on the south border of James's Bay, in 51° 28′ N. Lat. Besides these, are several smaller establishments, particularly Severn House, dependent on York Fort, in 56° 12′ N. Lat. and East-main, or Prince Rupert's, in 53° 24′, connected with Moose Fort.

The climate around the Bay is extremely severe, especially at Churchhill Fort. From the middle of October to the middle of May, the country is buried under frost and snow. In the year 1775, one of the severest seasons remembered by the oldest residents, the snow at the latter end of May lay level with the wall of the west curtain of the fort; and the ice in the river and bay did not break up till the end of June. Even at York Fort, though two degrees farther south, Fahrenheit's thermometer has frequently stood at 50° below zero in the month of January; and brandy, or strong brine, exposed to the air for a few hours, will freeze to solid ice. In the cellars, eight or ten feet deep, and below the guard rooms, where a daily and almost perpetual fire is kept up, London porter has been so frozen, that only a few gallons could be got out of a whole hogshead; and the remainder, converted to ice, was found, upon being thawed, to have no strength remaining. The lakes and rivers, which are not above 10 or 12 feet deep, are frozen to the ground; and the springs are uniformly bound by the frost to the greatest depth that has been dug. The most piercing cold is felt at sun-rising; and is particularly intolerable during the prevalence of the north wind. The air is frequently filled with particles of ice, sharp and angular, and sufficiently perceptible to the eye, which, in blowing weather, occasion a most painful sensation of cold; and, if driven upon the face or hands, raise the skin in little, hard, white blisters, which, if not immediately rubbed, or warmed, are apt to break out into hot watery issues. The utmost precautions against the effects of the cold are necessarily employed by the European residents. The windows of the factories are very small, and provided with thick wooden shutters, which are closely shut 18 hours of the day in winter. As soon as the wood in their large fires is burnt down to a coal, the tops of the chimnies are stopped with an iron cover to keep the heat within the house; and, three or four times a day, red hot iron shot of 24 pounds are suspended in the windows of the apartments. Yet all this will not preserve the beer, wine, and ink, from freezing; and after the fires go out, the insides of the walls and bed-places are found covered with ice two or three inches thick, which is every morning cut away with a hatchet. For a winter dress, they use three pair of socks of coarse blanketing or Duffield for the feet, with a pair of deer-skin shoes over them; two pair of thick English stockings, and a pair of cloth stockings over them; breeches lined with flannel; two or three English jackets, and a fur or leather gown; a large beaver cap, double, to come over the face and shoulders, and a cloth of blanketing under the chin; yarn gloves, and a large pair of beaver mittens, hanging down from the shoulder, ready to receive the hands as high as the elbows. Yet, with all this covering, they are frequently severely frost-bitten, when they stir abroad during the prevalence of the northerly winds; and many of the natives even fall victims to the severity of the climate. Watery vapours, ascending from the open sea-water, and condensed by the cold, occasion thick fogs, which are carried to a considerable distance along the coast, and which obscure the sun completely for several weeks together. But, during the intense cold of winter, the atmosphere is commonly remarkably clear and serene; and the stars shine during the night with extraordinary lustre. The aurora borealis particularly is seen almost every night during winter, darting with inconceivable velocity over the whole hemisphere, exhibiting the greatest variety of colours, and often completely eclipsing the stars and planets by its brightness. Parhelia and paraselenæ, or mock suns and moons, as they are commonly called, appear very frequently during the colder months; and, at the same time, coronæ of different diameters and various colours are seen around the sun for several days together, from his rising to his setting.† The frost is never out of the ground; and even in summer, when the heat is oppressive, and the thermometer frequently at 90 degrees of Fahrenheit, the earth is thawed only to the depth of three or four feet below the surface. The climate, nevertheless, is extremely salubrious throughout the whole year; and Europeans, with the exception of accidental injuries from exposure to the cold, enjoy in general an excellent state of health in the country.

On the eastern coast of Hudson's Bay, the soil is completely barren; and about Lat. 60° vegetation entirely ceases. The surface of the country is extremely rugged, covered with enormous masses of stone; and in many places are seen the most frightful mountains of an astonishing height. Its barren vallies are watered by a chain of lakes, which are supposed to be formed merely by rain and snow, and of which the water is so cold, as to be pro-

* The recent history of the Hudson's Bay Company, particularly as connected with its disputes with the North-west Company, will be found in Lord Selkirk's Pamphlet, entitled *A Sketch of the British Fur Trade in North America, with Observations relative to the North-west Company of Montreal.* London, 1816.

† See our article GREENLAND, and HALO.

ductive only of a few small trout. A little moss, or a blighted shrub, may be seen here and there on the mountains, and a few stunted trees in the lower grounds. The soil about Churchhill Fort is extremely rocky and barren, and bare of vegetable productions. There are no woods within seven miles of the shore; and those which are found at that distance consist only of a few stunted junipers, pines, and poplars, scarcely capable of affording a sufficiency of winter's fuel to the Factory. Upon advancing northward from that settlement, the earth becomes gradually more unproductive and desolate, till at length not the least herb is to be seen, nor any trace of human step observed in the frigid waste. The produce of a few garden seeds, put into the ground about the middle of June, and shooting up with surprising rapidity, is all that the residents are able to gather from the adjoining soil. At York Fort, the soil, which is of a very loose and clayey nature, is nearly equally unfit for agriculture, even though the climate were favourable. Cresses, radishes, lettuce, and cabbage, are raised by careful culture, and, in some propitious seasons, peas and beans have been produced, but they rarely come to perfection. The face of the country is low and marshy; and the trees, though superior to those at Churchhill Fort, are still very knotty and diminutive; but, after proceeding inland towards the south, about Moose and Albany Forts, the climate is more temperate, and the trees of considerable size; potatoes, turnips, and almost every species of kitchen garden produce, are reared without difficulty; and it is supposed that corn also might be cultivated by proper attention. Upon advancing inland towards the west, the climate becomes still milder, and the soil more productive. Wild rice and Indian corn are produced in considerable quantities in the plains; various kinds of animals abound in the woods; the rivers and lakes are stored with the most delicious kinds of fish; and iron, lead, copper, and marble, have been found in the mountainous parts. In the woods of the more northern tracts, the only trees are, pines, junipers, small scraggy poplars, creeping birch, and dwarf willows. The ground is covered with moss of various sorts and colours, upon which the deer principally feed. Grass is not uncommon; and some kinds, especially rye-grass, are so rapid in growth, as frequently to rise, during the short summer at Churchhill Fort, to the height of three feet. Another species of grass, adapted for the support of the feathered tribes, is very abundant on the marshes and banks of lakes and rivers. Vetches, burrage, sorrel, coltsfoot, and dandelion, one of the earliest salads, are plentiful in some parts around Churchhill river. A herb called Wee-suc-a-pucka grows abundantly in most parts of the country, of which the leaves, and especially the flowers, make a very agreeable kind of tea, much used both by the Indians and Europeans, not only for its pleasant flavour, but also for its salutary effects. It is of an aromatic nature, and considered as serviceable in rheumatism, for strengthening the stomach, and promoting perspiration. It is likewise applied outwardly in powder to contusions, excoriations, and gangrenes; but in this view does not appear to possess any medicinal quality. Another herb, named by the natives jack-ashey-puck, resembling the creeping boxwood, is mixed with tobacco, to make it milder and pleasanter in smoking. Several small shrubs are found in the country, which bear fruit; of which the chief are, gooseberries of the small red species, which thrive best in rocky ground, and spread along the ground like the vine; currants, both red and black, are plentiful around Churchhill river, and grow best in moist swampy soils. The blackberries particularly are large and excellent; but in some persons both kinds occasion severe purging, unless when mixed with cranberries, which completely correct that tendency. Hips of a small size are found on the coast, but large and abundant in the interior of the country. Upon a bush, resembling the creeping willow, grows a berry similar in size and colour to the red currant, but of very unpleasant taste and smell. Cranberries are very abundant every where; and, when gathered in dry weather, and carefully packed with moist sugar, may be preserved for years. Heath-berries are also produced in great quantities, and their juice makes a pleasant beverage. Juniper berries are frequently seen, chiefly towards the south, but are little esteemed, either by the natives or the Europeans, except for infusion in brandy. Strawberries and raspberries, of considerable size and excellent flavour, are found as far north as Churchhill river, and are often most plentiful in those places where the underwood has been set on fire. The eye-berry, resembling a small strawberry, but far superior in flavour, grows in small hollows among the rocks, at some distance from the woods. There are also the blue-berry, which grows on small bushes, and resembles the finest plum in flavour; the partridge-berry, growing like the cranberry, but of a disagreeable taste; and the bethagotominick, or dewater-berry, which grows abundantly in swamps on a plant like the strawberry, with a high stalk, each bearing only one berry, and is accounted an excellent antiscorbutic.

The principal animals around Hudson's Bay are, the Moose-deer, rein-deer, buffaloes, musk oxen, and beavers; polar or white bear, black bear, brown bear, wolves, foxes of various colours, lynxes, or wild cats, wolverins, which are remarkably fierce and powerful animals, able to withstand the bear itself; otters, pine-martins, ermines, a smaller otter called jackash, which is very easily tamed, but, when angry or frightened, apt to emit a most disagreeable smell; the wejack and skunk, the last of which is remarkable for its insupportably fœtid smell; musk beavers, porcupines, hares, squirrels, castor-beavers, and mice of various kinds, one species of which, the hair-tailed mouse, is nearly as large as a common rat, and capable of being speedily tamed even after they are full grown. Amphibious animals frequenting the coasts of the Bay are, the walrus, or sea-horse, some of which have been killed of so enormous a size as to exceed the weight of two tons; seals of various sizes and colours; and sea-unicorns in the northern parts. Of the feathered race, there are eagles and hawks of various kinds, white and gray owls, ravens, cinereous crows, which are very familiar and troublesome birds, frequenting the habitations of the natives, and pilfering every species of provision; woodpeckers, ruffed grouse, pheasants, partridges, pigeons, thrushes, grosbeaks, buntings, finches, larks, titmice, swallows, martins, cranes, bitterns, earlows, snipes, plovers, gullemels, divers, gulls, pelicans, goosanders, swans, geese of different kinds, and ducks in great variety, particularly the mallard, long-tailed, wigeon, and teal. There are several kinds of frogs, as far north as the latitude of 61°, which in winter are generally found in a completely frozen state, yet capable of reviving when thawed. Grubs, spiders, and other insects, are found in the same icy condition, from which they can be recovered by exposure to a gentle heat. Several kinds of shell fish are found on the shores of the Bay, particularly muscles, periwinkles, and small crabs. The empty shells of cockles, wilks, scallops, and other sorts, are frequently thrown upon the beach; but none of these have been seen with the fish in them. There are few fish in Hudson's Bay. White whales are found in considerable numbers at the mouths of the principal rivers; and the Company's servants, in the settlements on the west coast of the Bay, have been known to send home in some years from eight to thirteen tons of fine oil. A small fish, called kepling, about the size of a smelt, and very excellent for eating, resorts in some years to the shore in great numbers, but at other times is extremely scarce. No other salt water fish is found in the country, except salmon, which are also very plentiful at some seasons, and equally rare at other times. It has been observed, in short, that every species of game, whether quadruped, fowl, or fish, is remarkably variable at different periods; and it thus becomes necessary to provide in plentiful seasons a quantity of such provisions as are most capable of being preserved. The geese are said to be particularly useful for this purpose, when properly salted; and it is nothing uncommon for 10,000 to be killed during a winter at the factories.*

The natives who inhabit the countries around Hudson's Bay may be distributed under these three general denominations,—the Southern Indians, the Northern Indians, and the Esquimaux. The Southern Indians occupy the country lying between the south coast of Hudson's Bay and the territories of Canada, and that part of the western coast of the Bay which is situated to the south of Churchhill river, and extends inland to the lake of Athabasca or Athapuscow. They are the same as the Indian tribes who occupy the regions to the north of Upper CANADA; and we refer to the account of that country for a general description of the leading nations. The principal tribes who reside in the interior to the south-west of Hudson's Bay, and who used formerly to repair to the Company's forts, but now find their wants supplied at the trading houses nearer their own homes, are the Ne-heth-a-wa, and Assinne-poetuc Indians. The latter are the same as the Assinipoils or Stone Indians, originally a branch of the Naudowessies, but latterly incorporated with the Knisteneaux or Killistinoes. They are a numerous tribe, who extend over a considerable tract of country, and bring many peltries to the traders. The former, the Nehethawas, or Neheaways, are supposed to spring from the same stock as the Chipawas or Chepewyans. From being scattered over an immense extent of country, they appear to be less numerous than they are in reality. They have been longest acquainted with the fur traders, and are the most debauched and corrupted in the southern tribes. The Southern Indians, in general, who have become known to the Hudson Bay traders, are of a middle size and copper complexion; their persons generally well formed, and their features regular and agreeable. Their constitutions are strong and healthy; and they are subject to very few diseases. They are chiefly affected with dysentery and a violent pain in the chest, which is ascribed to the intensity of the cold, but which is said rarely to prove fatal. The venereal disease is also common among them, but generally mild in its symptoms. They seldom live to a great age; but are observed to enjoy all their faculties to the last. They are capable of travelling on foot with great expedition, and for many days in succession, patiently enduring the utmost degree of cold, hunger, and fatigue. They excel in hunting, which is their sole mean of subsistence; and though long used to fire-arms, they are still remarkably expert in the use of their original weapons, the bow and arrow. When employed to procure provisions for the factories, at the rate of the value of a beaver skin for every ten geese, they frequently bring in 50 or 60 of these fowls a day, which they shoot readily on the wing. They are extremely artful, addicted to every species of fraud and pilfering, and ready to boast of their thefts when successfully executed, so as to escape detection. At the same time, nothing can exceed their honesty and fidelity when entrusted with a charge. They are frequently employed by the Hudson Bay traders to take packages into the interior parts, and to bring down the articles which are procured in return. An Indian with his wife will embark in his canoe packs of 60 or 70 lbs. each, containing articles which would enable him to live in affluence for many years, and with which it would be easy for him to abscond, without the possibility of being traced. Yet this valuable property, so completely in their power, they will convey hundreds of miles, through unfrequented lakes and rivers, and deliver at the place appointed, with the utmost punctutuality, for the reward of the value of six beaver skins for each pack. They are humane and charitable to the widows and children of their departed relatives, and are naturally mild, affable, and friendly in their manners; but, in their moments of intoxication, they are invariably roused by the slightest provocation to the fiercest quarrels and most barbarous murders. Even when the women have taken care to remove their weapons, they rarely fail, on such occasions, to mutilate one another with their teeth and nails. They are also extremely licentious in their sexual intercourse, and give themselves up without restraint to every species of incestuous debauchery, with mothers, sisters, and daughters. They have no manner of regular government or subordination; but choose a temporary leader when they go to war, or form a party for trade. By the use of spirituous liquors, which they drink to the greatest excess, and with which they are too readily supplied by the Europeans as the most alluring article of traffic, they are debased in their minds, enervated in their bodies, dejected in their spirits; and are daily becoming a more emaciated, puny, indolent, and worthless race.

The Northern Indians occupy the extensive tract of country which reaches from the 59th to the 68th degree of North Latitude, and which is upwards of 500 miles from east to west. Their territories are bounded by the Churchhill river on the south, by the country of the Athabasca Indians on the west, by Hudson's Bay on the east, and by the country of the Dog-ribbed and Copper Indians † on the north.

The Northern Indians are generally above the middle size, robust, and well proportioned; but have less of that activity of body and liveliness of disposition, which commonly distinguish the Indian tribes of the western coast of Hudson's Bay. Their features are of a peculiar cast, and different from those of any other race in those countries. Their foreheads are low, their eyes small, their cheek bones high, their noses aquiline, their cheeks fleshy, and their chins generally long and broad. Their complexion is of a copper colour, but rather inclining to a dingy brown; and their hair, like that of the other tribes, black, straight, and strong. Few of the men have any appearance of a beard till they arrive at middle age, and then it is very small in quantity, but exceedingly bristly. They endeavour to pull out the hairs by the root, though they seldom effect this very completely. They have no hair under their arm pits, or on any other part of the body, except in those places

* A French governor at Fort Bourbon affirmed, that his garrison of 80 men consumed in one winter 90,000 grouse and ptarmigans, and 25,000 hares, which, for 200 days, allows about $5\frac{1}{2}$ grouse and $1\frac{1}{2}$ hares to each man per day.

† These are, in every respect, the same people as the Northern Indians, and speak a dialect of the same language. They never visit the Hudson's Bay factories; but used to supply the Northern Indians with the greater part of the furs which these last bring to the Company's traders. They appeared, when visited by Mr Hearne, to be a hospitable and harmless tribe; and a gainful traffic might have been opened between them and the factories; but, about the end of the last century, a war broke out between the Dog-ribbed and Copper Indians, which terminated in the destruction of the latter people, except a small remnant, who found their way to the Canadian houses among the Athabasca tribes, where they are cheaply supplied with the European articles which they require, and for which the Northern Indians used to make them pay almost a thousand per cent. dearer than the Company's rates.

which nature directs them to conceal. The skins of the women are soft, smooth, and polished; and, when they are dressed in clean clothing, they are entirely free from any offensive smell. All the tribes of the Northern Indians have three or four parallel black strokes on each cheek, which are produced by introducing an awl or needle under the skin, and rubbing powdered charcoal into the wound after the instrument is drawn out. As almost the whole of their country is little better than a mass of rocks and stones, scarcely producing any other vegetable food than moss for the deer, they have few opportunities of collecting furs, and subsist chiefly by hunting and fishing. A few of the more active or restless among them, who have acquired a taste for European articles, collect the furs from the rest, or from the Dog-ribbed and Copper Indians, or from their own hunting excursions towards the inland districts, where the proper animals abound; and, after carrying these to the factories with great risks and fatigues, barter, on their return, the fruits of their traffic with their less ambitious countrymen for necessary food and clothing. But the greater part, though they may have visited the factories once in their lives, lead a happier life, and enjoy a more comfortable subsistence in their own country. Their real wants are easily supplied; and a hatchet, ice-chisel, file, and knife, are almost all that is requisite to enable them, with a little industry, to procure a plentiful supply of food and clothing. They subsist chiefly on venison, and generally spend the whole summer in hunting the deer on the open plains, or catching fish in the rivers and lakes. As they have no dogs trained to the chace like the Southern Indians, and as they seldom have powder and ball in sufficient abundance for the purpose, they make use of their bows and arrows in killing the deer, as they pass through the narrow defiles, into which they drive the herds in the following manner. Upon seeing the deer, they betake themselves to leeward, lest they should be smelled by the animals; and then search for a convenient place for concealing the marksmen. They next collect a number of sticks, like large ramrods, with a small flag at the top of each, and these they fix upright in the ground above fifteen or twenty yards from each other, so as to form two sides of a very acute angle, terminating in the defile, where the huntsmen are concealed behind loose stones, heaps of moss, &c. The women and boys then divide into two parties, and going round on both sides, till they form a crescent behind the herd, drive them straight forward between the rows of sticks into the place of concealment, where they are shot as they run along. The same mode is employed, in the winter season, to drive the deer into a pound or inclosed space fenced round with bushy trees. These pounds are of various sizes, according to circumstances, and are sometimes about a mile in circumference. The door or entrance is not wider than a common gate, and the inside of the space inclosed is so crossed with hedges as to form a kind of labyrinth, at every opening of which also are placed snares made of thongs. As soon as the deer are driven into the pound, the gateway is blocked up with trees and brushwood, prepared for the purpose; and while the women and children walk round the outside of the fence, to prevent the imprisoned animals from breaking through or leaping over, the men are employed in shooting those which run loose, or in spearing those which have been entangled in the snares. About the end of March, or beginning of April, when the snow, slightly thawed during the day, is frozen during the night into a thin crust, which easily bears the Indian on his snow shoes, but sinks under the hoof of the deer, it is a common practice to kill the moose deer, by literally running them down. The hunters, lightly clothed, and armed only with a bow and arrows, a knife, or broad bayonet, generally tire the deer in less than a day, though sometimes they continue the chace for two days before they can come up with the game. These animals, however, when incapable of running farther, make a very desperate defence with their head and fore-feet, and unless the Indians are provided with a short gun, or with bows and arrows, they find it necessary to fasten their knives or bayonets to the end of a long pole, in order to stab the deer, without coming within reach of their feet. The flesh of the animals killed in this manner is so over-heated by the long run, that it is never well tasted. In taking fish they make use of nets and hooks at all seasons of the year. Their fishing nets are made of thongs cut from raw-deer skins, (much inferior to those of the Dog-ribbed Indians, which are made of the inner bark of the willow tree,) and are furnished with various appendages, such as the bills and feet of birds, toes and jaws of otters, &c. which the superstitiously consider as essential to their success. These nets are always used separately, and placed at a distance from each other; and on no account would they unite them together, for the purpose of stretching across the channel of a narrow river; because they imagine that one net would become jealous of its neighbour, and would not catch a single fish. In fishing with hooks, they are equally influenced by superstitious notions; and all the baits which they use are compositions of charms, inclosed within a piece of fish-skin, so as to resemble a small fish. These charms are bits of beavers' tails, otters' teeth, musk-rats' entrails, squirrels' testicles, curdled milk taken from the stomachs of sucking fawns and calves, human hair, &c.; and almost every lake and river is supposed to require a peculiar combination of different articles. A net or hook that has taken many fish is valued accordingly; and would be taken as an equivalent for a number of new ones, which had never been tried, or which had not proved successful. In winter the hooks are let down through round holes cut in the ice, and are kept in constant motion, both to allure the fish, and to prevent the freezing of the water. From want of fuel, they are frequently obliged to eat their victuals in a raw state; and this they occasionally do from choice, especially in the case of fish, which they seldom dress so far (even where fire is at hand) as to warm it thoroughly. A few of them purchase brass kettles from the European factories; but the greater part still prepare their food in large upright vessels made of birch bark. As these vessels will not admit of being exposed to the fire, the water is made to boil by a succession of hot stones being introduced; a method which effects the purpose very expeditiously, but mixes much sand with the victuals, in consequence of the stones frequently mouldering down in the kettle. They employ also the ordinary methods of broiling their food, or roasting it by a string. They make a favourite dish, by boiling in a deer's paunch or stomach a mixture of minced meat, blood, and fat; but the fat is chewed by the men and boys, to prepare it for mixing more intimately with the other ingredients, and the half-digested food, found in the animal's stomach, is carefully added to the mess. In winter, when the deer feed upon a species of fine white moss, the contents of their stomach is accounted so great a delicacy, that the Indians frequently eat it warm out of the paunch, as soon as the animal is killed. In like manner, they pull out the kidneys of the deer or buffalo, and eat them warm from the newly slaughtered animals, without any dressing. They often drink the blood, as it flows from the wound in the carcase, and account it a most nourishing sort of food, as well as an excellent quencher of thirst. They are remarkably fond of the womb of the buffalo, elk, deer, &c. even when they are some time gone with young; and are not desirous of cleansing the bag very completely before boiling it for use. The young calves, fawns, beavers, &c. taken out of their mothers' bellies, are reckoned most delicious articles of food; and all the parts of generation, belonging to any animal which they kill, whether male or female, are carefully eaten by the men and boys, partly as a dish which they relish, and partly as a superstitious observance, which they consider essential to their success in the chace. The deer skins also, freed from the hair, and well boiled, are frequently used as food. Even the worms, which infest them after the rutting season, are squeezed out and eaten alive as great delicacies. When animal food is scarce, the natives boil a kind of hard crumply moss which grows upon the larger stones, and which forms a very palatable gummy preparation, sometimes used to thicken other kinds of broth, and particularly esteemed when cooked in fish liquor. All the Indians around Hudson's Bay, Southern, Northern, and Esquimaux, constantly swallow the secretion which comes from the nose; devour the maggots which are produced by the flesh fly; and delight in a handful of lice as much as a European epicure is known to relish the mites in a decayed cheese.

The clothing of the Northern Indians consists chiefly of deer skins, with the hair inwards; but, for summer use, they prepare from these skins a fine soft leather, with which they make their stockings, jackets, &c. To make a complete winter dress for a grown person requires the principal parts of eight or ten deer skins; and all these must, if possible, be procured in the month of August, or beginning of September, when the fur is thickest, and the skin least injured by worms. Each person is calculated to require annually ten more of these skins for the lighter parts of summer clothing, for thongs, lines, and other domestic purposes, besides what is needed for tents, bags, &c. The coverings of the tents are always formed of skins with the hair; and by the Northern Indians are commonly composed (differently from the practice among the Southern tribes) of separate pieces, containing about five skins in each. At the commencement of the winter season, they frequently sew a few of the skins of the deer's legs together in the shape of long portmanteaus, which they use as a kind of temporary sledge, till they reach a situation where wood can be procured. They then construct proper sledges of thin boards of larch fir; and make them of various sizes, according to the strength of the persons by whom they are to be dragged. In general they do not exceed eight or nine feet in length, and twelve or fourteen inches in breadth; but sometimes they are not less than twelve or fourteen feet long, and fifteen or sixteen inches wide. The boards, of which they are made, are only about a quarter of an inch thick, and five or six inches broad. They are sewed together with thongs of parchment deer skin, and several cross-bars are fastened on the upper side to strengthen the vehicle, and secure the ground lashing. The head or fore part of the sledge is turned up, so as to form a semicircle of fifteen or twenty inches diameter, to prevent the carriage from diving into light snow, and enable it to rise over the inequalities of the surface. The trace is a double line or slip of leather fastened to the head of the sledge, and attached to a collar, which is put across the shoulders of the person who hauls it, so as to rest upon the breast. They are sometimes dragged by dogs, but too commonly by the women. The snow shoes of the Northern Indians differ from all others in that country, in being made so as to be worn always on the some foot, having a large sweep or curve on the outside, but nearly straight in the inside. The frames are usually made of birch wood, and a netting of thongs from deer skin fastens the toes and heels to the bottom or sole. They are four feet and a half in length, and about thirteen inches broad.

The canoes of the Northern Indians are smaller and lighter than those of the Southern nations, so as to be carried by a single person on the longest journies; and are chiefly employed for crossing the rivers and lakes, with which they meet in their progress. These canoes are flat bottomed, and sharp at each end, so as to bear some resemblance to a weaver's shuttle. They seldom exceed twelve or thirteen feet in length; and are from twenty to twenty-four inches broad at the widest part. The forepart is unnecessarily long and narrow, and is all covered over with birch bark, so as to admit of nothing being laid into it. The hinder part is much wider, for receiving the baggage, or a second person, who must lie along the bottom, that the vessel may not upset, while the rower sits on his heels in the middle space, impelling the vessel with a single paddle. A hatchet, a knife, a file, and an awl, are all the tools which these Indians employ in making their canoes, snow-shoes, bows, arrows, and other kinds of wooden work. These few instruments they use with the utmost dexterity, and execute every thing in the neatest manner. In tanning their leather also, they use a very simple, yet efficacious process. The skins are first well soaked in a lather made of the brains, marrow, and soft fat of the animal; then dried before the fire, and even hung in the smoke for several days. They are next thoroughly steeped and washed in warm water, till the grain of the skin is perfectly open and moistened; after which they are carefully wrung, and dried before a slow fire, being in the meantime repeatedly rubbed and stretched as long as any moisture remains. Last of all, they are scraped smooth with a knife, and are extremely soft and beautiful, almost equal to shamois leather. The women of the Northern Indians, as in most other tribes, are more the slaves than the companions of the men; and are held in a state of unmitigated subjection. They are commonly rather of low stature and a delicate shape; but being inured to labour from their infancy, they are able to sustain all kinds of drudgery, and to carry very heavy loads on their journies. It is nothing unusual to see them bear on their backs a burden of eight or ten stone of fourteen pounds each, or haul in a sledge a much greater weight. They are expected also to dress the deer skins, make the clothing, cook the victuals, pitch the tents, carry home the game when killed, and perform all the work of splitting, drying, and preserving it for use. When the meal is prepared, they are not allowed to partake, till all the males, even the servants of their fathers or husbands, have eaten what they think proper; and, in times of scarcity, it is not unfrequently their lot to be left without a single morsel. They possess little beauty even in youth; and become old and wrinkled before they reach the age of thirty. But they are remarkably chaste, mild, and obliging creatures, making the most faithful servants, affectionate wives, and indulgent mothers. A plurality of wives is customary among all these Indians, and every man takes as many as he is able to maintain, or has occasion to employ in his service. It is not uncommon to see six or eight in one family; and they are changed or increased in number, at the pleasure of the husband. From the early age of eight or nine years, the girls are kept under the greatest restraint, and are not permitted to join in any amusements with the children of the other sex; but are obliged to be constantly beside the old women, learning their domestic labours. They are betrothed at an early period of life, without any choice of their own, but entirely at the will of their relations, who are chiefly anxious to connect them with men able to maintain them. No ceremonies attend their marriages, or divorces; and they are taken or dismissed as the husband chooses. When he suspects any of them of incontinency, or is not pleased with her accomplishments, he administers a beating and turns her out of doors, telling her to go to her lover or relations, as the case may be. It is also a daily occurrence among them to take by force the wives of others whom they may happen to fancy; and all that is necessary to decide the claim is to vanquish the former husband in wrestling. On these occasions, the by-standers never attempt to interfere; nor will one brother even offer to assist another, except by giving his advice aloud, which being equally heard, may be equally followed by both the parties engaged. In these contests, there is properly nothing like fighting; and it is very rarely that either of the combatants receives any hurt. The whole affair consists in pulling each other about by the hair of the head, or, if they should have taken care to cut off their hair and grease their heads before beginning the contest, they endeavour to seize each other around the waist, and struggle to prove their superior strength and title, by throwing their antagonist to the ground. When one of them falls or yields, the other is entitled to carry off the woman, who was the cause of contention; but as the children usually go with the mother, it is chiefly for the younger wives that these contests take place. It is a common custom among them to exchange wives for a night, as one of the strongest ties of friendship between the two families; and, in case of the death of either husband, the other considers himself bound to support the children of the deceased. The women among the Northern Indians are less prolific than the females of more civilized nations; and their children are commonly born at such intervals, that the youngest is usually two or three years old before another is brought into the world. The wife, when taken in labour, is removed to a small tent erected for her separate accommodation, at such a distance from the other tents that her cries cannot be heard; and no male above the age of childhood approaches the place. No assistance is offered by the other women to facilitate the birth, which is generally easy, and the recovery of the mother not less speedy. A woman after delivery, however, is accounted unclean for a month or more, and continues to occupy a separate tent with one or two female acquaintances; nor does the father, during all that time, even see the child, in the apprehension that he might dislike its appearance, before its countenance is duly formed. At certain monthly periods, also, the women are not permitted to remain in the same tent with their husbands, and are obliged to make a small hovel for themselves at a little distance from the rest. When these periods arrive, they creep out of the tent at the side where they happen to be sitting, as on such occasions they are not permitted to go out or in by the door; and it is said, that, upon any disagreement with their husbands, they often make a pretence of being in that situation, as a reason for a temporary separation. During these periods, a woman is restricted from walking on the ice of rivers or lakes, or where a fishing net is placed, or from crossing a path where the head of any animal has been carried, or from eating of any part of the head; and all this from a superstitious notion that by so doing she would impede their success in hunting. The children are not put in cradles as among the Southern Indians, but merely have a small bundle of dry moss placed between their legs, and are thus carried on the mother's back next her skin, till they are able to walk. Though managed in this awkward manner, very few deformed persons are seen among them. The children are named by the parents or near relatives; and the names of the boys are generally taken from that of some animal, place or season. Those of the girls are most frequently expressive of some quality or part of the martin, such as White Martin, Black Martin, Summer Martin, Martin's-head, Martin's-foot, Martin's-tail, &c. The men, though very indifferent about their wives, express much affection to their children, especially to the youngest; apparently actuated by no other principle than mere natural instinct.

When two parties of these Indians chance to meet, their mode of salutation is rather singular, and quite different from all European practices. When about twenty or thirty yards distant from each other, they make a full halt; and sit or lie down upon the ground, without speaking, for some minutes. At length the oldest on one side breaks silence, by relating to the other party all the misfortunes which have befallen him or his companions, since they had last seen or heard of each other, and also all the deaths or calamities of any of their countrymen, as far as may have come to his knowledge. A similar communication is made in reply; and, should any of the two companies be nearly affected by any of the bad news announced, they begin to sob and cry, in which all the rest unite with the utmost vehemence. They then advance by degrees, and mix together, the two sexes, however, always associating separately. The pipes are passed freely, if any tobacco can be found among them; conversation becomes general; the good news circulate; cheerfulness appears on every countenance; and small presents of provisions, ammunition, or other articles, are made, sometimes as gifts, but more frequently as speculations, to draw forth a greater present in return. Their principal amusements are, shooting at a mark with the bow and arrow; playing a game resembling that of quoits, in which they make use of short clubs sharpened at one end; or shifting a button, or small bit of wood from hand to hand, as in "which hand will you take?" in which the player, whenever he guesses rightly, receives a counter or chip of wood from his antagonist, and he who first gains all the sticks, is winner of the stake, which is usually an arrow, or a single load of powder and shot, or something of inconsiderable value. At times they amuse themselves with dancing, which is always performed during the night; but in which they have nothing peculiar to their own nation, and always imitate the songs and dances of the Southern tribes, or more commonly of the Dog-ribbed Indians. These dances are very simple, and are performed by three or four persons at a time, who stand up naked, or nearly so, close to the musician; and, with their hands close upon the breast, their heads inclining a little forwards, and their bodies kept quite stiff, lift their feet alternately in quick succession, and as high as possible. The music is produced by a drum or tabor, and sometimes a rattle made of buffalo's hide, shaped like an oil-flask, and filled with pebbles or small shot. These instruments are accompanied with the voice, repeating in a monotonous kind of tune, the words *hee, hee, hee, ho, ho, ho*, &c. The women are never allowed to join in these diversions, but sometimes dance by themselves, out of doors, to the music which serves the men within the tent. Their mode of dancing has still less meaning and motion than that of the men; and is performed by a number of them crowding close together in a straight line, shuffling themselves a little from right to left and back again on the same ground, without lifting their feet; and making, when the music stops, a kind of awkward curtsey, with a shrill cry of *he-e-e, ho-o-o-o-e*.

Few of the Northern Indians live to a great age; and the extreme fatigues which they undergo from their youth, in procuring their subsistence, is supposed to have no small effect in shortening their lives. Their most fatal disorders are fluxes and consumptions, which carry off great numbers of both sexes and of all ages. But the most prevalent diseases is, a kind of scurvy resembling the worst stage of the itch. It is seldom known to prove fatal, unless when conjoined with some internal affection; but it is extremely troublesome and obstinate, resisting all the medicines which have yet been applied at the Company's factories; and, when left to the power of nature, as is always the case among the natives, seldom removed in less than twelve or eighteen months. They make no use, indeed, of medicine, either for external or internal diseases, and attempt to cure them solely by charms. The modes most commonly employed are, sucking the part affected, blowing and singing to it, laughing, spitting, and uttering a multitude of unmeaning sounds and vocables. In the case of some internal complaints, such as colic, strangury, &c. the operator frequently blows into the anus or the adjacent parts, whatever be the sex of the patient, and continues the process as long and as violently as his lungs can act. The consequence of such an accumulation of wind is not unusually precisely the same as the effect of a clyster; and the reaction is sometimes so sudden, as to lodge the contents full in the face of the doctor; a scene which, however ludicrous to Europeans, never discomposes the gravity of any of the Indian parties or spectators. The medical practitioners are a class of conjurors, who no doubt impose upon the credulity of their countrymen, but who seem to have themselves a real belief in the efficacy of some of their operations. In cases of great danger, besides the usual modes of cure, they pretend to appease the power of death, and to procure a respite for the sufferer, by swallowing hatchets, ice-chisels, broad-bayonets, knives, &c.; and these feats they are described as performing, or rather appearing to perform, with wonderful dexterity. Some of their exertions are sufficiently real and laborious, as particularly described in a case witnessed by Mr Hearne. After one of them had performed the feat of swallowing a long board, he took with him other five men and an old woman into the house where the patient lay; and, having stripped themselves completely naked, began to suck, blow, sing, and dance around the sick man, "continuing so to do for three days and four nights, without taking the least rest or refreshment, not even so much as a drop of water. When these poor deluding and deluded people came out of the conjuring-house, their mouths were so parched with thirst, as to be quite black, and their throats so sore, that they were scarcely able to articulate a single word, except those that stand for *yes* and *no* in their language. After so long an abstinence, they were careful not to eat or drink too much at one time, particularly for the first day; and, indeed, some of them, to appearance, were almost as bad as the poor man they had been endeavouring to relieve. But great part of this was feigned; for they lay on their backs with their eyes fixed as if in the agonies of death, and were treated like young children. One person sat constantly by them, moistening their mouths with fat, and now and then giving them a drop of water. At other times, a small bit of meat was put into their mouths, or a pipe held for them to smoke. This farce only lasted for the first day; after which they seemed to be perfectly well, except the hoarseness, which continued for a considerable time afterwards." These conjurors profess to accomplish their cures by the aid of certain spirits or fairies, with whom they pretend to converse, and whom they often describe as appearing to them under the shapes of beasts, birds, clouds, &c. They are supposed to be equally able, by means of those supernatural allies, to take away as well as to prolong any one's life; and when they chose to threaten such a malign influence to any individual or family, the imaginations of their victims are so possessed by the conviction of their power, that the consequence is affirmed to have often proved fatal, without any apparent molestation being offered to the objects of their vengeance. Indeed, when any of their principal people die, their death, in whatever way it has taken place, is usually ascribed to some conjuring influence, either of their own countrymen, or of the Esquimaux, or of the Southern tribes. They never bury their dead, but always leave the bodies on the spot where they expire. They are understood to be generally devoured by beasts and birds of prey; and for this reason these Indians will not eat the flesh of foxes, wolves, ravens, &c. unless they be pressed by absolute necessity. Though thus neglectful of the mortal remains of their friends, they are deeply affected with grief for their loss; and express their sorrow by tearing off their clothes, and wandering about naked, till their neighbours or relatives come to their relief. After the death of a father, mother, husband, wife, son, or brother, they mourn for the space of a whole year, indicating their affliction, not by any particular dress, but by cutting off their hair, and crying almost perpetually. But the greatest calamity that can befal any of these Indians is old age. When any one is incapable to labour, he is treated, even by his own children, with the greatest neglect and disrespect, being always last served at meals, and then only with the worst of the victuals; being clothed in the clumsiest manner, with what the rest of the family despise to wear; and finally, when no longer able to walk, deliberately abandoned to perish of want. This practice is so general, that one half at least of the aged people of both sexes are supposed to die in this miserable manner. The absolute necessity of moving from place to place in quest of subsistence, and the want of any easy mode of conveyance among them, may be considered as the original causes of this unnatural custom.

The notions which these Indians entertain in religion are so extremely vague and limited, that they may almost be said to have no ideas at all on that subject. With regard to the origin of the world, they have a tradition, that the first person on earth was a woman, who, after being some time alone, found an animal like a dog, which followed her to the cave where she lived, and transforming itself during the night-time into the shape of a handsome youth, rendered her the mother of a family. Some time afterwards, a person, of such gigantic stature as to reach the clouds with his head, came to level the land, which had been hitherto a confused heap, and this he effected merely with the help of his walking stick, marking out, at the same time, the lakes, ponds, and rivers. He then took the dog, and, tearing it in pieces, threw its intestines into the waters, commanding them to become fishes; dispersed its flesh over the land, with a similar charge to form the different kinds of beasts; threw the pieces of its skin in the air, to give origin to the feathered tribes; commanded the woman and her offspring to kill, eat, and never spare, as he had charged these creatures to multiply for her use; and then returning to the place whence he came, has never been heard of since. They believe in the existence of several kinds of spirits, whom they suppose to inhabit the different elements, and to whose influence they attribute every change in their lot, whether favourable or adverse. They have no fixed creed, however, in these matters; but are continually receiving new fables from their conjurors, who profess to receive intimations in dreams from these invisible beings. They have no practical religious observances whatever, except perhaps speaking with reverence of certain beasts and birds, in which they imagine these spirits to reside. But they restrict the influence of these beings upon their welfare entirely to the present life, and have no idea whatever of a future state.* They have indeed a multitude of superstitious customs, some of which have already been mentioned, respecting success in hunting, fishing, &c. but which seem to partake more of the nature of civil than religious institutions. One of the most remarkable of these is that which they observed after having put to death any of their enemies in war. All those who have shed blood are, for many months afterwards, in a state of uncleanness, and obliged to perform a number of strange ceremonies. They are prohibited from cooking any kind of victuals for themselves or others; required to paint their faces with red earth before every meal; restricted to the use of their own pipe and dish; forbidden to eat various parts of animals, particularly the head, entrails, and blood; precluded from having their food prepared in water, so that, if they could not have it broiled on the fire or dried in the sun, they must eat it in a raw state; and finally denied the privilege of saluting any of their wives and children. When the appointed time is expired, they kindle a fire at some distance from the tents, into which they throw all their ornaments, pipe-stems, and dishes; and then partake of a feast, consisting of all those articles of food which they had been prohibited from using.

The Northern Indians are an indolent, improvident race; and are frequently in danger of starving from mere want of exertion and foresight, especially in their trading excursions to Prince of Wales Fort, the only one of the factories which they frequent. They are seldom guilty of stealing from one another, but are ready to pick up every kind of iron work which falls in their way at the Company's settlements. They excel in all the arts of defrauding and overreaching, and especially in playing the part of feigned want and distress. They are continually pleading poverty even among themselves; and, at the factory, they may be said to practise begging more than traffic. They are generally of a morose and covetous disposition, and remarkably deficient in gratitude. They are by no means a warlike people, and are not inclined to acts of cruelty, except towards their enemies the Esquimaux. Whatever losses or injuries they may sustain from one another, their revenge rarely extends beyond a wrestling match with the offender. Murder is almost unknown among them; and the perpetrator of such a crime would be treated by universal consent as an outlaw from their tribe. At the same time, they testify little humanity to the sufferings of others beyond the circle of their immediate relatives; and are known rather to ridicule, in the most unfeeling manner, the most afflicting cases of distress. They are not at all addicted to the use of spirituous liquors; and though some, who have intercourse with the factory, may learn to take them freely enough, when given gratis, they never think of them as an article of purchase. They are thus always sober, and are guilty of no greater rioting than what consists in abusive language. They are apt to become insolent and uncomplying when treated with indulgence; but nevertheless are by far the mildest tribe of Indians to be found on the borders of Hudson's Bay.

The Esquimaux who inhabit the northern coasts of Hudson's Bay,† (to whom alone the following particulars apply,) seldom approach the Company's fort at Churchhill River; but a sloop is regularly sent to trade with them at Knapp's Bay, Navel's Bay, and Whale Cove. It is only since the middle of last century, that the Company's servants could venture to land among them, (partly, perhaps, because they were considered by the Esquimaux as the allies of their most inveterate enemies, the Northern Indians,) but they have of late become so much civilized, and reconciled to the Europeans, as readily to welcome their arrival, and to treat them with every mark of hospitality. They have long been persecuted by their more powerful neighbours the Northern Indians with the most savage barbarity. No quarter is ever granted on either side; and the strongest party never fails to massacre every creature of the vanquished, without sparing even the women and children. Of late years, however, the company's servants have extended their protection to the oppressed Esquimaux, and have succeeded in establishing a peace between the two nations, so far at least that parties and individuals of both tribes can meet each other in a friendly manner, or rather without any disposition to plot each other's destruction. But the more distant Esquimaux, who reside so far to the north as to have no intercourse with the Europeans, are still exposed and often fall a sacrifice to the fury of their enemies. They are tolerably well protected in winter by their remote situation; and, in summer, they guard as much as possible against surprise, by residing chiefly on islands and peninsulas; but with all these precautions, they are often so harassed and closely pressed by their pursuers, as to be obliged to leave behind them those goods and utensils upon which they depend for procuring subsistence, and the loss of which they cannot replace without a great expence of time and labour. These more northern Esquimaux are of low stature and broad figure, but neither strong nor well proportioned. Their complexion is of a dirty copper colour, but some of their women are considerably fairer. They have a singular custom which distinguishes them as a peculiar tribe, namely, that all the men have the hairs of their heads pulled out by the root; but in most other respects, they resemble the Esquimaux of Hudson's Straits and Labradore. Their arms and utensils, from the want of proper tools, are very inferior in workmanship to those of the more southern tribes of their nation; yet even with the imperfect instruments in their possession, many of their articles of furniture are formed and ornamented with wonderful ingenuity, especially their stone kettles. They are made of a grey porous stone, of an oblong square shape, wider at the top than the bottom, with strong handles of solid stone left at each end, for the purpose of lifting them more conveniently, and are sometimes large enough to contain five or six gallons. They are all ornamented with neat mouldings around the rim, and occasionally with a kind of fluted work at the corners; and all this is executed with no other instruments than such as are made of a harder kind of stone. Their arrows, spears, darts, &c. are generally pointed with a triangular piece of black stone, or sometimes a piece of copper. Their tools for wood work are entirely of this metal, namely, hatchets, broad bayonets, and women's knives. The hatchets are made of a thick piece of copper, about five or six inches long, and from one and a half to two inches square, bevelled away at one end like a mortice chisel, and fastened at the other to a wooden handle about twelve or fourteen inches in length, so as to resemble an adze; but they have neither weight nor sharpness to act like an adze or hatchet, and are generally applied in working like a chisel, being driven into the wood with a heavy club. The bayonets resemble an ace of spades, and are fastened to a handle of deer's horn about a foot long. During summer, they live in cir-

* The Southern Indians consider the aurora borealis as the assembled spirits of their departed friends dancing in the clouds; but the Northern Indians have no belief of this nature, and merely speak of that phenomenon by the name of Deer, in consequence, it is said, of observing, that a hairy deer-skin, when briskly stroked with the hand in the dark, emits electrical sparks like these lights in the atmosphere

† For an account of the other tribes of that people, see Greenland and Labradore.

cular tents covered with deer skins, and employ themselves principally in fishing; but in winter they occupy small huts, the lower half of which is sunk below the surface of the earth, and the upper part formed with poles which meet at the top in a conical form. Those who reside near Churchhill river travel, in winter, from lake to lake, or from river to river, where they have magazines of provisions, and heaps of moss for fuel; but as those stations are often far distant from each other, they frequently pitch their tents on the ice, and cut holes in the ice within the tent, where they sit and angle for fish, which, for want of fire, they eat in a manner alive as they come out of the water, and are altogether a miserable starving race of beings.

The original Hudson's Bay Company appear to have acted upon the most liberal and benevolent principles. Their instructions to their factors contain the most explicit directions, to use every mean in their power for reclaiming the Indians from a state of barbarism, and inculcating on their minds the principles of Christianity. They were, at the same time, admonished to trade with them equitably, and to take no advantage of their native simplicity; to explore the country, and to study to derive such benefit from its soil and produce, as might redound to the interest of the mother-country, as well as to their own emolument; to watch over the behaviour of the European servants, especially as to sobriety, temperance, and veneration for the services of religion. The chief person in command at each settlement is called the governor of the fort, and sometimes there is one appointed to act under him, termed the second. These, with the surgeon and the master of the sloop attached to the place, constitute a council, who deliberate together in all matters of importance, or cases of emergency. The governors are appointed for a period of 3 or 5 years, and have from 50*l.* to 150*l.* per annum as fixed salary, with a premium upon the trade, which consequently fluctuates according to its amount.* The labouring servants, who are chiefly procured from the Orkney islands, are generally engaged for three, four, or five years, and, about twenty years ago, received six pounds per annum as wages, independent of maintenance. Their employments consist principally in carrying fuel, sledging the snow out of the avenues of the factory, and hunting. The company export muskets, pistols, powder, shot, brass and iron kettles, hatchets, knives, cloth, blankets, baize, flannels, gunworms, steels and flints, hats, looking-glasses, fish-hooks, rings, belts, needles, thimbles, glass-beads, vermilion, thread, brandy, &c. with which they purchase from the natives skins, furs, whalebone, train oil, ivory, eider-down, &c. The trade was understood, in its original flourishing state, to be the most profitable in the world; and the proprietors of the stock were generally supposed to gain about 2000 per cent. It has been denounced, however, as proportionably detrimental to the mother-country; and it has been affirmed, that, if laid entirely open, the number of persons employed, and the quantity of wares exported, might easily be increased ten fold. The company are charged, at the same time, with transacting all their affairs with the greatest secrecy, and always shewing the utmost reluctance to expose the details of their trade to public view. On the other hand, during a parliamentary inquiry into their proceedings in 1749, they produced documents to prove, that their profits were sufficiently limited, as appears from the following summary of their expenditure and returns, in the space of ten years, from 1739 to 1748, inclusive:

| | |
|---|---|
| Charges of shipping, factories, &c. in ten years . . . . . . . | *L.* 157,432 14 4 |
| Exports during that period . . | 52,463 9 0 |
| Total expences . . | *L.* 209,896 3 4 |
| Amount of sales . | 273,542 18 8 |
| Clear profits from the trade in ten years | *L.* 63,646 15 4 |
| Dividends in one year among 100 shares of *L.*100 each . . . | *L.*6364 13 6 |
| For each proprietor of *L.*100 stock . | *L.* 63 12 11 |

The following account of imports and sales for one year, from Michaelmas 1747 to Michaelmas 1748, may afford a more detailed view of the articles of the trade, and their respective values:

| Articles. | Number. | | *L.* | *s.* | *d.* | |
|---|---|---|---|---|---|---|
| Beaver skins . . | 52,716 | at | | 7 | 6 | per skin |
| Martins . . . . | 8,485 | at | | 6 | 8 | do. |
| Otters . . . . . | 1,445 | at | | 9 | 7¼ | do. |
| Cats . . . . . | 1,199 | at | | 10 | 10½ | do. |
| Foxes . . . . . . | 527 | at | | 8 | 1¼ | do. |
| Wolverins . . . | 977 | at | | 5 | 0 | do. |
| Bears . . . . | 371 | at | 1 | 2 | 7 | do. |
| Wolves . . . . | 1,663 | at | | 9 | 6¾ | do. |
| Woodshocks . . | 32 | at | | 10 | 7 | do. |
| Elks . . . . . | 50 | at | | 6 | 7 | do. |
| Deer . . . . | 105 | at | | 2 | 3 | do. |
| Bed-feathers . . | 5,838 lbs. | at | | 1 | 2 | per lb. |
| Castor . . . . | 308 | at | | 6 | 2¼ | do. |
| Whale fins . . . | 226 | at | | 2 | 0½ | do. |
| Minks . . . . | 33 | at | | 3 | 1 | per skin. |
| Racoons . . . . | 26 | at | | 1 | 7 | do. |
| Goose quills . . . | 43,000 | at | | 15 | 0 | M. |
| Musquash . . . | 268 | at | | 0 | 9¼ | per skin. |
| Badger . . . . | 80 | at | | 1 | 1 | do. |
| Total value . | *L.* 30,160 | | | 5 | 11 | |

The Company's establishments in the Bay, in the year 1790, may be seen at one view in the following Table.

| Settlements. | Number of Servants. | Indian Settlements. | Ships consigned to. | Sloops in the country. | Trade on average. |
|---|---|---|---|---|---|
| | | | Ships. Tons. | Sloops. Tons. | |
| Churchhill Fort . . . . | 25 | | 1 of 250 | 1 of 70 | *L.*10,000 |
| York Fort } Severn-house } . . . | 100 | 4 | 1 of 250 | 1 of 60 | 25,000 |
| Albany Fort . . . . | 50 | 2 | | | 5,600 |
| Moose Fort . . . . | 40 | 2 | 1 of 280 | 1 of 70 | 7,000 |
| East Main . . . . | 25 | | | 1 of 70 | |
| Total . . | 240 | 8 | 3 780 | 4 270 | *L.*47,600 |

* The Second has about 40*l.*; an assistant, 25*l.*; and a clerk, 15*l.* per annum.

In forming a standard of trade with the natives, the beaver skin is taken as the universal measure; and a comparative valuation made of the other kinds of peltry, &c.

| | | | |
|---|---|---|---|
| A full grown moose | skin | 1 as | 2 beavers. |
| Cub ditto | | 1 | 1 |
| Old bears | | 1 | 3 |
| Cub ditto | | 1 | 1 |
| Foxes, black | | 1 | 4 |
| Ditto, grey | | 1 | 3 |
| Ditto, white | | 2 | 1 |
| Ditto, red | | 1 | 1 |
| Ditto, brown | | 2 | 1 |
| Wolf | | 1 | 2 |
| Wolverins | | 1 | 2 |
| Cats | | 1 | 2 |
| Otter, old parchment | | 1 | 1 |
| Ditto, cub and drest | | 2 | 1 |
| Martins, prime | | 2 | 1 |
| Ditto, ordinary | | 3 | 1 |
| Deer, buck | | 1 | 1 |
| Ditto, doe | | 2 | 1 |
| Musquash | | 6 | 1 |
| Goose feathers | lb. | 10 | 1 |
| Ditto quills | No. | 2000 | 1 |
| Castor | lb. | 2 | 1 |

With these the trading goods are bartered, or rather directed to be bartered, at the following rates:

| | | | |
|---|---|---|---|
| Glass beads | lb. | 1 as | 1 beaver. |
| China ditto | | 1 | 6 |
| Kettles, brass | | 1 | 1½ |
| Coarse cloth | yard | 1 | 3 |
| Blankets | No. | 1 | 7 |
| Tobacco, Brasil | lb. | ¾ | 1 |
| Ditto, leaf | | 1 | 1 |
| Ditto, English roll | | 1 | 1 |
| Shirts, check | No. | 1 as | 2 |
| Ditto, white | | 1 | 2 |
| Stockings, yarn | pair | 1 | 2 |
| Powder | lb. | 1 | 1 |
| Shot | | 4 | 1 |
| Duffels | yard | 1 | 2 |
| Knives | No. | 4 | 1 |
| Guns | No. | 1 | 14 |
| Combs | | 1 | 1 |
| Flints | | 16 | 1 |
| Vermilion | lb. | 1 | 16 |
| Pistols | No. | 1 | 7 |
| Small burning glasses | | 1 | 1 |
| Gartering | yard | 1½ | 1 |
| Orrice lace | | 1½ | 1 |
| Rings, brass | No. | 3 | 1 |
| Files | | 1 | 1 |
| Tobacco boxes | | 1 | 1 |
| Awl blades | | 8 | 1 |
| Boxes, | barrel | 3 | 1 |
| Hawks-bells | pair | 12 | 1 |
| Sword blades | No. | 1 | 1 |
| Ice chisels | | 1 | 1 |
| Gun worms | | 4 | 1 |
| Hats, coarse | No. | 1 | 4 |
| Trunks, small leather | | 1 | 4 |
| Needles | | 12 | 1 |
| Hatchet | | 1 | 1 |
| Brandy, English | gallon | 1 | 4 |
| Medals | No. | 12 | 1 beaver. |
| Thimbles | | 6 | 1 |
| Collars, brass | | 1 | 2 |
| Fire steels | | 3 | 1 |
| Razors | | 2 | 1 |
| Thread | lb. | 1 | 1 |

Out of this standard, however, which is in itself sufficiently hard upon the Indians, the factors are allowed, for their own emolument, to raise a surplus-trade; so that the natives often pay at the rate of one-third, or even one half, more than the preceding rates. In consequence of this griping traffic, and the alleged supineness of the company, the trade has been gradually decreasing, though the articles procured have been bringing a higher price at home. This is partly ascribed to the competition of the Canadian traders since 1773, who penetrate into the interior, and establish trading ports nearer the abodes of the natives, who often collect more skins than they are able to convey to the settlements on the coast, and are glad also to find a market without needing to seek it through a long and laborious journey. By these enterprising competitors under Mr Joseph Frobisher, the company's trade suffered so severely, that, in 1775, it fell short nearly one half of what it had been in 1774. They immediately commenced pursuit of the retreating trade, by erecting trading houses in the interior. In 1775, they formed a settlement at Sturgeon Lake, in north latitude 53° 56′, and west longitude 102° 15′; in 1793, their traders repaired to the south-east of Portage de Traite, among the Knisteneaux, whom they term their home guards; and, about the beginning of the present century, to Athabasca river, in north latitude 56° 42′, among the Chepewyans. Since the establishment of these trading houses, which are maintained at a great expence, the Indians have in a great measure ceased to visit the factories on the coast of Hudson's Bay, which have thus become little better than storehouses for the articles of the trade. Still, however, in spite of these endeavours to secure the *traffic* of the natives, they have found the adventurers from Canada in every respect an overmatch for their people in the business; a circumstance for which it is difficult to account, when it is considered how much nearer to the Indian hunters is the residence of the Hudson's Bay traders, and in how much shorter a time they can procure a return upon their goods. The directors of the Company appear to have readily authorised their agents to pursue the inland trade since the encroachments of the Canadians, of which a proof may be adduced from the following manuscript notes in a copy of Mackenzie's Voyages, by one of their factors at that period.* "When chief factor at York Fort, I sent inland several young men with the Indians, to observe the movements of the Canadian adventurers. They found bands of them, with servants and coureurs des bois, pursuing the fur trade with more spirit than their predecessors the French. From that date, 1762 to 1764, I yearly sent inland, and repeatedly informed the directors of what was going forward. The Company's trade at York Fort increased for two or three years after the conquest of Canada; but decreased after Findlay, Currie, &c. penetrated to Saskatchiwine river. Anno 1774, I advised the directors to establish settlements inland, with which they readily complied; and have continued to do so at an enormous expence. I do affirm, the Company spare no cost to promote trade in every branch. This I say from my own experience, having been 26 years in their service, greater part of that time governor and chief factor; and since I left the employment, have been highly honoured

* The late Andrew Grahame, Esq. Prestonpans.

with their esteem, and application for advice on the subject. But our countrymen from Canada are bold adventurers, and far superior to the Company's servants: the former work for their own benefit, while the latter do not." "I repeatedly advised the Directors to prosecute the trade to Athabasca; but the servants never would venture, making as excuse, that they would be in want of food." The company, however, have been loudly and publicly charged with making only the most languid exertions, with failing from an ill-judged parsimony to animate their servants by adequate salaries, and with injudiciously employing in the carrying part of the inland trade the native Indians, who are so much less active than the Canadian servants, and who are thus withdrawn from their more profitable service as hunters. It has been affirmed, in short, that were they to prosecute the trade with spirit, the Canadian associations would be obliged to relinquish it entirely; and it has been consequently urged, that so inefficient a monopoly should be thrown open to the exertions of the public. These charges, however, are made chiefly, and rather inconsistently, by the rival fur traders from Canada, who have certainly been the greatest gainers by the remissness of those from Hudson's Bay; and who must be convinced, that, if the trade were thrown open, it would naturally be prosecuted rather through the more favourable stations on Hudson's Bay, than through the circuitous route of the St Lawrence. See Foster's *History of Voyages and Discoveries in the North*; Hearne's *Travels to the Northern Ocean*; Mackenzie's *Voyages through the Continent of North America*; Umfreville's *State of Hudson's Bay*; and Long's *Travels in Canada*. (*q*)

HUET, Peter Daniel, Bishop of Avranches in France, an eminent scholar, was born of a good family at Caen in Normandy, on the 8th of February, 1630. His parents died while he was but an infant, and left him to the care of guardians, who neglected him; but his natural abilities and innate love of learning overcame all disadvantages, and before he was thirteen years of age he had finished his studies in the *belles lettres*. Having entered into the study of philosophy, he found an excellent guide in father Maimbrun, a Jesuit, who directed him to begin by learning a little geometry. Huet, however, went farther than his tutor desired, and contracted such a relish for the mathematics as had almost induced him to abandon his other studies.

Having finished his elementary studies, it was his object to apply himself to the law, and to take his degrees in that faculty; but from this pursuit he was diverted by two books which were then published. These were, "The Principles of Descartes," and "Bochart's Sacred Geography." To the philosophy of Descartes, of which he was a great admirer, he adhered for many years; but afterwards abandoned it, when he discovered the fallacy of its principles. The immense erudition displayed in Bochart's work made a great impression on him, and inspired him with a strong desire to become conversant with Greek and Hebrew learning. To assist his progress in these studies, he contracted a friendship with Bochart, who was minister of the Protestant church at Caen.

At the age of twenty, he was emancipated, by the custom of Normandy, from the tuition of his guardians; and soon after made a journey to Paris, with the view of purchasing books, and becoming acquainted with the learned men of the times. About two years afterwards, he accompanied Bochart to the court of Christina, queen of Sweden, and had thus an opportunity of introducing himself to the learned in other parts of Europe. The queen, it is said, wished to have engaged him in her service; but owing to the jealousy and intrigues of Bourdel, another physician, Bochart's reception had not been very gracious; and Huet, being aware of the fickle temper of Christina, declined all offers, and returned to France after an absence of three months. The principal advantage which he derived from this journey, besides the acquaintance he formed with the learned men in Sweden and Holland, consisted in the acquisition of a copy of a manuscript of *Origen's Commentaries upon St Matthew*, which he transcribed at Stockholm. While engaged in translating this work, he was led to consider the rules of translation, as well as the different manners of the most celebrated translators; and in 1661, he published his thoughts upon this subject at Paris, under the title *De interpretatione libri duo*; a work written with great vigour and elegance, in the form of a dialogue between Casaubon, Fronto Ducæus, and Thuanus. In 1664, he published, at Utrecht, an elegant collection of Greek and Latin poems, which was afterwards enlarged in several successive editions. At length, in 1668, he published at Rouen his *Origenis Commentarii*, &c. *cum Latina interpretatione, notis et observationibus*, in 2 vols. folio; to which was prefixed an ample preliminary discourse, containing all that antiquity relates concerning Origen.

In 1659, Huet was invited to Rome by Christina, who had abdicated her crown and retired thither; but he again declined the invitation. About ten years after, when Bossuet was appointed preceptor to the Dauphin, Huet was chosen for his colleague, with the title of sub-preceptor. He accordingly went to court in 1670, and remained there till 1680, when the dauphin was married. It is to this appointment, probably, that the learned world is indebted for the editions of the classics *in usum Delphini*; for although the first idea of the commentaries for the use of the dauphin was started by the Duke de Montausier, it was Huet who digested the plan, and directed the execution of this useful undertaking. Although necessarily much occupied with the duties of his situation, he found leisure, at this period, to compose his *Demonstratio Evangelica*, which was published at Paris in 1679, in folio, and has since been reprinted in various forms. He was admitted a member of the French Academy in 1674.

At the age of forty-six, Huet entered into orders; and in 1678 he was presented by the king to the abbey of Aunay in Normandy, whither he retired every summer after he had left the court. In 1685, he was nominated to the bishopric of Soissons, which, with the consent of the king, he exchanged with the Abbé de Sillery for the see of Avranches. In 1689, he published his *Censura philosophiæ Cartesianæ*; and in 1690, his *Questionis Alnetanæ de Concordia Rationis et Fidei*, which work is written in the form of a dialogue, after the manner of Cicero's Tusculan Questions.

In 1699, he resigned his bishopric of Avranches, and was presented to the abbey of Fontenay, near the gates of Caen. Soon after, he removed to Paris, and lodged among the Jesuits in the Maison Professée, to whom he bequeathed his library, reserving to himself the use of it while he lived. Here he resided during the last twenty years of his life, and employed himself chiefly in writing notes on the vulgate translation of the Bible; for which purpose he is said to have read over the Hebrew text twenty-four times, comparing it, as he went along, with the other Oriental texts. In 1712, he was seized with a severe illness, from which, contrary to the expectation of his physicians, he gradually recovered, and applied himself to the writing of his life, which was published at Amsterdam in 1718, under the title of *Pet. Dan. Huetii, Episcopi Abricensis, Commentarius de rebus ad eum pertinentibus*. The critics have wondered how such a master of the Latin language as Huet should have been guilty of so great a solecism in the very title of his book, by using the pronoun *eum* instead of *se*. This performance, although composed in an amusing style, is by no means equal to his other works, his faculties being then a good deal impaired. He died on the 26th of January, 1721, in the 91st year of his age. The Abbé Olivet relates a most remarkable singularity of Huet, viz. that for two or three hours before his death, he recovered all the vigour of his genius and memory.

Besides the works we have mentioned in the course of the preceding narrative, Huet published a variety of other treatises upon literary and philosophical subjects. He had been, throughout the whole of his long life, a hard student; and he left behind him the reputation of one of the most learned men of the age. See *Eloge Historique de M. Huet, par M. l'Abbé Olivet*, prefixed to his *Traité Philosophique de la foiblesse de l'Esprit humain*; Aikin's *Life of Huet*, London, 1810; and *Gen. Biog. Dict.* (z)

HUGUENOTS, a name of uncertain origin, given to the Protestants of France. A full account of their history will be found in our article FRANCE.

HULL, or KINGSTON-UPON-HULL, is a seaport town of England, in the east riding of Yorkshire, situated on the west side of the river Hull, and on the northern side of the river Humber, about twenty miles from its mouth.

The town, which lies on a level tract of ground, extends nearly in a direct line along the river Hull, from the Humber bank to very near the church of Sculcoates, a space of about two miles. It stretches nearly as far in another direction, from the High Street on the river Hull towards Beverly, Anlaby, and Hessle. The dock, or artificial harbour, divides the town into two principal divisions. The one to the north of the dock belongs to the parish of Sculcoates, and is without the original boundaries of Hull. It consists of several very spacious streets, which have been built chiefly within the last thirty years. The principal streets of Hull are clean and spacious, and the whole town is paved, flagged, and lighted.

The public buildings of Hull are numerous, but by no means elegant. The Trinity church, which was partly built about the year 1312, is a magnificent and beautiful structure, built in the Gothic style. It occupies a space of 20,056 square feet. It extends 279 feet from the west door to the east end of the chancel. The nave is 144 feet long, the breadth of the transept 28, and the length of the chancel 100. The breadth of the nave is 72 feet, and the breadth of the chancel 70 feet. St Mary's church, commonly called the Low church, was built a few years later than the preceding. Its length is 74 feet, and the height of the steeple is 74 feet. St John's church, a neat and simple brick building, was erected at the sole expence of the Rev. Thomas Dikes, and finished in 1792. It is 86 feet long, and 59 broad. It is wholly built upon arches, raised seven feet above the surface, and contains more than 70 vaults for burying the dead. The town contains several places of worship belonging to the three denominations of dissenters, to the Methodists, and other sectaries. The Methodist chapel in Waltham Street is spacious and elegant.

Among the charitable institutions of Hull, that of the Trinity-house is the most ancient. It was established in 1369, for the reception of decayed seamen who have been admitted members of the institution; but it has, for many years past, been set apart for the widows of such seamen as have attained the age of fifty. In 1787, the Trinity-house built an hospital for decayed seamen and their wives; and in the same year they founded a marine school, for preparing boys for the sea service. Thirty-six boys are now educated at this seminary, each member of the corporation appointing one. They continue at school three years, and are annually clothed in a neat uniform. The present house was erected in 1753, and is of a quadrangular form, inclosing a spacious area. The different apartments, and the curiosities which they contain, are well worthy of being examined.

The Charter-house Hospital was founded by Michael de la Pole in 1384, for the support of poor pensioners, under the superintendance of a master. It is a plain building, with two projecting wings, and is built of handsome brick, covered with blue slate. It contains 44 apartments, well fitted up for the accommodation of the pensioners, who are allowed 3s. 6d. per week each, besides coal, turves, and occasional payments. The chapel, which is spacious and neat, is in the body of the building. The minor charities are, Lister's Hospital, for the reception of 12 paupers; Gregg's Hospital; Crowle's Hospital, for 12 paupers; Watson's Hospital, for 14 poor; Gee's Hospital; Harrison's Hospital; and Ratcliffe's Hospital.

The Charity Hall or Work House was established in the reign of King William III. The house is decent and commodious, and has a house of correction adjoining to it.

The public charities supported by voluntary contribution are very numerous. The General Infirmary was established in 1782 upon the most liberal and humane principles. The building is of brick, ornamented with stone, and is neat and handsome. It is situated in a healthy spot, and can accommodate seventy in-patients. The ranges of wards open into a long, wide, and airy gallery, for the purpose of obtaining a perfect ventilation. The total number of patients admitted between 1782 and 1816 is 15,129, of whom 11,248 have been cured, and 193 greatly relieved. The total number of persons vaccinated, up to January 1, 1816, is 5,566.

The Lying-in Charity appears to have been established about 1802. More than 4,281 patients have been admitted since the 5th April 1802, and the number of children born 4,314. The Hull Female-Penitentiary was opened in July 1811. More than 100 females have been admitted, and a great proportion of these have been restored to their friends. The Hull and Sculcoates Dispensary has been recently established, and a Humane Society, for the recovery of persons apparently dead, was founded in 1800.

The *Grammar School* of Hull was founded and endowed in 1436 by John Alcock, Bishop of Ely. The School Room is esteemed one of the best in England. The *Vicar's School* is a free institution, founded in 1734 by William Mason, vicar of the parish, and the father of the poet, for the education of 60 scholars. Coggan's Charity School educates 20 poor female children. Besides these, there are subscription schools in Salthouse Lane, which originated in 1786. They consist of two day schools for girls, each containing 30, and four Sunday schools for boys. The buildings are capacious, and no fewer than 250 boys and 150 girls are educated here on Bell and Lancaster's system.

The other public buildings at Hull are, the citadel, the exchange, the custom-house, the theatre, the gaol, the Hull subscription library, &c. The *citadel*, intended for the defence of the harbour and town, is situated on the east bank of the river. The ancient castle, called the Magazine, is a mere storehouse for arms and ammunition. A battery of 21 guns faces the Humber, and the embrasures on the mounds are well furnished with cannon. The citadel is surrounded with a ditch palisadoed in the middle. The garrison generally consists of a few companies of invalids. The exchange was opened on the 1st of January 1794. It is a brick building, on a most substantial plan, with a spacious flagged area in front of it. The public subscription news room is above the exchange. The custom-house is a spacious and handsome building, situated in White Friar Gate. The theatre, erected in 1809, is a large building in Humber Street. The present gaol, which contains very healthful accommodations, was erected in consequence of an act of parliament passed in 1789. The Hull subscription library was instituted Dec. 6, 1775; and the foundation stone of the present building in Parliament Street was laid on the 21st of June 1800. The library possesses a spacious reading-room, which is open to the subscribers every day. The collection of modern books is excellent, and the number of subscribers is nearly 500.

The avenue from the market-place to the Humber was widened some time ago, by removing the guildhall, on the site of which the most elegant and well ventilated shambles were erected in 1806. The east end of Trinity church is thus exposed to the market-place, in the centre of which is a beautiful equestrian statue of King William III. erected in 1734 by subscription, and executed by Mr Sheemaker.

Hull may be considered as one of the first commercial towns in the united kingdom. It carries on a great intercourse with the Baltic, and sends an immense number of ships annually to the whale fishery.

The wet dock, which was originally intended to receive all the ships engaged in the trade of Hull, was begun in virtue of an act of parliament passed in 1774. The foundation stone was laid on the 19th Oct. 1775, and the whole was completed in four years instead of seven, as required by the act. Government gave a grant of the ground, and of 15,000*l*. It occupies the place where the walls and ramparts once stood, and it enters immediately from the river Hull, about 300 yards from its mouth. It is 700 yards long, 85 wide, 22 deep, and is capable of containing 130 vessels of 300 tons. Including the wharfs and quays, it covers an area of 13 acres, the area of the dock being 48,188 square yards, and that of the quay 17,479. The subscribers are incorporated under the title of the "Dock Company at Kingston-upon-Hull." The number of shares was originally 120; but acts were passed in 1802 and 1805, empowering the Company to raise them to 180. The money arising from this increase in the number of shares, amounting to 82,390*l*., was appropriated to the construction of another wet dock, called the Humber Dock.

The foundation stone of the Humber Dock was laid on the 13th April 1807, and it was completed in 1809, at the expence of 220,000*l*. The area of the dock is 7 acres and 18 perches, and that of the road and wharfs is 3 acres and 33 perches, amounting in all to 10 acres 1 rood and 11 perches. It opens into the Humber by a lock, which will admit a fifty gun ship, and which is crossed by an iron bridge. By extending the dock a little farther to the north, to the extremity of White Friar Gate, the old town may be completely insulated. Hull possesses also several dry docks for repairing vessels. The following Table, shewing the amount of the customs in different years, will exhibit a correct view of the progress of the trade of Hull:

| | | | |
|---|---|---|---|
| 1701 | *l*. 26,287 | 1805 | *l*. 386,070 |
| 1778 | 78,229 | 1806 | 374,907 |
| 1785 | 91,366 | 1807 | 340,825 |
| 1792 | 199,988 | 1808 | 198,487 |
| 1802 | 438,459 | 1809 | 276,811 |
| 1803 | 379,675 | 1810 | 311,780 |
| 1804 | 287,210 | | |

The following Table exhibits the state of the Greenland fishery, from 1806 to 1811 inclusive:

| Years. | Ships. | Whales. | Seals. | Unicorns. | Bears. | Sea Horses | Tons Oil. |
|---|---|---|---|---|---|---|---|
| 1806 | 37 | 239 | 1804 | 10 | 3 | 6 | 3382 |
| 1807 | 35 | 377 | 722 | 24 | 9 | | 4253 |
| 1808 | 27 | 467 | 552 | 13 | 4 | 2 | 4330 |
| 1809 | 26 | 419 | 311 | 9 | 7 | | 4230 |
| 1810 | 34 | 449 | 1238 | 8 | 13 | | 4912 |
| 1811 | 42 | 552 | 993 | 2 | 2 | | 4782 |

The inland trade of Hull exceeds that of any other English port. In the year 1792, merchandise, stores, coals, &c. to the value of 5,156,998*l*., were conveyed to and from the Aire and Calder navigation alone.

The following Table contains the number of ships that entered inwards and cleared outwards, from 1804 to 1810, inclusive.

| Years. | With Cargoes. | | In Ballast. | | Coasting Vessels. | |
|---|---|---|---|---|---|---|
| | Inw. | Outw. | Inw. | Outw. | Inw. | Outw. |
| 1804 | 728 | 279 | 51 | 380 | 1560 | 1547 |
| 1805 | 658 | 232 | 47 | 327 | 1626 | 1602 |
| 1806 | 513 | 226 | 29 | 272 | 1576 | 1636 |
| 1807 | 525 | 158 | 9 | 335 | 1484 | 1614 |
| 1808 | 207 | 67 | 109 | 135 | 1557 | 1733 |
| 1809 | 473 | 256 | 55 | 223 | 1806 | 1938 |
| 1810 | 622 | 193 | 30 | 427 | 1786 | 2033 |

Various manufactures are carried on in Hull. One of the principal is, the expressing and refining oil from lintseed, and preparing the residue for feeding cattle. Many of the mills for this purpose, and for grinding corn, are from about 80 to 100 feet high, and contain excellent machinery. The other manufactories are, an iron foundery, a large soap-work, two sugar-houses, several white lead manufactories, several breweries, and several ropeworks and shipbuilders yards.

The civil authority of the county of Kingston-upon-Hull, which includes a district of more than 18 miles, comprehending the villages of Hessle, Anlaby, Kirk Ella, West Ella, Swanland, and North Ferriby, is vested in the corporation, consisting of the mayor, the recorder, the sheriff, two chamberlains, and twelve aldermen. The town sends two members to parliament, who are elected by the burgesses.

The following is an abstract of the population returns for the town of Hull in 1811:

| | |
|---|---|
| Number of inhabited houses | 4611 |
| Do. of uninhabited houses | 306 |
| Do. of families | 6541 |

| | |
|---|---|
| Number employed in agriculture, . . . | 305 |
| Do. employed in trade and manufactures . | 2608 |
| Do. not included in any of these classes . | 3628 |
| Males . . . . . . . . . . . . | 11,998 |
| Females . . . . . . . . . . . | 14,794 |
| Total population . . . . . . . . | 26,792 |

See the *Guide to Hull*, published by Mr Craggs, who has favoured us with the proof sheets of it before it was published; Tickhill's *History of Hull*; and the *Beauties of England and Wales*, vol. xvi. p. 447—537.

HUMBER, the *Abus* of Ptolemy, is a large river or estuary in England, which runs into the German Ocean after separating the counties of York and Lincoln. Below the confluence of the Ouse with the Trent, the former of which carries off almost all the waters of Yorkshire, the united streams receive the name of the Humber. It is gradually enlarged to the breadth of two or three miles, and below Hull it swells into an estuary about six or seven miles broad. The Humber has been compared to the trunk of a vast tree, spreading its branches in every direction, and commanding the navigation and trade of a very extensive and commercial part of England. See ENGLAND.

HUME, DAVID, an eminent historian, metaphysician, and general literary character, was the younger son of a very respectable Scottish family, and was born at Edinburgh on the 26th of April 1711. He lost his father when an infant, and the care of his education devolved on his mother, whom he describes as a woman of great merit, who performed in a most exemplary manner the duties of an only parent. In his youth he made a creditable appearance as a scholar, and acquired a high ardour for literature. This did not, as often happens, subside as soon as those more serious occupations to which, in the common calculations of mankind, literature is reckoned preparatory and subservient, were presented to his mind. His fortune being slender, he was destined to the profession of the law. But this pursuit, with all the prospects of honour and wealth which it presents to an aspiring mind, had not for him sufficient charms to eclipse the attractions of classical literature and philosophy. Nor was Mr Hume even content to cultivate the two pursuits in conjunction, the one as the means of his future livelihood, and the other as having a more immediate relation to man as a thinking being. The contrast of their intrinsic character had the effect of disgusting him with the study of law, which he wholly neglected in order to devote himself to literature. He therefore renounced entirely these professional pursuits. Not entertaining the hope, however, of supporting himself comfortably by literary occupations, he was prevailed on, at the age of twenty-three, to make a feeble attempt to enter on a mercantile employment in the city of Bristol. This he soon relinquished, as totally unsuited to his turn of mind; and at last, combining a regard for his favourite studies with the dictates of prudence, he formed a plan for leading the life of a literary man. He resided for two years in France, first at Rheims, and afterwards at La Fleche in Anjou, where he practised a strict economy, and prosecuted with much industry his literary studies. In this retreat he probably had not access to extensive libraries, and depended chiefly on a small collection of his own, with such assistance as was furnished by the convents of the country. Here he was chiefly occupied in the composition of that ingenious, but singular and somewhat paradoxical work, his *Treatise on Human Nature*. He acknowledges that, in the midst of these studies, he was not certain of the utility of his labours, and was in some measure puzzled by the interminable problems which his own ingenuity had raised; yet he gave himself up to the bent of an inquisitive mind, regardless of conclusions, trusting that investigation, if free from bias, could not be too keen or persevering, and that all its apparent disadvantages must be accidental and temporary. He studied human nature in a point of view which was in a great measure his own, without consulting the prevailing taste, either in the choice of his subject, or in the style and manner in which he chose to handle it. He has been accused of a passion for singularity; but we find him in this instance regretting, that opinions which he found inevitable were so different from those which prevailed around him. He published his treatise in London in 1738, and then returned to his friends in Scotland. But all the visions of a sanguine author were now severely mortified. He had been prepared to encounter opposition and outcry. These he expected, and he seems to have pleased himself with contrasting his own unanswerable theorems with the shallow replies which would be zealously and from numerous quarters elicited. But his work excited no interest; it was neither known nor read, and, as he himself expresses it, "fell dead-born from the press." He continued, however, to value the opinions which it contained; and endeavoured, by various persevering efforts, to conciliate to them the public attention. The admirers of his metaphysics reckon it the most profound of his works, and consider his subsequent writings on the same subject as losing in depth what they gained in popularity of manner.

His disappointment, though keenly felt, was surmounted by a cheerful and sanguine temper; and he prosecuted, with renewed industry, his literary labours in the country. In 1742, he published the first part of his *Essays*, which met with a reception sufficiently favourable to console him for his first disappointment. In 1745, he resided as a companion to the Marquis of Annandale in England for twelve months; and, from his appointments during that time, acquired a considerable accession to his small fortune. About this time the professorship of moral philosophy in the university of Edinburgh becoming vacant by the resignation of Dr (afterwards Sir John) Pringle, Mr Hume became a candidate for that situation; but the sceptical principles which he had advanced in his first work were too offensive to allow the magistrates, who were the patrons, or those learned persons whom they consulted, to receive him as a public instructor of youth, and that application was consequently ineffectual.

In 1746, he accompanied General St Clair, as his private secretary, in an expedition destined for Canada, which terminated in an incursion on the coast of France. In 1747, he attended the same gentleman in his military embassies to the courts of Vienna and Turin. From this cause his literary occupations were suspended for two years; but he enjoyed with much relish, that polished society which he highly ornamented, and in which he was a general favourite. At this time he attempted to give a more popular form to his first speculations, in a work entitled *An Inquiry concerning the Human Understanding*; which, however, had little better success than the original *treatise*. A new edition of his *Essays* was also published, which met not with a much better reception. Mortified in some degree, but not discouraged, by these miscarriages, he continued his efforts to rouse the attention of the world to his favourite subjects. He had now returned to his brother's house in Scotland, where he composed his *Political Discourses*, and his *Inquiry concerning the Principles of Morals*. His opinions had gradually worked themselves into notice; an effect which the plausibility of his reasonings, the charms of his language, and the importance of the subjects, could not fail to produce. Being adverse to the prevailing philosophy, as well as bearing strongly on the religion of the age, and considered by many persons as alarming in their tendency, they could not, of course, be permitted to extend their influence, without having their validity subjected to the most rigid scrutiny. Mr Hume, either unalterably confident in the justness of his views, or considering them as less important than his fame, was principally disposed to look on the appearance of a succession of replies, as flattering symptoms of his rising reputation, and derived from them encouragement to proceed in his career. In 1752, his *Political Discourses* were published. This was the first of his works which gained immediate attention, and general approbation. He also now published his *Inquiry concerning the Principles of Morals*, a work which met with little notice, though more highly valued by the author than any other. It appeared to correspond too much with the sceptical principles of his other writings on moral subjects, by referring all moral distinction to utility. It certainly, however, displayed much acuteness of research, and contributed to remove much of the rubbish by which questions of this nature had been encumbered. The dangerous character which Lord Kames, and some others of his opponents, attached to a theory which reduced all moral differences to utility, as leaving them to the arbitrary decisions and varying judgments of individuals, is more or less applicable to every theory on the subject. The agreement or disagreement of mankind on particular moral questions, is rather matter of fact than of theory. The apprehensions of any dangerous tendency attached to the theory of Mr Hume, imply, in their most obvious sense, a contradiction in terms. Utility is, in itself, real and precise, however obscurely understood; and in its very essence excludes all idea of danger. We have, indeed, heard particular acts represented as inculcated by utility, while their danger was capable of being painted in the most convincing terms. These arguments only prove, that the character of utility may be rashly applied, while some circumstances essential to it are omitted. Utility, indeed, is not a simple original principle. It is a general feature, applicable to a variety of phenomena, among which human actions are to be numbered; and even with those who grant that there are prior principles of our nature which serve to suggest moral distinctions, all such suggestions must be allowed to become the subjects of computation; and in all discussions of the propriety of particular actions, utility is the ultimate test to which we are referred, and is necessary to stamp them with the character of rectitude.

In the same year, he was made librarian to the Faculty of Advocates of Edinburgh, a situation which not only gave him command of the invaluable library belonging to that body, but forcibly directed his attention to the character of the works which it contained. It was now that he began to write his *History of England*, that highly pleasing performance, which, however censured in some of its parts and tendencies, is read with delight by all classes of persons, and does high credit to the country which gave birth to its author. The first volume that was published, commenced with the accession of the house of Stuart, and contained the reigns of James I. and Charles I. It appeared in 1754. The public, however, were not so easily won by the splendour of his narrative, and that air of easy philosophy which dictated the remarks of the historian, as to give any quarter to his obnoxious sentiments. He offended the Christian world, by treating religious systems too lightly, and even the advantages which this characteristic might at first seem to promise to the spirit of toleration, were found to be coldly withheld. His displeasure is chiefly directed against the complaints, and even the non-conformity, of the people; and he palliates in the conduct of princes all deviations from patriotism and law, as well as that offensive arrogance which set at nought the object of general satisfaction. He construes the slightest incongruity in the complaints of the nation, which was capable of being turned to ridicule, into a vindication of the most arbitrary and intolerant conduct on the part of the sovereign. The party questions relating to the rights which king or people respectively derived from precedent and law, were of much less moment than the spirit in which the contending parties maintained their point. Appeals to the original and universal rights of man are reckoned dangerous, as being subject to the widest differences of opinion, and therefore *precedents* in favour of liberty had been chiefly appealed to by the Whigs. Precedents, however, were to be found on both sides; and Mr Hume points out the shallowness of any pretence to make the ultimate decision of great and general questions in politics depend on them. It is with the degree of correctness and generosity of the spirit in which the king and the people approached to one another for the adjustment of their differences, that an unbiassed historian is chiefly concerned in measuring to each party his share of approbation and of censure. This was certainly so offensive and unconciliating on the part of the Stuarts, as to amount to a forfeiture of all submission, and even of all sympathy, from the party which they laboured to crush. That the dissensions of the times rendered the duties of a sovereign arduous, must be acknowledged, and strong measures might have been on some occasions necessary. But the measures of these princes had neither the merit of strength, nor the inoffensiveness of total inactivity. They were both irritating in their tendency, and destitute of efficiency. The exertion of a despotic authority, if evidently directed to ends substantially good, might have saved the country, and preserved the dynasty. But the Stuarts made their right of power a matter of ostentation, rather than an instrument of good government, and thus insulted the nation, instead of ruling it. There were errors on all sides. The people were often fanatical, and their complaints were sometimes inconsistent. All these facts should come alike under the scrutiny of the historian. But the plausible coolness of Hume degenerates into a cavalierly insensibility: his sarcasms are directed only against the great mass of the nation, while his sympathetic feeling and indulgence are reserved for kings and their ministers.

Dr Herring and Dr Stone, the one primate of England and the other of Ireland, were the only persons from whom the author heard favourable sentiments of his work. Both of these gentlemen wrote to him not to be discouraged. The impression made on his mind by the unfavourable reception of his work, was however very deep. Although on looking to the periodical publications of that day, we find the due tribute repeatedly and even liberally given to his merits as a writer, he seems not to have been at all prepared to meet with any opposition or neglect. He showed on this occasion, the overweening importance which authors are disposed to attach to their own powers, and how little they calculate on the difficulty of making any impression in opposition to the general sentiments of the public. He confesses that his mortification would have now determined him to retire to a corner of France, to change his name, and never more revisit his native country, had not a war breaking out between the two nations, prevented the execution of any such scheme.

He next published his *Natural History of Religion*, which was attacked with considerable acrimony by Dr Hurd, and, though otherwise not much attended to at the time, produced, at a subsequent period, no slight sensation in the religious world, as tending to reduce the general principles of religion to an uncertain and even a frivolous origin in the human mind.

A second volume of the History of England, which brought it down to the revolution, was published in 1756. This, containing fewer obnoxious sentiments, was better received than the first, and even served to impart to it a degree of adventitious character.

In 1759, he published his *History of the House of Tudor*. In this publication he displayed considerable address in supporting his Tory principles. While he details facts which demontrate the duplicity of the character of Elizabeth, he gives her a character far higher than these facts can warrant. At the same time he describes her conduct, as well as that of her predecessors of the same family, as so offensively harsh, that the maxims of the Stuarts, reckoned by many tyrannical, must on the contrast appear mild and liberal. He neglects to give the due weight to the beneficial tendency and the magnanimous justice which marked some of her most arbitrary acts, and the activity which she displayed in managing the vital interests of the state. These characteristics were widely different from the vexatious and idle exaction of reluctant homage which the Stuarts delighted to make from their subjects. Habit had now rendered Mr Hume callous to the impressions of public opinion, which he affected to despise; yet he owed his equanimity in some measure to the increased forbearance of his opponents, and the tribute of admiration which some of his qualities as a writer extorted from all. In 1761, he published the two volumes which contain the earlier part of the English history. The copy money given to him by the booksellers much exceeded any thing of the kind formerly known in England, and his circumstances were in consequence rendered opulent.

At this time a storm of ecclesiastical censure was preparing by some members of the church of Scotland, directed against Mr Hume, and intended to include Lord Kames, and various other writers, who, though differing in their opinions, agreed in treating religious subjects with coolness, and subjecting them to metaphysical analysis. A motion was made in the *committee of overtures* of the General Assembly, in which Mr Hume was named as the most obnoxious author. It was proposed to call him before that court, to answer a list of accusations, on the tendency of the principles which he had published. This, however, was afterwards abandoned, as it was supposed that the influence of such discussions was limited to a narrow circle, and that there could be no propriety in extending them to the common mass of readers, who might, from the sympathy naturally felt for a man subjected to violent opposition, be led to an undue bias in favour of his opinions.

In 1763, he attended the Earl of Hertford on his embassy to Paris, where he was loaded with great civilities. He expresses himself highly pleased with the politeness and information which characterised the society of that metropolis.

In 1766 he returned to England, and then to Edinburgh. On this occasion he brought with him the celebrated Rousseau, who was exposed to some trouble in Switzerland and France, for the opinions which he had published on religious subjects, and had it in contemplation to take up his abode in a retired situation in England. Mr Hume, admiring his genius, and attached to him by fellow feeling as a free-thinker, exerted himself to provide for his comfort. But the morbid sensibility of Rosseau disappointed every scheme of kindness that could be adopted. He conceived himself to be neglected by the world, and was prone to suspect his best friends of intending to undermine his interests, and subject him to ridicule and scorn. Mr Hume soon perceived the troublesome temper of his friend; yet he treated him with great tenderness, making allowance for an excess of natural irritability, heightened by a severe bodily disorder under which he laboured. He even found that one of his complaints, that of extreme poverty, was an entirely false pretence, held out for exciting the interest of others. These frailties Mr Hume deplored, but did not cease to do what lay in his power to serve him. At last Rousseau suspected Mr Hume of being the author of a very improper sarcastic letter, which was circulated in the name of the King of Prussia, as addressed to Rousseau, and was the work of Mr Horace Walpole. Suspicions of all kinds accumulated in his gloomy mind, till they burst forth in a storm of invective in the form of a long letter to Hume. To this Hume published a reply by the advice of the Parisian literati, though contrary to that of Mr Walpole, who thought Rousseau's letter a sufficient answer to itself, and the whole business unworthy of notice. Nothing could have rendered it necessary to answer an effusion so absurd, and so evidently the offspring of disease, except the celebrity of Rousseau, the interest which his admirers took in every thing he did and felt, and their disposition to vindicate the most far-fetched of his insinuations as the dictates of sentiment and sagacity, as to reiterate with zeal his reproachful complaints against other less favourite characters. This friendly connection was thus inevitably dissolved. Every part of it bore testimony to the humanity, tenderness, and sincere friendship of Mr Hume, who, far from neglecting to make due allowances, seems to have exceeded the ordinary limits of human patience.

In 1767, he was invited by Mr Conway to be under secretary of state; a situation which he accepted and held till 1769, when he returned to Edinburgh.

In 1775, his health began to decline. He was attacked with a disorder in his bowels, which gradually increased, and which he perceived at last, at the time that he drew up his short account of his life, to be mortal and incurable. But he continued his former occupations and amusements, and enjoyed unabated good spirits both in his private studies and in company. He lived in a house in James's court in Edinburgh, surrounded by the friends whom he most highly valued. The literary society of Edinburgh at this time contained a few men of the first genius and talent, along with many other persons who made the various objects of liberal study their principal delight. Dr Robertson, principal of the university, the historian, was one of the most eminent, and notwithstanding the wide difference of opinion which existed between him and Hume on the most important subjects, yet as all hope of proselytism on either side was cut off, they avoided all disputes which tended to agitate the passions, and by mutual consent enjoyed the pleasure and improvement, which in other respects they were fitted to impart to one another. The zeal of Dr Blair prevented him from being equally circumspect; and Hume found himself obliged to intimate to that worthy clergyman the necessity of abstaining from all topics which implied serious differences of sentiment, if they were ever to enjoy one another's society. This is decidedly, though delicately, expressed in the letter which he wrote to him, after the perusal of the work of Dr Campbell on Miracles, which Dr Blair had sent to him. Dr. Joseph Black, the celebrated professor of chemistry, and Dr Adam Smith, were among the most intimate of his friends. The latter, however, was now engaged in the composition of that work which has associated his name, in an indelible manner, with the great interests of society, his *Inquiry into the Nature and Causes of the Wealth of Nations*, and lived in a state of retirement with his mother at Kirkcaldy, a town on the opposite shore of the Frith of Forth. This separation was vexatious to Hume, who often ineffectually urged his friend to take up his residence in Edinburgh. They had both written on the origin of moral ideas; they had embraced different opinions, and found it interesting to make the discussions implied in them part of the subject of their conversation. They were both ready to enter on any subject to which the ingenuity of either was directed, and a delightful diversity of topics was undoubtedly suggested by the fates, characters, and all the *memorabilia* of many literary friends, whom, on former occasions, and in different parts of the country and of Europe, they had known. Lord Kames, Mr Smellie, Allan Ramsay the painter, (son of the Scottish poet,) were also among the number of the literati who, in the days of Hume, adorned the circle of this metropolis. The manners of literary men were particularly easy, and they had the character of great frankness and ready accessibility. No cause of political enmity operated as a source of division; differences of religious opinion were tempered in their expression by good manners; the facility of intercourse was not obstructed by affectation, or a harsh incommodious etiquette; literary controversies and private debates were managed without occasion of offence. If any excess existed, it seems to have been on the side of familiarity, which admitted of an indulgence in a coarse species of raillery. From this school issued the following curious sentiment, to be found in Lord Kames's *Art of Thinking:* "You are a fool, you dream, and such like, are expressions we may easily bear from friends. Among free spirits I love freedom. Let the words go the full length of the thought. In a manly society, familiarity is agreeable, because it has nothing effeminate or ceremonious." These manners may be consistent with correctness when of spontaneous origin; but when recommended and studied, they become flat and unmeaning. Familiarity degenerates into insipidity, and those who have indulged it begin to envy the ceremony which, though at first stiff and forbidding, preserves mutual respect, and obviates the cloying influence of extreme freedom. Men oscillate from one inconvenient bias to another, and those who can do it without going far into either extreme are the most happy. Such, in general, is the literary society of Edinburgh. Sober convivial clubs of men of taste and genius have at different times been formed, some of which have been supported with much greater steadiness than the precarious nature of such institutions renders generally practicable. They are soon broken up by the admittance of unaccommodating characters, and on the other hand, they are apt to lose the stamp of liberality, when conducted on a principle of fastidious selection. It is therefore chiefly by a quick succession of them, formed by the buoyant spirit of liberal sociality readily surmounting occasional causes of separation, that they prove agreeable and useful.

The philosophical opinions of Mr Hume subjected him to many controversial attacks. To these he never published any formal reply, but satisfied himself with making occasional private observations, and availing himself of public criticism for amending his works in subsequent editions.

In the manner in which he expressed himself towards those who wrote against him, he shewed himself extremely sensible to the pleasing influence of civility, and the galling effects of disrespect or rudeness. He was pleased with Dr Campbell's *Essay on Miracles*, with an anonymous tract, entitled *A Delineation of Morality*, written by Mr Balfour, an advocate and professor of moral philosophy. But such severities as those of Hurd, Warburton, and Beattie, teeming with petulance and abuse, produced in his mind the strongest feelings of alienation and contempt. His good humour probably too much depended on the cultivation of that radical hauteur which sometimes forms the man of fashion, and was too little cherished by that steady forbearance, and that system of universal allowances, which would have better suited the character of a philosopher.

The progress of his bodily disorder was rapid. In April 1776, he set out for London at the intreaty of his friends, who hoped that a long journey might improve his health. At Morpeth he met with Dr Adam Smith, and Mr Home, the author of the tragedy of Douglas. The latter remained with him in England, while Dr Smith returned to the north. Mr Hume finding himself seemingly improved when he arrived in London, went next to Bath to drink the waters, which contributed still farther to a temporary recovery. But his complaint relapsed with additional violence, and he returned to Edinburgh under a deliberate expectation of soon finishing his days. He employed himself in correcting his works, reading books of amusement, and conversing with his friends. He encouraged his friends to speak to him in the frankest manner as to a dying man. It is evident that he did not entertain a belief in any future state. Yet the constant expressions of a hope of this sort which a man is accustomed to hear in the course of early education, and in the common intercourse of life, render the mind familiar with an imagery founded on that hope to which the most sceptical occasionally recur for amusement, even while they reject a belief which appears to them incongruous. Some of them playfully indulge in supposing themselves to have been imbued with the belief of a mythology belonging to a different age or country, and thus balance the influence of present systems against that of others. Mr Hume had too much respect for society to indulge in any open scurrility directed exclusively against the religious sentiments of the age: but he playfully retailed the conversations which were likely to take place between himself and Charon, the ferryman of the river Styx, at the moment of his transit from the present to the unknown world. He did not affect any great wish to speak on the subject for the purpose of displaying his indifference or his courage, and only touched on it occasionally in reply to the enquiries of his friends. His strength very gradually declined. When no longer able to converse, he continued to read in a state of composure; and after four or five days passed under this degree of debility, he died on the 25th of August 1776.

In stature Mr Hume was above the ordinary size. His countenance was open and free, a just picture of his benevolent and cheerful temper. His features were large, and were exempt from that trifling smartness and habitual intensity of expression which characterise a bustling fashionable ambition. Lord Charlemont, on this account, considered them as blank and unmeaning, and wondered that the ladies at the court of Turin valued so much his company and conversation. His attractions seem to have consisted in the liberality of his mind exhibited in the jolly openness of his countenance. See Hardy's *Memoirs of Lord Charlemont*, and the critique on them given in the *Edinburgh Review*.

The manner in which he died has sometimes been made the theme of injudicious comment, for the purpose of elucidating the merits of particular views of philosophy or religion. The equanimity displayed in his last moments has been boastfully represented as a triumph to infidelity, and a proof that a philosopher may die in tranquillity. Such were the sentiments inculcated in a tract, entitled *An Apology for the Life and Writings of David Hume.* But the eagerness with which a single instance of this kind is grasped at might be plausibly construed into a presumption of the general fallacy of the remark. On the other hand, it is equally unfavourable to candour to embrace, with exclusive keenness, those anecdotes, whether well or ill supported, which represent persons of these sentiments as doomed to the agonies of remorse in the hour of death. This spirit has given rise to some misrepresentations of fact, which fall under the character of pious frauds. We are told, that though a man may lead the life of a fool, by advocating the cause of Deism, yet a fool he cannot die; and then an anecdote is told of some noted infidel, which bears the marks of evident fabrication. That this direction of zeal is wholly superfluous and insufficient in the support of religion, we may be satisfied, when we reflect, that such anecdotes are only circulated concerning those who are infidels by profession. It is maintained that many who, from motives of policy, apparently acquiesce in the religion of the age, do not believe it in their hearts. Such persons might be supposed to labour under the double weight of infidelity and hyprocisy; yet we hear nothing of their death-bed agonies. Allowing, therefore, facts of that kind to which we have alluded to be as general as they have been sometimes represented, they must be otherwise accounted for than by being considered as the unmingled effects of the power of truth on the human conscience. They will be explained in a more satisfactory manner, if ascribed to the influence of that contrariety which an individual of solitary professions feels between himself and the rest of society, oppressing a mind bereft of its energy by the decay of nature. Weak man, even in his most vigorous moments, needs company to support him in the enjoyment of his opinions; and the influence of this principle enters much deeper into the private comfort of individuals than most men are willing to allow. We should always beware of resting questions of so grave moment on data thus precarious.

The character of David Hume as a man has been variously estimated. About his agreeable qualities there could be no difference of opinion; and those who abhorred his principles allowed that he possessed as much worth as was compatible with infidelity. The chief difference, therefore, depends on the amount of that degree of praise. One tells us that he was a pattern of good humour, benignity, and self-command; and as near to perfection as the lot of humanity will admit. Such is the character assigned him by his friend Dr Smith. Another writer says, we may find fault with the measure of his faith, but we cannot deny him the credit of good works. To this Bishop Horne replies, that the promotion of religion is the best of works; and a conduct the reverse of this the worst and most infamous. As for religious principles, and every quality that is strictly implied in them, Mr Hume's character must be given up: and if such terms as virtue, morality, and goodness, are to be so restricted, he cannot be allowed the credit of them. But if we take such words in the sense in which they have been used by the world at large, and by men who scarcely entertain any religious knowledge or sentiment, we must acknowledge Mr Hume to have been honourably distinguished from the great mass of mankind, whether infidel or religious. Some have remarked, that, by his own confession, his ruling passion was the love of fame, and that this is at best a selfish principle. The validity of this reflection involves a question concerning the comparative propriety of preferring the ends of self-love or the good of others in adjusting the motives of human conduct. We seldom object to a man's character because he has a ruling passion, although it should not be the most dignified in its nature. With regard to selfish ends, even a man who enters on holy orders is allowed to be possessed of real worth, though his chief motive is the procuring of a living, provided he is attentive to his professional duties: and some of our gravest and best moralists represent the cultivation of a fund of internal happiness as the first duty of a man, and a far more copious source of benignant conduct than could be formed by cultivating social feelings as the first and leading object of attention, and making personal happiness a subordinate consideration. With the amplest allowance for differences of opinion, and taking benevolence in the most accommodating acceptation which licentiousness itself could desire, possessing also the fullest conviction of Mr Hume's personal sincerity, we cannot consider the general strain of his philosophical writings as indications of a pure benignity, even though we should proceed on the hypothesis of the truth of his speculative views. They had an evident tendency to make many persons unhappy: hard struggles are required from an admiring reader to surmount this tendency,—struggles for which the author furnishes but feeble assistance. Though he entertained no belief in the most consoling doctrines which had been cherished among mankind, benignity would not have led him to begin with overturning them, but rather with showing that happiness might be enjoyed independently of them, and thus he might have been considered as contributing to the creation of habits of feeling which were more to be relied on for their permanence, and as labouring to prepare the mind more completely for the comfortable exercise of a curiosity free from control. Yet by persons whose reading on these subjects is extensive, the works of Mr Hume may be read with advantage. The German philosophers, whose conclusions are the most liberal and pious, look up to Hume as an author, who materially contributed to guide intellectual research, though his system stood in need of some ulterior steps to bring us to the truth; and they speak with great contempt of the data on which the British writers endeavoured to subvert his doctrines. We find such observations as these emanating from the school of Kant, which, though chargeable with obscurity, is not destitute of acuteness.

The censure which we have expressed is most of all applicable to two tracts published after his death, one *On the Immortality of the Soul*, and the other *On Suicide*. The former is little more than a compression of doctrines which he had advanced, or to which he had at least pointed in his other works, but expressed in more dogmatic language. His tract *On Suicide* contains an argument which he had not formerly touched upon; and it must be admitted to have a most pernicious tendency. We read without unpleasant emotions the sentiments which the Romans entertained on this subject, because they cultivated a species of manliness, mistaken indeed, but plausible, and apparently consistent. Mr Hume, on the contrary, encourages that temper which leads to suicide, not by cultivating a heroic contempt of death, but by laying the mind open to the most wretched discontent. He maintains, that those whose happiness is marred by the gloom of superstition have the most urgent motives to rid themselves of life, yet are cruelly prevented by the dread which their belief of future punishment inspires. This remark, inculcated with all the zeal of apparent sincerity, tends to generate the utmost degree of moral confusion; and the motive which could have prompted any writer to commit such a sentiment to paper cannot well be assigned, except by referring it to the perverseness which is so incident to the human mind. If the superstitious are deceived in the dread which they entertain of suicide, they must also be deceived in entertaining a belief in those gloomy opinions which render their lives miserable; and a philosopher, wishing to emancipate them from their errors, can have no reason for recommending suicide, since he relieves them from the evils which generated a weariness of life. The only tendency that such a sentiment can have is, by superadding a new doubt to their former perplexities, either to produce a still more wretched life, or give rise to an act of suicide, committed in a tumult of horror, and degraded by cowardice. Whoever the person was that published this posthumous piece, he could not have any motive that could bear examination.

It is as a historian that Mr Hume is most generally popular. The beauty of his diction, and the interest which his elegant turn of thought imparts to the course of events described, render it on the whole the most pleasing book of English history in our language. Many who are sensible of the faults formerly mentioned, do not substitute any other for it in their recommendations to general readers. It might perhaps be rendered less exceptionable in its tendency, and more valuable for common use, if accompanied with *corrective* notes, and references in the most faulty places, to other authors. It would require much delicacy, however, to do this without spoiling the effect, by a harsh interruption of the current of the narrative, and an interference with the general spirit of the historian. Fox's historical fragment, published uniform with some popular edition of it, would greatly contribute to render it worthy of general perusal, by correcting the distrust produced by the peculiar colouring of the author.

See *Hume's Life*, *written by himself*, prefixed to his History; Smellie's *Lives;* Ritchie's *Life of Hume;* and a variety of anecdotes scattered in different biographical tracts, as Professor Stewart's *Lives of Dr Robertson and Dr Smith*, Lord Woodhouslee's *Life of Lord Kames*, and the Memoirs of Mr Gibbon in his *Posthumous Works*. HUMIDITY. See HYGROMETRY.

# HUNGARY.

THE Huns, from whom the kingdom of Hungary derives its name, are the Hiong-nau of the Chinese, and were a nation of Tartars, who had their ancient, perhaps their original, seat in an extensive barren tract of country, immediately on the north side of the great wall of China. But the valour of the Huns extended their dominions; and their chiefs, who assumed the appellation of Tanjou, gradually became the sovereigns of a formidable empire. Towards the east, their victorious arms were stopped only by the ocean. On the west, near the head of the river Irtish, their enemies were numerous: in a single expedition, twenty-six nations or tribes are said to have been subdued. On the side of the north, they are said, but on dubious authority, to have extended their empire to the ocean; it is more probable that the Lake Baikal was the limit of their conquests in this direction. Towards the south, they were most desirous of extending their empire; and, in the third century before the Christian æra, a wall of 1500 miles in length was constructed to defend the frontiers of China against the inroads of the Huns.

Their cavalry frequently consisted of 200,000 or 300,000 men, who managed their bows and their horses with matchless dexterity; they supported the inclemency of the weather with hardy patience; and marched with incredible speed, being seldom checked by any obstacle. The Chinese were unable to oppose them, or to protect their empire, notwithstanding the defence of the great wall. A regular payment of money and silk was stipulated as the condition of a temporary and precarious peace; and by a more disgraceful and degrading condition, a supply of women was annually given to the Huns; and the Tanjou was united in marriage with the imperial family of China. In the verses of a Chinese princess, who laments that she had been condemned by her parents to a distant exile under a barbarian husband, some particulars of the mode of life of the Huns at this period are given: she complains that sour milk was her only drink, raw flesh her only food, and a tent her only palace.

In the long reign of Vouti, the fifth emperor of the powful dynasty of the Han, which continued for the space of 54 years, from the year 141 to the year 87 before Christ, the Huns were frequently defeated by the Chinese. About the year 87, the camp of the Tanjou was surprised in the midst of sleep and intemperance, and though he cut his way through the ranks of his enemy, he left above 15,000 of his troops on the field of battle. But the power and empire of the Huns were not weakened so much by their defeats, as by the policy pursued by the Chinese emperors of detaching the tributary nations from their obedience; and these generally became their inveterate and formidable opponents. The Tanjou himself was at last obliged to renounce the character and privileges of an independent monarch, and to perform the duty of a respectful homage to the Emperor of China. The monarchy of the Huns after this gradually declined, till, about A. D. 48, it was broken by civil dissension into two hostile and separate kingdoms. One of the princes retired to the south with eight hords, which composed between 40,000 and 50,000 families: he fixed himself on the verge of the Chinese provinces, and attached himself to the service of that empire. The Huns of the north continued to languish about fifty years, till they were oppressed on every side by foreign and domestic enemies. The *Sienpi*, a tribe of oriental Tartars, retaliated upon them their former injuries; and, in the year A. D. 93, the power of the Tanjous, after a reign of 1300 years, was utterly destroyed. The emigrations of the Huns now began: above 100,000 persons, the poorest of the people, were contented to remain in their native country, to renounce their name, and mix with their conquerors. Fifty-eight hords, about 200,000 men, retired towards the south, and claimed and received the protection of the Chinese emperors. But the most warlike and powerful tribes of the Huns sought more distant countries, and moved westward in two great divisions. The first of these colonies established their dominion in the fruitful and extensive plains of Sogdiana, on the eastern side of the Caspian Sea. Here their manners were softened, and even their features were sensibly improved; and they obtained the appellation of *White* Huns, from the change of their complexions. The only vestige of their ancient barbarism was the custom which obliged all, or nearly all, the companions who had shared the liberality of a wealthy lord, to be buried alive in the same grave. Their vicinity to the kingdom of Persia involved them in frequent and bloody contests, in the course of which they gained a memorable victory, but, unlike their ancestors, they were moderate and mild in their use of it.

The second division of the Huns gradually advanced towards the north-west; and, by their intercourse with tribes more savage than themselves, their native fierceness was exasperated. As late as the 13th century, their transient residence on the eastern banks of the Volga was attested by the name of Great Hungary. In the winter they descended with their flocks and herds towards the mouth of that river.

It is impossible to give even an outline of the history of the Huns from this period till they became known to the Romans; but there is reason to believe that the same force which had driven them from their native seats, still continued to impel their march towards the frontiers of Europe. In their first irruption into the Roman empire, they are mentioned by ancient historians under a variety of appellations, all comprised under the general name of *Ugri* or *Hunni*. The more general distinction, however, was the Nephthalite or White Huns, who possessed a rich country on the north of Persia; and the Sarmatian or Scythian Huns. The latter are exhibited to us under the character of savages, without faith, laws, or any form of religion: living in the open air without houses, or huts, which they denominated the sepulchres of the living; quite unacquainted with the use of fire, their only food being roots and raw meat, and their only clothing the skins of animals. They were also distinguished by their broad shoulders, flat noses, small black eyes deeply buried in the head, and the want of beards. This race, inured to all manner of hardships and deprivations, and having no fixed settlements, were delighted with the first accounts which they received of the rich and fertile kingdoms of the west. Crossing, therefore, the Volga under Balamir, one of their chiefs, they overwhelmed the Alans and Goths, who inhabited the extensive country between the Volga and the Danube; and, having either driven them out, or forced them to submission, established themselves in Dacia in A. D. 376. Theodosius I. dreading their presence in the frontiers of the empire, and wishing to attach them to his service, encouraged many of them, by large sums of money, to enter into the Roman armies. They continued for some time in their new possessions without molestation to the empire, till A. D. 391, when they passed the Danube, and being joined by the Goths, committed dreadful ravages in Mœsio and Thrace.—They were soon stopped, however, by the army of Stilicho, the imperial general, who overthrew them with great slaughter, and would have completely destroyed them, had not Theodosius agreed to terms of reconciliation.

Not discouraged by their late disasters, they broke unexpectedly into the eastern provinces, penetrated as far as Antioch, destroying all with fire and sword, and committing everywhere unheard of cruelties. St Jerome, speaking of this irruption, says, "All the East trembled when the dismal news were brought, that swarms of Huns, coming from the far distant Mœotis, and dwelling between the frozen Tanais and the country of the savage Massagetes, flew up and down, and filled all places with blood and slaughter.—The cruel enemy roved without controul, where they pleased, preventing by their speed the report of their coming. They had no regard either to religion or dignity; no age they spared, nor were they softened by the tears of the crying infant; but put those to death who had scarce begun to live, and who, not apprized of their danger, smiled, when in their enemies' hands, at those very weapons that were immediately to destroy them." After having overrun and plundered several provinces, they returned home loaded with spoil, and carrying with them an immense number of prisoners. From this time they made regular incursions into the empire, always extending their settlements; and in 432, we find them in possession of Panonia, on the south side of the Danube. Their arms, however, were sometimes also employed in defence of the empire. They joined the army of Ætius against the Burgundians and Goths; but no sooner was their pay as auxiliaries withdrawn than they renewed their hostility, and Theodosius II. was compelled to buy a peace from Rouas their king, with an yearly pension of 350 pounds weight of gold.

Rouas was succeeded by his nephew Attila, the fiercest and most magnanimous of their kings. The countless nations between the Danube and the Volga obeyed his summons, and he became the terror alternately of the Eastern and Western Empires. The court of Constantinople complied with his demands with servile submission; but the court of Ravenna prepared to repel his inroads by force; and at the memorable battle of Chalons, Attila for the first time sustained a complete defeat, and was compelled to recross the Rhine before Ætius the Roman general. For the exploits of Attila, and the progress which the Huns made under his dominion, see Attila.

Some idea, however, of the manners and civilization of the Huns, during the reign of Attila, may be formed from the account which Gibbon has given us of the entrance of that monarch into his capital, and of the royal feast. "The entrance of Attila into the royal village was marked by a very singular ceremony. A numerous troop of women came out to meet their hero and their king. They marched before him, distributed into long and regular files: the intervals between the files were filled by white veils of thin linen, which the women on either side bore aloft in their hands, and which formed a canopy for a chorus of young virgins, who chanted hymns and songs in the Scythian language. The wife of his favourite Onegesius, with a train of female attendants, saluted Attila at the door of her own house, on his way to the palace; and offered, according to the custom of the country, her respectful homage, by entreating him to taste the wine and meat which she had prepared for his reception. As soon as the monarch had graciously accepted her hospitable gift, his domestics lifted a small silver table to a convenient height, as he sat on horseback; and Attila, when he had touched the goblet with his lips, again saluted the wife of Onegesius, and continued his march."——

"The Romans both of the East and of the West, were twice invited to the banquets, where Attila feasted with the princes and nobles of Scythia. Maximin (the Roman ambassador) and his colleagues were stopped on the threshold, till they had made a devout libation to the health and prosperity of the king of the Huns; and were conducted, after this ceremony, to their respective seats in a spacious hall. The royal table and couch, covered with carpets and fine linen, was raised by several steps in the midst of the hall; and a son, an uncle, or perhaps a favourite king, were admitted to share the simple and homely repast of Attila. Two lines of small tables, each of which contained three or four guests, were ranged in order on either hand; the right was esteemed the most honourable, but the Romans ingenuously confess, that they were placed on the left; and that Beric, an unknown chieftain, most probably of the Gothic race, preceded the representatives of Theodosius and Valentinian. The barbarian monarch received from his cupbearer a goblet filled with wine, and courteously drank to the health of the most distinguished guest, who rose from his seat, and expressed in the same manner his loyal and respectful vows. This ceremony was successively performed for all, or at least for the illustrious persons of the assembly; and a considerable time must have been consumed, since it was thrice repeated as each course was set upon the table. But the wine still remained after the meat had been removed; and the Huns continued to indulge their intemperance long after the sober and decent ambassadors of the two empires had withdrawn themselves from the nocturnal banquet. Yet before they retired, they enjoyed a singular opportunity of observing the manners of the nation in their convivial amusements. Two Scythians stood before the couch of Attila, and recited the verses which they had composed, to celebrate his valour and his victories. A profound silence prevailed in the hall; and the attention of the guests was captivated by the vocal harmony, which revived and perpetuated the memory of their own exploits: a martial ardour flashed from the eyes of the warriors, who were impatient for battle; and the tears of the old men expressed their generous despair, that they could no longer partake the danger and glory of the field. This entertainment, which might be considered as a school of military virtue, was succeeded by a farce, that debased the dignity of human nature. A Moorish and a Scythian buffoon successively excited the mirth of the rude spectators, by their deformed figure, ridiculous dress, antic gestures, absurd speeches, and the strange unintelligible confusion of the Latin, the Gothic, and the Hunnic languages; and the hall resounded with loud and licentious peals of laughter. In the midst of this intemperate riot, Attila alone, without a change of countenance, maintained his stedfast and inflexible gravity; which was never relaxed, except on the entrance of Irnac, the youngest of his sons: he embraced the boy with a smile of paternal tenderness, gently pinched him by the cheek, and betrayed a partial affection, which was justified by the assurance of his prophets, that Irnac would be the future support of his family and empire. Two days afterwards the ambassadors received a second invitation; and they had reason to praise the politeness, as well as the hospitality of Attila."

On the death of Attila, Ellac, by the will of his father, succeeded to an extensive empire, which, however, was soon embroiled in civil war by the ambition of his younger brothers. They insisted upon an equal division of their father's dominions, and immediately took up arms to support their demand. This afforded a favourable opportunity to the nations that had been subjected by Attila to throw off the yoke. Ardaric, king of the Gepidæ, accordingly declared that he would no longer obey the sons of Attila; and other nations, led by his example, hastened to join his standard. Ellac, who possessed both intrepidity and experience in war, marched against him with all his forces. The two armies met on the banks of the Netad in Panonia, where the Huns were utterly routed; and king Ellac fell in the field, after having performed prodigies of valour worthy of the representative of the great Attila. They afterwards received repeated defeats, both from the Goths and Romans, and were compelled to confine themselves to their own settlements for nearly sixty years.

In 539, however, the Cuturgurian and Uturgurian Huns united, broke into the empire, and laid waste Thrace, Greece, Illyrium, and all the provinces from the Ionian sea to the very suburbs of Constantinople. They then retired without molestation, with immense booty, and 120,000 captives. The Uturgurian Huns proceeded to their own country on the Euxine Sea; but the Cuturgurians received lands in Thrace, and an annual pension from the Emperor Justinian, upon condition of their serving when wanted in the Roman armies. Unable, however, to restrain them from committing continual depredations in the neighbouring provinces, Justinian had recourse to the Uturgurians; and by means of presents, and offers of pensions, embroiled the two nations in a bloody war, which lasted many years, and by which they were so weakened, that they were long prevented from offering farther molestation to the empire.

From this time, no credible historian makes particular mention of the Huns, till A. D. 776, when the remains of this nation, reinforced by the Avars, and other northern tribes equally barbarous with themselves, and with whom they are frequently confounded by historians, seem to have recovered their strength, and we find them masters of Dacia, Upper Mœsia, and the two Panonias. Two of their princes sent ambassadors to Charlemagne, desiring his friendship and alliance. Charles received them with extraordinary distinction, and readily agreed to their request; but a misunderstanding afterwards arising between him and them, he entered their territories with two numerous armies, ravaged the country with fire and sword, the Huns being unable to keep the field against so powerful an enemy. After a war of eight years continuance, he reduced them to complete subjection, and built strong fortifications along the Raab to repress their predatory irruptions into his territories.

They remained within this boundary for more than a century, when Arnolph, emperor of Germany, invited them to his assistance against the king of Moravia. Equally ferocious with their ancestors, and glad of an opportunity to renew their devastations, they ravaged Bavaria, Suabia, and Franconia. Germany afterwards became a prey to their fury; and Louis IV. submitted to an annual pension to get rid of them. In the reign of Conrad I. who also became their tributary, they again devastated Germany, penetrated into Lorraine and Languedoc, plundering and massacreing the inhabitants wherever they went.

The Huns were at this time subject to petty chiefs, whose precarious authority rested on no solid foundation, and were respected only because the choice fell on the bravest. Fear naturally attached them to the man whose vengeance they dreaded, or to whom they looked for protection in the continual wars in which they were engaged. Their last irruption into Germany was severely chastised by the valour of Otho the Great, and the united power of the German princes, who compelled them, after a dreadful slaughter, to retire within the limits of Hungary, and to fortify with a ditch and rampart the most accessible passes into their country.

In process of time, and by their intercourse with other nations, civilization began insensibly to spread among them; and in 997, under their first king *Stephen*, they assumed a place among the nations of Europe. This monarch established the Catholic religion in his dominions, and received from the Pope the title of *Apostolic*, which the sovereigns of Hungary to this day retain. From him also they date the origin of many of those institutions and laws by which the state is still governed. On his death, the respect in which his memory was held by his subjects, led them to choose his son as his successor to the throne; and, without renouncing their right of election, to maintain the royal dignity in his family for more than three centuries.

There were twenty-four kings of the dynasty of Stephen, few of whom, however, deserve to be drawn from oblivion. The most remarkable were: *Ladislaus*, surnamed the Saint, on account of the purity of his life, who added Dalmatia and Croatia to his dominions, and flourished near the end of the eleventh century. *Geicza* or *Geiza* II. expelled the Saxons, Austrians, and Bavarians, from Poland and a part of Hungary, where they had committed great ravages. *Bela* III. after having freed his territories from the brigands which infested it, employed himself in the internal administration of his kingdom. He instituted many judiciary regulations, which still remain in force, and was the first who divided the kingdom into counties, appointing a governor to each. His son, *Andrew* II. was one of the most renowned sovereigns of his age. He joined the Crusade in the beginning of the thirteenth century, with a numerous army, and acquired great glory by his bravery and skill in war; and the nobles, as a reward for their services on this occasion, received from him very extensive privileges. In his reign, the regulations of his father were perfected and formed into a national code, called the *Golden Bull*, which every king at his accession was obliged to confirm by a solemn oath. The famous clause, however, which granted to every noble the right of *veto* in the election of their monarchs, had been so often the occasion of civil wars, that it was abolished in the reign of Leopold I. in 1687. The reign of *Bela* IV. is remarkable for the invasion of the Scythians, who, after having overrun Russia and Poland, penetrated as far as Pesth, spreading terror and rapine throughout the kingdom. Bela, surprised in his camp, was compelled to fly. The Scythians continued in possession of the country for nearly three years; but Bela, with the assistance of the Knights of Rhodes, dispersed the invaders, and regained this throne. His son Stephen V. was celebrated for his victories over the kings of Bohemia and Bulgaria. His daughter Mary espoused Charles, king of Sicily, from whom sprung the famous Charles Martel, the father of Charles of Anjou, who afterwards became king of Hungary. Andrew IV. the last, and perhaps one of the most illustrious of the dynasty of Stephen, received the surname of *Venetian*, from his conquests over the Venetians. He died without issue at Buda in 1301.

Hungary then became a prey to all the calamities which anarchy brings along with it. Competitors for the crown appeared in the King of Bohemia and the Duke of Bavaria. The son of the former was elected by a party, and was kept upon the throne for six years, in opposition to the wishes of the nation, and amidst the greatest troubles. Being recalled to Bohemia by his father, the Duke of Bavaria was immediately crowned; but Ladislaus, waywode of the Jazyges, took him prisoner, and drove him from his throne and the kingdom. On the termination of these civil dissentions, Charles of Anjou was solemnly proclaimed king in 1310. Under his reign, Hungary, which had lately been regarded merely as a fief of the empire, became more powerful than the dominions even of the emperors. Dalmatia, Croatia, Servia, Transylvania, Bulgaria, Bosnia, Moldavia, and Walachia, received the laws of Charles. His marriage with the sister of Cassimir, king of Poland, who had no offspring, also secured a throne to his family. He died in 1339, beloved by his subjects and all his neighbours. The veneration which his memory inspired, and also the personal qualities of his son, fixed the choice of the nation on Louis. The reign of this prince was even more brilliant than that of his father. He pushed his conquests as far as Naples, to revenge the assassination of his brother Andrew, who had been strangled by his own wife Queen Jane; and appointed the waywode of Transylvania as governor of that kingdom, which however he afterwards restored. Part of Russia submitted to his dominion, and he drove the Tartars beyond the Euxine. He was acknowledged also as king of Jerusalem; but, while Hungary rose in power and estimation during his life, his death plunged her again into new calamities and dissentions.

Louis leaving no male issue, the Hungarians, as by a general impulse of admiration and enthusiasm, called his daughter Mary to the throne, under the title of Maria Rex. She had been married to Sigismund of Bavaria, who was as yet under age, and in the mean time she shared the cares of government with her mother Elizabeth. The tyranny, however, of Nicolas Gara the Palatine, who in her name actually governed the kingdom, soon made her subjects regret their imprudent homage to the memory of Louis. They therefore offered the crown to Charles, king of Naples, the nephew of Louis, and the son of the unfortunate Andrew. But scarcely had he entered Hungary, than he was assassinated by the Palatine, with the direction and countenance of Mary and Elizabeth. John Horvat, bann of Croatia, in revenge for the murder of a prince to whose interests he was attached, slew the assassin, and, after having made Mary and her mother be dragged as common criminals by the hair, cast Elizabeth into the river Bozota. Mary was reserved for the infamous brutality of Horvat, and then shut up in prison. Horvat, however, dreading the rage of Sigismund, who was approaching with an army to reclaim his crown, set the Queen at liberty, after making her promise upon oath that she would forget her injuries. These injuries, however, were too cruel to be erased from her memory, and repelling the oath which fear alone had extorted from her, she visited them upon the fierce avenger of Charles in a manner still more cruel and barbarous. Sigismund was twenty years of age when he ascended the throne; but the whole of his reign was only a succession of wars, troubles, and calamities to Hungary. Mary dying without children in 1392, new dissentions arose; and the Turks, taking advantage of these, seized upon Bulgaria. Sigismund was defeated and put to flight at the battle of Nicopolis; when his subjects revolt against him, seize his person, and confine him in prison. The conspirators then offer the crown to Ladislaus, king of Naples. But Sigismund seemed to triumph over fortune and all his enemies. Escaping from prison, and collecting a considerable army, he obliges Ladislaus to desist from his pretensions, and recovers his kingdom. In 1410, he was elected emperor of Germany. At his death, Albert, archduke of Austria, who had espoused the only daughter of Sigismund by a second marriage, inherits all his possessions, and ascends the throne of Hungary in 1437. This event forms the earliest basis of the Austrian claim to the Hungarian monarchy.

The reign of Albert, however, was very short, and his death was succeeded by civil wars, which continued to desolate this kingdom for another century. Ladislaus, king of Poland, was invited to the throne; but soon after perished in the battle of Werna against the Turks. The famous John Hunniades was then appointed regent; and on the decease of another Ladislaus, the posthumous son of Albert, in 1457, Mathias Corvinus, the son of Hunniades, receives the crown from the states assembled in the field of Rakos, near Pesth. Mathias seized Vienna and the other Austrian states, which he retained till his death; and is regarded as the greatest prince that ever held the Hungarian sceptre. He was brave, prudent, and generous, the friend of letters and arts, and a man of letters himself. He founded the magnificent library of Buda, which he furnished with the best Greek and Latin authors, and many valuable manuscripts.

The descendants of Albert again fill the throne; but upon the death of Louis II. the son of Ladislaus, who lost both the battle and his life in the plains of Mohats in 1527, the Hungarians were divided into two factions. John Zapolya, waywode of Transylvania, was proclaimed king by one party, while the nobles assembled at Presbourg, offered the sceptre to Ferdinand of Austria, who had conducted some succours to the Hungarians against the Turks. Zampolya was unable to resist the forces of his rival; and after his defeat at Tokay, was compelled to evacuate the kingdom, when Ferdinand was crowned at Stuhl-weissenbourg. Some time after, the waywode returned with the Sultan Soliman, at the head of a formidable army, who pushed his conquests as far as Vienna; but on the death of Zampolya, his partisans, indignant at the conduct of the Turks, and preferring the dominion of Austria to that of the barbarian, immediately joined Ferdinand, who was crowned a second time. This monarch was afterwards called to the empire; but he retained the crown of Hungary till

1563, when he resigned it to his son Maximilian. The Hungarians, however, bore the Austrian yoke with much impatience, and every new election called forth their aversion to their masters, who regarded them as their lawful inheritance. But their efforts were fruitless, and those who ventured to support the rights of the nation were silenced by the stroke of the executioner. In vain did Tekely raise all the provinces to revenge these outrages; and, supported by the Turks, to whom the Hungarians in their despair had surrendered themselves, laid siege to Vienna. All Germany immediately armed against the common enemy, the Turks, who were driven back into their own territories. Rakotzy, who, after Tekely, endeavoured to support their efforts of independence against tyranny, was equally unfortunate. The Archduke Joseph, son of Leopold I. was acknowledged king in 1687, and the crown was declared hereditary in the male descendants of the house of Austria. This line, however, failed at the death of Charles VI.; but the Hungarians, exhausted by continual wars, and fatigued by so many fruitless revolutions, had lost that ardent love of liberty for which they were so conspicuous, and which led them to brave so many dangers. They therefore submitted to the accession of Maria Theresa, the daughter of Charles, in 1741. She had gained and deserved their love and affection. Her husband, the emperor Francis, was associated with her in the government, and their descendants still hold the Hungarian sceptre. The preceding sketch of Hungarian history is all that our limits will allow.

## STATISTICS OF HUNGARY.

Hungary, properly so called, a kingdom in Europe, and under the dominion of Austria, lies in Latitude 44° 33′ 18″—49° 26′ 20″ North; and in Longitude 13° 45′ 2″—22° 46′ East of Paris. Nature herself points out the boundaries of this kingdom. The Carpathian or Krapak mountains separate it on the north and east from Moravia, Silesia, Galicia, Buckovina, and Transylvania: on the south, the Danube and the Drave divide it from Servia, Sclavonia, and Croatia; and on the west, the Morau, or Morava, with a range of mountains lying between the Drave and the Danube, form its boundary with the Archduchy of Austria. According to Captain Lipsky, it contains 4051 German square miles;* its greatest length from west to east being 136, and its greatest breadth from north to south 77 German miles.

The kingdom of Hungary is divided by modern geographers into four circles, comprehending forty six counties, besides the districts of *Jazyg*, *Great Cumania*, *Little Cumania;* the sixteen cities of the *Zips;* the six cities of *Heidukes*, which enjoy peculiar privileges; and the two frontier regiments of the Bannat, and the battalion of *Tschaikistes*. The whole, according to the following Table, contained, in 1805, 42 royal free cities, 8 episcopal cities, 590 towns, 9214 villages, 2338 *prædien*,† and 22 cities of Zips and Heidukes.

The configuration of this country presents to us the most opposite regions and climates; rugged and enormous mountains, where reign sterility and eternal snows, and which cover almost one-third of the whole kingdom; extensive flats, irrigated by numerous rivers and lakes, where winter is scarcely known; plains of sand driven by the wind, which threaten the traveller with instant death; fertile and smiling vallies, producing every necessary, and many of the luxuries, of life in the greatest abundance; numerous morasses, which cover the surrounding country with their noxious exhalations; and immense forests, where the foot of man has never penetrated.

On entering the Bannat of Temeschwar on the east, the country appears like Flanders, flat, and entirely destitute of wood, excepting in the vicinity of the villages. The soil is extremely fertile; and the prospect as we advance exhibits immense pastures covered with cows, sheep, and horses; or wide fields of corn without enclosures. Silk plantations, and orchards of peach, cherry, and plum-trees, are every where common. Proceeding westward, the country towards Szegedin becomes sandy; and after crossing the Thiesse low swampy plains, full of stagnant pools, where nothing is heard but the croaking of toads, fill up the distance to Ketschkemet. From thence the country, though well cultivated in some places, is flat and sandy, resembling the *steppes* of Russia; and, on approaching the Danube, a chain of mountains appears, which rise with grandeur on the western side of the river. From Buda, towards Gran, the country is rich, populous, and highly cultivated. The hills are covered with vineyards to their very summits; and every where are seen delightful villages filled with healthy inhabitants. On the north of the Danube, the mountainous district towards Schemnitz is agreeably picturesque; and as we approach that town, the scenery becomes sublime. "The appearance of this beautiful country," says Mr Cripps, "although surrounded by mountains, reminded us of the county of Kent. The cottages are remarkable for their great cleanliness; and there are numerous villages. The district between *Zeilitz* and *Lewa* is the most beautiful imaginable, being full of rich meadows and fields of corn, every where thick set with noble oaks." Dr Clarke also remarks, that "the road, although constructed in the midst of mountains, is not inferior, either in breadth or excellence, to any of the roads about London; and the traveller, surrounded by the sublimest natural scenery, sees to his surprise the greatest artificial labours accomplished with neatness, ornament, and economy; beautiful roads through recesses, and over steeps, that would otherwise be impassable; churches crowning the most elevated summits; towns and villages; gardens and vineyards; all decorating without diminishing the wild grandeur of the Hungarian Alps." Indeed, the whole of this district, as far as Presbourg, is exceedingly rich and beautiful.

The most prominent feature of the Hungarian landscape are the mountains, the principal of which is the Carpathian chain, or mountains of Tatra, which run in a semicircular direction from west to east, about 500 English miles; and its summit, which consists of huge naked rocks completely destitute of vegetation, at its greatest height, in the county of Zips, is about 1350 toises above the level of the Black Sea. The mountains situated in the east and south-east, are separated from the northern chain by a plain, which extends from Hungary into the grand duchy of Transylvania. They take their rise in the latter province; and, following the direction of the Marosch as far as Arad, strike towards the south by the Bannat upon the confines of Transylvania and Walachia; the highest of these are Szemenik and Montye le mare, or the high mountain. Those on the western part of the kingdom, run from the county of Eisenbourg in a crooked chain towards Stiria and Austria, as far as the Leitha; and some of them equal the Alps nearly in height. Besides these, there are other considerable mountains in the counties of Pesth, Gran, Veszprim, and Szalad, some of which are covered with impenetrable forests of oak.

The northern part of the Carpathians is composed chiefly of granite, and its summits are covered with limestone, or spread with a kind of brown freestone. Granite forms also an essential part of the mountains of Konigsberg, and of the rocks of Tatra, which are adjacent, and stretch into the southern part of the counties of Zips, Goemor, Sohl, Liptau, and into the western part of the counties of Arw, Thurotz, and Trentschin. It also abounds in the northern part of Zips, where the mountains of Fleischbank, Porte de Fer, Altendorf, and some others, are entirely composed of it. Near Altendorf it begins to disappear, and is replaced by a greyish free stone, which covers almost three leagues of country, and forms the great mountain of Babagura. This stone extends along the extremity of the western frontiers of Tatra, Godivilk, and towards the south the county of Arw. From the eastern extremity, it extends still more along the frontiers of Hungary, and into the counties of Zips, Scharosch, Zemplin, and Unghwar. There another kind of stone presents itself; clay slate covered with brown free-stone. It is likely that the clay-slate commences in the higher mountains of the north, as it begins to appear in the county of Goemor, near Rosenau, from whence it stretches into the southern part of the county of Zips, and into the northern part of the county of Abaujwar. The central mountains of the Carpathian chain and its promontories, produce limestone and porphyry. The other generations which are formed in the accessary mountains are, mica, clay-slate, trap, basalt, and breccia. There are also found volcanic stones, pumice stone, and different kinds of opals. The body of the Carpathians on the north-east, consist principally of clay-slate. The chain which stretches along the valleys of Marmarosch and the borders of the seven mountains, as far as the Theisse, and traverses the counties of Szathmar and Ugotsch, is composed chiefly of porphyry and grey free-stone. In the eastern mountains, and, in general, in those of the Bannat, there is a great deal of lime-stone; which prevails also in the interior mountains. The other stones that are found there are clay-slate, brown free-stone, and porphyry. The neighbouring mountains of Stiria and Austria contain lime-stone, free-stone and granite.

The mountains of Hungary, especially the Carpathian chain, abound with grottos of various dimensions, the principal of which are, *Mazarna* and *Dupna* in the county of Thurotz, *Drachenhole* in the county of Liptau, *Holgocz* in Zips, *Agtelek* in Goemor, and *Sziliacz* in Torn. Bones and skeletons, partly petrified, are found in these grottos, and the most beautiful stalactites of every size and form. Those of Drachenhole and Sziliacz are particularly curious, being filled during the summer with ice, which is formed in spring, and melts at the approach of winter. The grotto of *Veteranische Hole* is famous for the defence which General Veterani, with a few followers, maintained against the Turks, in 1694. It is situated on the left bank of the Danube, a little above the village of Ogradina. The rock of which it is formed is inaccessible on every side except at the entrance of the grotto, which is about four feet high and two broad, and secured by an iron gate. The interior is large enough to accommodate a thousand men; and, from the embrasures cut out in the rock, it has the complete command of the navigation of the Danube. Here also, in the last war of Austria against the Turks, the brave Major Stein, with a battalion of infantry, defied the whole power of the Turkish army, and after enduring for three weeks the most painful privations, made an honourable capitulation, and marched out at the head of his surviving followers with their arms and baggage.

The interior of Hungary consists of one almost continued flat, excepting a chain of mountains which, taking their rise near the Danube, run through Gran, Pesth, and the neighbouring counties, and divide the country into two immense plains, called the Upper Plain and the Lower Plain. The former is the smallest, and is of a circular form. It extends from the lake of Neusiedl for about twenty German miles, to the foot of the mountains on the north, and then streches as far as the Drave, upon the confines of Croatia. The Lower Plain is of much greater extent, and comprehends all the east part of the kingdom, as far as Transylvania; and where it approaches the mountains, is finely diversified with hills and vallies. The level is evidently higher in the upper than in the lower plain, as the rivers in the former almost uniformly direct their course towards the Danube; and the lowest spot in the whole country is at its south-eastern extremity, near Orsova.

The Carpathian chain gives rise to innumerable rivers, which flow in all directions, according to the declivity of the ground and the sinuosity of the vallies, but which eventually fall into the Thiesse or the Danube. The *Thiesse* has its source in the county of Marmarosch. Its course from its commencement is full and rapid while it continues among the hills; but when it reaches the plain its rapidity slackens, and, bending towards the west, receives innumerable tributary streams from the northern mountains. Taking a southerly direction, it is joined by the Marosch, near Szegedin, and, after a course of about 420 miles English, falls into the Danube not far from Belgrade. As the banks of this river are low, it often overflows them, and occasions extensive inundations, particularly in the neighbourhood of Tokay. Few rivers in Europe abound more with fish than the Thiesse; and it is a common saying in the country, that it contains two parts of water, and one of fishes. It is navigable as high as Szegedin. The *Waag* or *Woh* fertilizes the counties of Thurotz, Trentschin and Neutra. Circumscribed in its channel, it dashes its impetuous waters over frightful rocks, and forms during its course above a hundred whirlpools. It enters the plain at Sillein, and discharges itself into the left branch of the Danube, which forms the island of Schutt. Besides these, the other principal rivers which commence and finish their course within the boundaries of the kingdom are, the Gran, the Gollnitz, the Hernad, the Torisza, the Sajo, the Nera, the Temesch, and the Bega.

The rivers which have their sources in other countries, but which water, in some part of their course, the kingdom of Hungary, are the Danube, (of which a particular description will be found in vol. vii. p. 574.); the *Drave*, which rises in the Tyrol, and flows with such rapidity that its banks are neither so high nor so solid as to retain its waters. It is navigable during the whole of its course through Hungary, and falls into the Danube above Essek; the *Samosch*, the *Marosch*, and the *Korosch*, which take their rise in Transylvania, and fall into the Thiesse; the Morava, which gives its name to the province of Moravia, washes the western boundary of the kingdom; the Raab, which rises in Stiria; and the Leitha in Austria.

The lakes and marshes of Hungary are both numerous and extensive. In the Upper Plain the most considerable are, Lake *Balaton*. The Lake of *Neusiedl*, which the Hungarians call Tento, lies between the counties of Oedenbourg and Wieselbourg. Its western bank is formed by hills, which are covered with vineyards, woods, and cultivated fields, while the opposite shore is low and marshy, producing nothing but reeds. It is about thirteen miles (English) in length, by four in breadth, but so full of shallows and sand banks, that its navigation is both difficult and dangerous. In the Lower Plain, the principal is the lake of *Palitsch*, in the county of Batsch. It is about eight miles (English) long, having a hard bottom covered with alkaline salt. Its water is used in the neighbouring baths, and is considered very salubrious in nervous disorders. The most remarkable of the Carpathian lakes is the *Grune-See*, which is formed by an enclosure of rocks, and is about 300 paces in circumference. It takes its name from the green colour of its waters, which is produced by the reflection of the surrounding pines. Its banks are covered with gravel and blocks of granite, and its water is pure and transparent, and excellent for drinking.

Marshes of various extent pervade almost every quarter of the kingdom, and are in general formed by the inundations of the rivers. The most considerable are those of *Saretje*, *Mohatsch*, and *Etsed*. In the plain of Bannat, they cover more than a third of the county of Toronthal, almost the whole of Temeschwar, and the greatest part of the district of the frontier regiment of Bannat. The marsh of *Hansag*, which joins the lake of Neusiedl, is five miles long by three broad. The water appears only in the middle, the greatest part being covered with turf, and studded with trees. It produces plenty of hay; but it is dangerous to cross it, unless well acquainted with the particular direction of the paths.

It would be proper to notice also the sandy plains, which overspread many parts of this country, the most extensive of which are, *Ketschkemeten-Heide*, or the heath of Ketschkemet, lying between the Danube and the left bank of the Thiesse; *Debreczin*, in the county of Bihar; and the *Ager Romanorum*, near Delliblat. Besides these, there are others in the counties of Tolna, Stuhlweissenbourg, Baranje, and particularly in Schumegh, which is one continued ocean of sand moving with the wind.

The morasses and swampy plains which abound in this country are supposed to render the air damp and unwholesome, the cold of the night rivalling the heat of the day; but this evil is in some measure remedied by the wind from the Carpathian mountains; and the inhabitants in general are rather remarkable for health and vigour. In some of the counties on the north-west, the atmosphere is particularly pure and bracing; but in the Bannat, on the north-east part of the kingdom, it is quite the contrary. The transitions of temperature are extremely sudden. Agues and inflammatory fevers are very prevalent; and in Temeschwar, the capital, a healthy person is scarcely to be seen. Baron Born, when here, fancied himself in the realms of death, inhabited by carcases in fine tombs, instead of men; and at a dinner, to which he was invited, all the guests had a fit of the fever,—some shivering, and others gnashing their teeth.

If we except the barren heaths and the mountainous districts in the north, the soil of Hungary is equal to that of any other country in Europe. It contains 5,897,218 acres of arable land, and produces the finest grain, without manure, and almost without cultivation; and were the exertions of the husbandman to keep pace with the abundance of his crops, the produce of the kingdom would be doubled. After a very superficial ploughing, the seed is thrown into the ground; a few branches of trees tied together serve the purpose of harrows; and without farther care the harvest is luxuriant. But much of the grain is lost, by the manner in which it is separated from the straw and stored. It is allowed to stand in the field after it is cut until the tithe is gathered, by which time it has begun to vegetate. They afterwards tread it out with horses and cattle in the open air, by which operation a third of it nearly is destroyed; and then, instead of receiving it into granaries, of which they have none in Lower Hungary, it is put into pits dug for the purpose, and there kept for future use. These pits are lined in the bottom and sides with straw and reeds, and contain from 100 to 200 bushels each. They are then covered in with straw and earth.

This method of rural economy, however, applies only to the lower and central parts of Hungary, which are by far the most fertile. In the northern districts, and on the frontiers of Austria and Stiria, the soil requires all the industry of the inhabitants to make it produce even a tolerable crop; and were their exertions and method of culture (though still imperfect) transferred to the southern parts of the kingdom, Hungary would become the granary of Europe. An insuperable obstacle, however, to all improvement in this respect, lies in the tenure, by which the farmer holds his lands. The lands are parcelled out into farms, half farms, quarter farms, &c. A farm is measured by the seed it requires, being 48 bushels, and 12 *tagwerk* of meadow; if the soil is poor, the arable land is augmented in proportion. In Croatia they distinguish three kinds of land, good, middling, and bad. A farm of the first quality is 21,000 square toises; of the second 34,000; and of the third 40,000. The annual burdens attached to a farm in Hungary are, fifty-two days work with two horses, or four oxen, beginning at sun-rise, and finishing at sun-set; a fourth part of them must be performed during the winter, and, in the time of harvest, the proprietor can demand two in the week: a ninth part of the crop, and also of the sheep, goats, lambs, and bee-hives; and if the number is under nine, 4 kreutzers for every lamb, 3 kreutzers for every goat, and 6 kreutzers for every hive; 2 hens, 2 capons, a dozen of eggs, and half a pint of melted butter: 30 farms together pay a calf or a florin, and 30 kreutzers in money; every married peasant to give eighteen days work, and pay a florin for the rent of his house, and all others to give twelve days work: every vassal to beat the bushes three times a year in the hunting season: four peasants, each possesing a farm, to unite in forming a job with four horses at the distance of two days journey, excepting the time of harvest or vintage: two florins for permission to distil *aqua vitæ*, and to spin six pounds of lint. The proprietor furnishes his vassals with wood for fuel and building; and, in return, they must cut a *cord* of wood in the forest, and transport it to the castle. The respective rights and obligations of the noble and his vassals are regulated by a statute, which is called *urbarium*, and which was provisionally confirmed by the diet in 1791. The peasant, however, holds his lands only from term to term, and must resign them, when proper warning has been given by his lord.

Notwithstanding these disadvantages, the soil is so productive, that the annual exportation of grain to Italy and Germany is very considerable. Wheat is the principal object of cultivation; and in the mountainous parts of the country, where the soil is lighter and the climate colder, rye, barley, and oats, are produced of good quality, and in abundance. They have also plenty of maize, rice, peas, potatoes, turnips, melons, cucumbers, pumpkins, onions, and garlic. Lint and hemp are cultivated in many of the counties; also poppies, saffron madder, and woad. Tobacco forms a considerable branch both of agriculture and commerce; and in 1779, when American tobacco was very scarce, the city of Trieste alone exported Hungarian tobacco to the amount of 100,759 pounds in powder, and 3,263,136 pounds in leaves or carrots. The best tobacco is produced at Tolna, Kospalogh, and Szegedin.

The vineyards of Hungary are very extensive, and are general throughout the country, unless in seven of the northern counties, where the temperature is too cold. They occupy nearly 911,984 acres, and produce upon an average 18,239,680 *eimers* annually. The wine of Tokay is the most valuable, and is drunk by the rich in every country in Europe. The vines which furnish the real Tokay grow on the mountain of *Hegy-Allya*, in the county of Zemplin; but as this mountain produces a very inconsiderable proportion of what passes under the name of Tokay, they sell for it the wines of Mada, Tallya, Zumbor, Szegu, Zsadany, Toltschwa, Benye, &c. which few but a Hungarian palate can distinguish. Next to the wines of Tokay, the most esteemed are those of Rust and Œdenbourg, which are cultivated with great care and intelligence. The others of consequence are the wines of Erlau, Buda, Neustadtel, Menesch, Scohmla, Resmil, and Ratschdorf.

Although the climate of Hungary be very favourable for the cultivation of all kinds of fruit, very little attention is paid to them in the Lower Plain. The orchards are confined chiefly to Œdenbourg, Presbourg, Neutra, and the neighbouring counties, where chesnuts, almonds, apricots, peaches, apples, and pears abound, and are of the first quality. Entire forests of plumtrees flourish in the counties of Trentschin, Neutra, and some others; and their fruit, both fresh and dried, is exported in great quantities to Austria and Prussia.

The meadows and pasture grounds of Hungary are very much neglected. They cover 1,483,003 acres, and yield about 17,085,935 quintals of hay. The northern and western districts of Hungary abound in immense forests of fir, pine, and oak, interspersed with yews, ash, hazel, and linden, which overspread nearly nine millions of acres. In the district of the frontier regiment of Walachia, the forests cover 465,362 acres, and afford employment and profit to many of the inhabitants. In 1802, there were drawn from these woods the following articles, which will give the reader some idea of their value and importance.

| | |
|---|---|
| 58,446 | pieces for the construction of wheels. |
| 1,414 | cubic toises of ash. |
| 108,732 | staves for casks. |
| 2,725 | do. for scuttles. |
| 2,560 | do. of oak. |
| 30,920 | do. of beech. |
| 344 | cubic toises of oaken joists. |
| 702,800 | staves. |
| 2,363 | planks a foot square. |
| 900 | green poles. |
| 11,013 | planks for boat building |
| 5,293 | laths. |
| 1,704 | planks for scaffolding. |
| 40,624 | do. of linden and maple. |
| 1,099 | do. of hazel. |
| 196 | posts of do. |

The forests of Hungary produce an immense quantity of gall-nuts, which, from their exportation during ten years, (from 1777 to 1786,) yielded 516.679 florins of revenue. In the south, however, from Pesth to Debretzin on the one hand, and from the mines of Bannat in the county of Kraschow to Peterwardein on the other, a wood is scarcely to be seen. In this district the fuel, on account of the scarcity of timber, consists chiefly of reeds, and cow dung made into bricks with straw.

On the pastures of Hungary are reared a great number of cattle, which forms one of the principal sources of national opulence. The oxen are nearly equal to those in Kent, which are the finest in Europe. They are generally of a whitish colour, or light grey, and are valued for their great weight, and the fine flavour of their flesh. About the conclusion of the last century, there were reckoned in Hungary 797,540 fat oxen, 89,805 bulls, and 1,508,177 cows; and according to the commercial tables, during ten years of the same period, the exportation of oxen amounted to thirty millions of florins, when a pair of oxen sold only for 50 or 60 florins.

The horses in general are small, but are equal to any in Europe in elegance and swiftness. They have been, however, much neglected; and notwithstanding the many attempts that have been made by the government for their improvement, they are still far removed from that state of perfection of which they are capable. The royal studs at *Mezoehegyes* in the county of Tschanad, and *Babolna* in the county of Komorn, were established by the Emperor Joseph II.; and from them 60 stallions are regularly distributed every year throughout the country, to produce a more noble breed. In 1795, the stud of Mezoehegyes consisted of 10,000 horses, of which 1000 were mares, and 60 stallions. It is under the direction of a major, 12 officers, 50 sub-officers, and 200 soldiers, besides grooms and labourers; and is obliged to furnish annually 1000 horses for the army. There are also several private studs, of which the most considerable are those of the lordship of Holitsch, established by Francis I., of Prince Esterhazy at Uzor, and of Count Palfy at Dertrekoe. The small size of the Hungarian horses may be attributed to their being too young when brought to the yoke, and to their scanty nourishment. They seldom give them hay, but drive them out at all seasons to pasture; and even when on a journey, they are sent into the fields, to find at the same time food and rest.

The Hungarian sheep are very beautiful, especially those with forked horns, of which none are reared in any other country, except on Mount Ida, and in some of the islands in the Archipelago. Their wool, however, which is long and hairy, is used only in fabricating coarse stuffs, which are worn by the peasants. In 1773, the Austrian government attempted to improve the wool of the native sheep, by the introduction of Spanish rams; but it was long before this practice became general. At present, however, many of the nobles possess immense flocks of the improved breed, and draw from the sale of their wool a considerable revenue. Some of these flocks produce annually about 1500 quintals of wool, worth 274,000 florins. Flocks of every description pass the winter in the open fields. The shepherds, whom they call *juhasz*, are very little removed from savages. They burrow under ground with their dogs, and, except a boy or two, who assist them and bring their food from the village, and the merchants who in the beginning of summer come to make purchases, they seldom see a human face. Yet, retired as they are from the world, they are fond of ornaments in their dress; and though their clothes are of the coarsest description, and besmeared with grease, they trim their hats with ribbands of various colours, and have their leathern girdles thick studded with bright metal buttons.

As bacon is a favourite dish with the Hungarians, they rear an immense quantity of hogs; and the head of a family, who had not a piece of fat pork on his table at Christmas, would be regarded as a very bad economist. The consumption of this animal in the country is so great, that they have none of their own to spare for exportation; but they carry on a very lucrative traffic, by buying them in Turkey, and selling them to their neighbours. According to the Commercial Tables, they annually purchased in Turkey to the amount of 531,973 florins, which they sold for 895,337 florins.

Among the animals of this country may also be mentioned a race of shepherds' dogs, of a white colour and noble size, and also a breed of immense mastiffs. Bees and silkworms form considerable branches of industry in this country, and it abounds also in poultry and game. Fish are so abundant in Hungary, that they form an important branch of industry and commerce; and sturgeons, salmons, pikes, carps, perches, &c. are to be found in all the principal rivers. In 1803, they were exported to Austria to the amount of 98,230 florins.

Hungary abounds in minerals of every description, gold, silver, copper, lead, iron, mercury, cobalt, antimony, salt, slate, &c. which, in their exploration and manufacture, afford employment to a great proportion of its inhabitants. Native gold is found in the beds of many of the rivers; and in the Koeroes, pieces of the size of a nut are picked up by the inhabitants of the Bannat, who upon an average gather to the amount of 900 ducats. In general, however, it is extracted from the auriferous sand, which is not only taken from the channels of the rivers, but also from their banks, and from pits in the adjacent ground. In these pits, which are generally about four feet deep, the first stratum consists of vegetable mould; the second of loam, and an alluvial deposit of pebbles; the third, of the auriferous sand and pebbles; and the fourth of slate, clay, marl, and coal. The washing of the auriferous sand is practised by the gypsies, who, from long experience, are so expert that hardly a particle of gold escapes them. The operation is very simple, and is performed by means of a plank of lime-tree six feet in length, and about three in breadth, with grooves or furrows cut across. This plank is placed at an angle of about 45 degrees, and at the upper end is a trough where the auriferous sand is put. The sand is then washed down the sloping of the board by plenty of water, when the gold dust falls into the higher grooves, and is afterwards scraped or brushed off. Sometimes the plank is covered with woollen cloth, to which the gold adheres, or, when they cannot obtain cloth, they substitute a fleece in its place. Many thousands of florins of gold are produced in this manner.

The great emporium of the precious metals, however, are the mines, which surpass in richness those of any other country in Europe. The most valuable are those of Schemnitz in the county of Hont, and of Cremnitz in the county of Barsch. In these mines, the gold is always found united with silver; and they estimate the value of the ores, by calculating that one quintal (cwt.) of ore yields so many *lotos* of silver, and one mark of silver contains so many *deniers* of gold. At Schemnitz the metallic veins extend north and south, running parallel to each other; and their inclination or dipping from west to east is at an angle of about 60°. There are six principal veins, besides many smaller ramifications.

The first on the west is called *Theresa-schadt*, at an average about two fathoms wide. The matrix of the ore is principally *clay* and *red ferruginous jasper* or *sinople*, every where traversed by small veins and crystals of *quartz;* and the ore itself is for the most part *lead*. About 120 fathoms eastward is the *Hospital vein*, which is much broader, being 22 fathoms wide, although not pure throughout this width. It contains many foreign substances belonging to the mountain in which it lies. Both these veins lie near the surface; they are very rich, and were the earliest discovered. The third vein is called *Oberbiber-stohln*. It differs essentially in its nature from the others, the matrix of the ore being *clay*, but without any *sinople ;* and containing a great deal of lime, and a small portion of quartz. The next is *Johan-schadt*, about a hundred fathoms from *Oberbiber-stohln*, and containing the same ores. They both lie about one thousand fathoms deep. The fifth is that of *Stephano-schadt*, which may be considered as an assemblage of several contiguous parallel veins, reaching to the breadth of eight fathoms. At present it is the most famous of all the mines of Schemnitz, and is wrought upon a more magnificent scale than any of the others; the galleries being better constructed, and the machinery of greater magnitude. The last is the *Green-stohln* vein, where the matrix of the ore is *schistus*, indurated clay, and *pyrites*. It is the last which has been discovered at Schemnitz, and is hardly known. The average value of the Schemnitz ores is thus rated: a quintal (cwt.) of the ore contains from five to ten *lotos* of silver; and one mark of the silver, from three to six *deniers* of gold. This, however, is liable to very considerable variation, for one quintal of the ore of the *Oberbiber-stohln* vein has been known to yield 2200 lotos of pure silver, after its separation from the gold.

At Cremnitz, the direction of the vein in the principal mine is north and south, inclined from the west towards the east, according to an angle which varies from 25° to 30° and 40°. The ore consists of *auriferous quartz*, speckled with minute glittering particles of auriferous pyrites, and penetrated either by a buff-coloured clay, or by an *argentiferous* sulphuret of *lead*, and the oxide of *iron*.

"The manner of working the mines is fourfold. 1*st*, By a horizontal level, following the direction of the *vein*. 2*dly*, By an inclined plane, ascending according to its inclination; forming always stages of wood, as galleries for the workmen. 3*dly*, By an inclined plane, descending in the contrary direction. 4*thly*, By an excavation on either side of the vein, which is the most frequent at Schemnitz, owing to the great width of the veins." The apparent care, neatness, and advantage, with which the works are carried on; the spacious entrances into their mines; their dry, airy, and cleanly levels; and the great encouragement given to the study of mineralogy, and to all mining speculation, shew that the Germans surpass every other nation in skill and industry in the art of mining.

Dr Clarke, from whose excellent work we have extracted the preceding account of the Hungarian mines, has given us the following description of the process employed for the reduction of their ores:

"1*st*, The first operation with the produce of the mine is of course that common to all mines, of *stamping* the *ore*. But the richer ores are not submitted to the stamping machines.* They are carefully broken with hammers into small pieces about the size of beans, which, being mixed with lead, a single operation of the furnace is sufficient for their reduction. With regard to the common ores, after being *stamped* and *washed*, they are brought in the form of a fine powder or sand to Cremnitz. Here they are exposed to what is called the *crude fusion*, being simply smelted into a compound regulus, which is called *lech*, consisting of all the following metals, besides *sulphur: gold, silver, lead, copper, iron, arsenic, bismuth*, and *cobalt*. This is the first operation.

2*d*, The second operation relates to the treatment of the *lech*, or result of the first crude fusion. This is exposed to a furnace, the fire of which is regulated in the following manner: First, there is a layer of wood, then a layer of charcoal, and lastly a layer of the *lech*, broken into pieces. The fuel being ignited, the *lech* is here roasted for the evaporation of the sulphur.

3*d*, A third operation then follows: After the lech has been roasted, they add to it powder of the richer ores, and the whole is smelted in another furnace. This is called the *second fusion*, or the *fusion enriched*.

4*th*, The result or *regulus* obtained from the second fusion is then carried to another furnace. Here it is again smelted, with the addition of the richest ores. This *third fusion* is called the *fusion upon lead;* because, when the furnace is tapped, and the metal begins to flow into a receiver made with charcoal and clay, they cast lead upon it: this, after smelting, combines with the gold and silver, and falls to the bottom of the vessel. During this operation, the lighter metals, such as copper, iron, cobalt, bismuth, and arsenic, rise to the surface, and are raked off in the form of *scoriæ*, which they carry, as *lech*, to be fused again in the first operation. The lead, thus combined with gold and silver, is collected into large crucibles, and carried to the *fourth fusion*, or fifth operation, for the separation of the lead.

5*th*, The furnace used for the separation of the lead is called a *purification furnace*. The shape of it resembles a hollow sphere, whereof the upper part is so contrived, that it may be taken off like a lid, being raised by large chains. Here the richest ores that can be procured are added to the compound of lead, silver, and gold; and the whole is fused, not with charcoal, but by means of a flame drawn over the superficies, uninterruptedly, for twenty-four hours at least. During this process, the lead becomes calcined. A portion of it is absorbed by the bottom of the furnace, consisting of *wood-ashes* and *silica;* another portion escapes in a gaseous form; but the greater part is raked off as it rises to the surface, in the form of *galena*, by men employed with instruments for that purpose. During all this operation, the gold and silver concentrate more and more, until at the last they are found pure and combined together in a cake of metal, at the bottom of the pu-

* The rule is this: When a *quintal* of the *ore* does not contain two *lotos* of silver, it is sent to the stamping machines.

rification furnace. Then follows the *sixth* and the most beautiful of all the operations,—that of separating the gold from the silver.

6*th*, The *cake*, or combined regulus of gold and silver, obtained from the purification furnace, is separated into thin pieces in this manner: It is melted, and, in a state of fusion, cast into cold water. By this means it is obtained with a very extended superficies, and easily divided into a number of thin scales. These are put into immense glass retorts, of a spherical form, nearly filled with *nitric acid*. Here the silver dissolves, a gentle heat being communicated to the retorts, to accelerate the solution. It has been usual to exclude foreigners from the great *laboratory*, where this takes place; but as we had witnessed every operation, we were also permitted to view the interior of this chamber. The sight was beautiful. It was a spacious and lofty hall, filled with enormous globes of glass ranged in even rows, whence the *nitrous gas* was escaping in red fumes to the roof; the solution of silver being visible in all of them by the effervescence it caused; the gold falling at the same time, in the form of a black powder, to the bottom of every retort. After the solution of the silver is completely effected, the *acid* containing the silver, by augmenting the heat, is made to pass into another retort, and the gold is left behind in the former vessel. Afterwards increasing the heat to a great degree on the side of the silver, the whole of the acid is driven off, and the silver remains beautifully crystallized within the retort. All the glass globes containing the crystallized silver are then cast into a common furnace, where the glass, by its levity, remaining on the surface of the metal, is removed in the form of scoriæ. This is the last operation. The gold is smelted into ingots of 12,000 florins each."

"In the essaying laboratory, instead of the long process we have described for extracting the precious metals from their ores, two simple and easy experiments are sufficient. The first is a trial of the pulverized ore by *cupellation*. About a tea-spoonful of the pulverized ore, first weighed, is put into a small *cupel* made of calcined bones: this being exposed to the heat of a powerful furnace, the lead, semimetals, &c. are either absorbed by the cupel, or they are sublimed. Nothing remains afterwards in the cupel but a small bead of combined gold and silver; and by the proportion of its weight to the original weight of the ore, the value of the latter is determined. The gold is then separated from the silver by the solution of the latter in nitric acid; and the difference of the weight of the gold from the whole weight of the two metals, combined, determines the quantity of silver dissolved by the acid." "A hundred pounds weight of their richest ores contained from four to five *marks of silver*, and each mark of the silver about 15 *deniers* of gold."

The mines are wrought partly at the expence of the crown, and partly at the expence of individuals, who pay a duty called *urbur*, and are besides obliged to deliver the metal at a fixed price to the royal treasury.

The number of miners employed by the crown at these mines amounts to 9,500, of whom 8000 are at Schemnitz; and the expence to government of working is estimated at 50,000 florins a month, and the clear profits during the same period 12,000 florins, about 1333*l*. calculating the pound sterling equal to nine florins. The workmen are paid, when the ore is *rich*, according to the quantity and quality of the ore raised, but when it is *poor*, they receive wages. The Schemnitz ores, in the space of thirty-three years, (from 1740 to 1773) produced seventy millions of florins in gold and silver; and those of Cremnitz thirty millions during the same period. The greatest produce, however, was derived from them in 1780, when they yielded 2,429 marks of gold, and 92,267 marks of silver, making 3,043,000 florins. In common years, according to the calculations of Born and Ferber, these mines, including the copper mine of *Neusohl*, where one quintal of copper produces twelve ounces of silver, yield from 58,000 to 59,000 marks of silver, and from 1,200 to 1,300 marks of gold.

The silver mines in Upper Hungary at Nagy-Banya, Felsoe-Banya, and Lapos-Banya, in the county of Szatl.-mar; at Metzenseif, in the county of Bihar, with the copper mines of Retz-Banya and Schmoelnitz, according to Mr Ferber, give an annual produce of from 12,000 to 15,000 marks of silver, and from 300 to 400 marks of gold. The copper and lead mines in the Bannat at Oravitza, Saszka, Dognaszka, and Moldava, yield annually about 111,04 marks of silver, and 20½ marks of gold.

The copper mines of Hungary produce annually from 30,000 to 40,000 quintals. The richest are situated at Schmoelnitz in the county of Zips, and in the Bannat.

The lead mines in 1786 were wrought to the extent of from 14,000 to 15,000 quintals, but this produce is now considerably diminished.

The iron mines in this country are almost inexhaustible. The best is drawn from a mountian called Hradek, near Esetnek; but as this metal is not subject to any duty or tithe, the annual produce of these mines have not been ascertained. In the county of Goemor, including the district of Kleinhont, there are eight great furnaces, a floating furnace, eighty-seven small ones, and forty-nine forges, which furnish annually 94,200 quintals of iron, worth 1,304,240 florins. But, notwithstanding the great quantity of iron which this country produces and exports, they are obliged to be indebted to Austria for most of their tools and vessels made of this metal.

*Manganese* is found near Felsoe-Banya, and in some of the iron mines; *titanium*, in the county of Goemor near Roeze; and *tellurium*, which was discovered by Dr Kietaibel in a mineral of Deutsch-Pilsen in the county of Hont. Many valuable and beautiful minerals are found in the Hungarian mines. Among them may be mentioned, *amethysts* invested by efflorescent *manganese-spar*, in a minute crystallization upon the surface of the amethystine crystals; rich *sulphurets of silver*, called by the Germans *Weisgulden Erz*, or "white money ore," which is so malleable, that medals have been struck from the unwrought ore; *sulphurets of silver*, both massive and crystallized; *red antimonial*, or *ruby silver* crystallized: *dodecahedral* and *primary* crystallizations of *quartz*; phosphates and carbonates of *lead* crystallized; red sulphurets of *arsenic* crystallized; diaphanous crystals of the sulphuret of *zinc*, and of the sulphate of *barytes*; *pearl-spar* in spheroidal tubercles, upon silver ore; native gold crystallized, &c.

Of the precious stones of Hungary, the vallies of Konigsberg afford emeralds and rubies, and its mountain contains topazes, hyacinths, and chrysalites; granites are very common, and rock crystals of various forms; small crystals, remarkable for their brilliancy, are found in the county of Marmarosch, and receive the name of *Hungarian diamonds*. There are also amethysts of various colours, opals, jaspers, and agates.

The salt mines of Hungary are very productive, particularly those in the counties of Scharosch and Marmarosch. In the former county, near the village of Sevar, great quantities of rock salt were extracted during the 16th century; but towards the end of the 17th century, the quarries were inundated by salt springs, which contain a remarkable quantity of muriate of soda. Since that time other inundations have taken place; but, without neglecting the extracting of rock salt, establishments have been formed for obtaining common salt. These mines produce 27 per cent. All the salt pits and mines are under the direction of the crown, and produce annually about a million and a half of quintals. The price is fixed by the government, and cannot be augmented but by the king, with the consent of the diet. As the profits arising from the sale of this commodity form a part of the regal duties, it is not allowed to any individual to appropriate to his own use any saline earths or springs which he may have discovered, even on his own property.

Hungary abounds in quarries of limestone, and marbles of various colours. Alabaster and chalk are also common.

Manufactures and the arts are still in their infancy in Hungary, and do not nearly supply the consumption of its inhabitants. Linen and woollen cloths are made throughout the country; but there is only one cotton manufactory, which is established at Sassin, in the county of Neutra. In 1800 it employed 20,000 individuals in different parts of the country, and circulated every year nearly half a million of florins. There was formerly another cotton factory at Lisza, which consumed annually about 150 quintals of cotton, and yielded a gain of 18,000 florins; but the proprietor several years ago removed it to Baad in Austria. According to M. Schwartner, this manufacture in 1796 kept 1,700 looms in employment, which produced 25,000 pieces of cotton cloth. Those in the northern districts, though still very imperfect, are the most flourishing, and have made considerable progress within the last twenty years. The other branches of industry that are deserving of notice are, the manufacture of oils, paper, potashes, spirits, liqueurs, tobacco, woad, hats, soap, leather, alum, earthenware, glass, copper, and iron.

The Germans were the first who introduced the arts into this kingdom in the 12th century; and from that time the principal artisans have been of that nation. A true Hungarian would consider himself degraded by being employed in any other labours than those of agriculture or arms. This repugnance is very general; and though their national *costume* has always been a hussar dress, covered with lace and fringe, yet it is only within these fifty years that the capital possessed a single lace-maker.

Considering the extent of this kingdom, its commerce may be divided into two branches; the trade carried on between its different districts, and its trade with foreign countries, or its *internal* and *external* commerce. The inhabitants of the north, who, with their utmost industry, are unable to raise sufficient corn for their own consumption, exchange their iron, salt, cloths, and other manufactures, for a portion of the luxuriant harvests of the south; and this traffic is greatly facilitated by the establishment of fairs, of which there are 1640. The itinerant merchants, however, who frequent these fairs, and travel through the country, though they are serviceable in supplying the inhabitants with many articles which they could not otherwise easily obtain, are supposed to have done considerable injury to trade in general, and also to the revenue of the state. The merchants stationary in the towns presented a memorial to the diet on this subject in 1802, complaining that their itinerant brethren possessed neither knowledge nor character proper for merchants; that they defrauded the revenue, by smuggling articles of import; that they imposed upon the inhabitants with damaged goods, and exorbitant prices; and thus destroyed that confidence which the public ought to have in the merchant. Notwithstanding this remonstrance, however, the fairs are still continued.

The external commerce of Hungary was so very inconsiderable as late as 1779, that it yielded only 27,347 florins; but by the exertions and speculations of a few spirited individuals, who employed every possible mean for establishing foreign relations, it was brought, in the beginning of the present century, to 3,631,553 florins. Many difficulties, however, must be overcome, before Hungary can be formed into a commercial country. Its geographical situation is very unfavourable to commercial operations, being sixty-eight leagues from the maritime coasts of Austria; and consequently the expence of transportation precludes it from competing in foreign markets with those countries which are more favourably situated. Its productions, in spite of these obstacles, are carried into Austria, Italy, Switzerland, Germany, Prussia, Russia, and other northern states. These consist chiefly in grain, tobacco, wine, gall-nuts, cattle, wool, skins, tallow, honey, wax, buckthorn, antimony, and potashes. Grain is exported into the frontier states of Austria, and by the Adriatic. In 1803, Vienna alone received from this country 543,083 Presbourg measures of wheat and rye, 316,163 of barley, and 591,839 of oats. Hungary supplies Austria and the German states with tobacco, and exports wine into all the northern kingdoms and states of Europe. Vienna alone consumes annually from 30,000 to 35,000 *eimers*.

The imports of Hungary are derived chiefly from Austria, the government having prohibited the admission of goods through any other channel. Turkey, however, is excepted, as a prohibitory system with respect to this country could not be carried into effect without great difficulty and expence. The great magazine for Turkish produce, which passes into Hungary by land, is at Schuppanek. A considerable quantity enters also by the Danube at Panczova, Kubin, and Homolitz. The imports from Turkey by the city of Schuppanek, during the years 1803 and 1804, amounted to 2,652,473 livres: viz.

| | *Livres.* | | *Livres.* |

| Beef tallow | 4 419 | Cordage | 5,750 |

The imports which enter by the Danube are of the same description as those in the preceding Table; but their amount is comparatively inconsiderable. Of colonial produce, Hungary consumes annually about 8,000 quintals of coffee, and 10,000 quintals of sugar. Upon the wh

the

notwithstanding its commercial difficulties and obstructions, the exports of Hungary are to its imports in the proportion of more than four to three. According to the calculations of Schwartner, during ten years, (from 1777 to 1786,) its exports were valued at 148,229,177 florins, and its imports at 106,721,371 florins.

The money, weights, and measures of this country correspond nearly with those of Austria. In money, the common reckoning is in *florins* and *kreutzers*,—60 kreutzers being equivalent to one florin. The copper coins are, the *polturak*, equal to a kreutzer and a half; the *groszel*, value of half a polturak; and the *ungrisch*, of which five are equivalent to three kreutzers. The ideal or fictitious money of Hungary consists of

| | | | | |
|---|---|---|---|---|
| the *bauer-gulden* | = | 49½ | kreutzers | |
| the *kurze gulden* | = | 50 | do. | |
| the *vonas-gulden* | = | 51 | do. | and |
| the *ort* | = | 12 | do. | |

The measure prescribed for corn throughout the kingdom is the Presbourg bushel. In the county of Zips this measure is called a *kubel*, and is divided into two *koretzs*; but in other places the kubel is divided into four koretzs or *veka*. The *eimer* is the general measure for wine, but it varies in its contents in different parts of the country. At Oedenbourg it contains 84 *halben* or pints, and at Buda only 60. The great eimer of Debretzin is 100 pints, and the small one 50. In consequence of this discrepancy of measures, the merchants presented a remonstrance to the committee of commerce appointed by the diet. On this subject they remarked, that such a variety of measures were hurtful to commerce, and destroyed their credit among foreigners; that an *antal* of Tokay wine, which ought to hold an eimer and a half, in general contained scarcely an eimer; and that a *piece* of wine, which ought to contain 64 halben, has seldom more than 58.

The *foot* of Vienna is the standard square measure for surveying. According to a regulation called *urbarium*, the *joch* or acre is fixed at 1600 square toises; but in some of the counties, where this regulation has not been introduced, this measure varies greatly; as at Oedenbourg, for instance, the acre measures only 900 square toises.

The weights are in general the same as at Vienna, (except the *stein* used in Upper Hungary, which weighs 20 pounds,) viz.

| | | |
|---|---|---|
| 1 quintal (cwt.) | = | 100 pounds |
| 1 pound | = | 2 marks |
| 1 mark | = | 16 loths |
| 1 loth | = | 4 *quintales* or drams |
| 1 *quintale* | = | 4 deniers |

The greatest obstructions to the commerce of this country arise from the difficulty and expence of conveyance. Except in the districts on the north and west, there are few made roads in Hungary, and these are kept in very bad repair. The bridges in general are wretched, and almost all built of wood, which the rising of the rivers often carries away and destroys. Some of the flying bridges, however, used in this country, are very magnificent, and are adorned with considerable elegance. That over the Danube at Gran consists of a large platform constructed across two barges, and held by other boats at anchor. It is provided with several small houses, a large bell and cupola, images, &c. and is capable of conveying, at the same time, a great number of carriages, passengers, and cattle. From Pesth, the centre of Hungarian commerce, the road to Vienna passes through Komorn, Raab, and Wieselbourg; to Gallicia, by Erlau, Kaschau, and Eperies; to Transylvania, by Debretzin, and also by Ketschkemet, Szegedin, Temeschwar, and Lugosch; to Walachia, by Temeschwar, Karansebes, and Schuppenek; to Semlin and Belgrade, by Theresienstadt and Neusatz; to Croatia, by Stuhlweissenbourg, Veszprim, and Kanischæ; and to Stiria and Trieste, by Veszprim, Somogy, and Pettau.

The transportation of goods by water, though more expeditious, suffers many interruptions, from the shallows and rapids in the rivers. The Danube itself is far from being free of these inconveniences; but boats with from 6000 to 8000 quintals of grain can pass as high as Komorn. The formation of canals, however, which has of late become an object of improvement, promises to facilitate greatly the internal commerce of this country. Those that are finished are, the canal of Baatsch, the Bega canal, and the Tranzisci canal. The Bega canal commences near Facsed in the county of Krascho, and after forming a communication between the rivers Bega and Temesch, traverses all the Bannat, and falls into the Theisse. The Tranzisci canal was first opened only in 1802. It receives the waters of the Danube at Monoflor-Segh, and discharges itself into the Theisse at Foldwar; and in its whole extent requires only four sluices. In 1804, there passed through this canal 634 boats, many of which carried from 4000 to 5000 quintals; and their cargoes, which we here present to the reader, will enable him to form some idea of the internal commerce of this country.

The population of Hungary is much less, in proportion to its extent, than that of the neighbouring countries of Austria, Moravia, or Bohemia; and this may easily be accounted for from the immense plains of sand, and the great numbers of morasses and heaths, which render a great portion of the lower plain entirely uninhabitable. According to M. Demian, the number of inhabitants amounts to 6,620,637, making 1654 to every square mile. These consist of a variety of nations, Hungarians, Slavons, Walachians, Germans, &c.

The Hungarians, or Huns, who settled here near the end of the ninth century, and gave their name to the country, have established themselves in the best and most fruitful part of the kingdom. They inhabit almost all the lower plain, beginning at Marmarosch, and the western part of Hungary, and form the population of 3,668 towns and villages. The true Hungarians are of a free and independent character, and affect to despise the Germans. They prefer the trade of arms, or the labours of agriculture, to every other employment. The dress, called *Hessian* in England, consisting of pantaloons and military half-boots, with spurs fastened to the heels, is so universal, that it is worn both by boys and men; and the Hussar uniform, which is peculiar to this nation, and consists of a tight vest, mantle, and furred cap, with the whiskers, give them a graceful and military appearance.

The Sclavons are more numerous, and are daily increasing. They are divided into several branches: Slowacs, Ruszniacs, Croats, Vandals, and Servians or Rasciens. The *Slowacs* inhabit chiefly the counties on the north and north-west, particularly those of Presbourg, Neutra, Trentchin, Thurotz, &c. and occupy 3,768 towns and villages. Of all the inhabitants of Hungary, this people are the most fruitful; for wherever they have established themselves among Hungarians or Germans, these have ceased to prosper, and their families have become extinct in a few generations. The *Ruszniacs* have settled in the counties of Marmarosch, Beregh, &c. bordering on eastern Gallicia. According to the *conscription tables* of 1787, they amounted to nearly half a million of souls, and peopled 702 towns and villages. The *Croats* dwell principally on the banks of the lake Neusiedl, and the counties of Wieselbourg and Oedenbourg; and the Vandals on the mountainous parts of Eisenbourg. The *Rasciens* or Servians came as colonists to Hungary during the reign of the emperor Sigismund. They occupy a great part of the military frontiers, and also many places in the interior, and have had considerable privileges granted to them by the kings of Hungary.

The *Walachians*, who are supposed to be the descendants of the ancient Roman colonies, dwell chiefly in the Bannat, on the confines of Walachia, and in the counties of Arad, Bihar, and Szathmar, in 1,024 towns and villages. Those of the Bannat bear a very bad character. They are noisy and quarrelsome, and fond of gambling. They commit many disorders and crimes, which have been attributed to the influence of their priests, who are called *Popes*; and it has been calculated, that in twenty executions for capital offences, there is always one pope.

The *German* population is scattered almost equally over all the kingdom, but it predominates in 921 villages and towns in the counties of Zips, Eodenbourg, and Wieselbourg, and in some of the royal free cities. They are almost all Suabians, and their reception as colonists into Hungary is of a late date, chiefly between the years 1765 and 1787. In the last of these years alone more than thirty villages were built for them. In general the establishment of new colonies in Hungary have cost the government more than six millions of florins. The population of the royal free cities varies from 30,000 to 1,100 inhabitants. Presbourg, Pesth, and Debretzin, are the most populous; but Rust, on the lake of Neusiedl, in 1794, contained only 1,105 inhabitants. Of the towns, the principal are, Ketschkemet, containing, in 1803, 24,000; Nagy-Koros, 12,000; Szarwasch, 9,000; Sazbereny, 12,000; and Bekesch, 11,000 inhabitants. The villages are very unequally peopled. In the lower plain, some are found with six, ten, and sometimes twelve thousand souls; but in the mountainous districts they seldom exceed 700.

Besides these principal nations, there are also *Macedonians*, or Modern Greeks, who have no settled habitations, but travel over the country, engaged entirely in commerce; *Jews*, who are chiefly itinerant merchants; *Armenians*, who are employed in agriculture; and *Bohemians*, or gypsies. This vagabond race are very numerous in Hungary; and, in spite of all the attempts of the Emperor Joseph II. to reform and civilize them, they still maintain their ancient customs and habits. Those of the Bannat get their livelihood as itinerant blacksmiths or musicians. During summer they go almost naked, and are then employed in washing gold from the sand of the rivers; and in winter they cut spoons, ladles, troughs, and other implements of wood. They form the orchestra at all weddings and merry meetings; and many of the richest nobles invite them to their castles, to amuse their guests with their music and national songs. Schwartner, in his Statistics of Hungary, attempts to account for this variety of population: "From the earliest history, Hungary has been the native abode of the Sarmatians or Sclavonic tribes. Since the fourth century, it has been the hospitable region where reposed the innumerable hordes which overturned the Roman Empire,—the asylum of many Tartar nations that were driven from their own homes,—the passage of those fanatic bands of crusaders, whom the knavery and avarice of monks sent to perish in Palestine, that they might take possession of their wealth in Europe,—as the frontier of Christendom, the theatre of European valour and Turkish ferocity,—and for a long time the cherished homes of the gypsies, the *El-Dorado* of the Germans, especially of the laborious Saxons, and numerous Suabians."

The inhabitants of Hungary may be classed under three heads, viz. the nobility, the citizens, and the peasants. The nobility are very numerous, and are calculated at 325,894 individuals, making nearly one for every twenty-one inhabitants and a half. These consist of the barons of the kingdom, or officers of state, and the order of *Magnats* (*liberi barones*). Of the latter there were, according to the Political Almanack of 1805, 95 families of counts, 79 of barons, and 297 of noble strangers, who had obtained letters of naturalization since the commencement of the Austrian sovereignty. There are only three families whose heads enjoy the title of *prince*: Esterhazy, Bathyany, and Grassalkovics. The first is supposed to be the richest subject in Europe. Among the nobility, also, are included all gentlemen who possess landed property, as the individual doing so is *ipso facto* ennobled. The title of citizen or burgher belongs only to the inhabitants of the royal free cities, who have particular privileges; and their number, including the inhabitants of the six free cities of Croatia and Sclavonia, amounts to nearly 366,000. The peasants are the inhabitants of the country, who belong neither to the noblesse, the clergy, nor the military, but who live entirely by husbandry, the cultivation of the vine, or the rearing of cattle. Of these they reckon 509,825. With them may also be classed 788,993 other individuals, whom thep call *haüsler*, who have no lands to cultivate, but who live by their own labour.

The government of Hungary is a limited monarchy, where the king enjoys great authority and influence; but where the nobility also have extensive rights and numerous privileges. The order of succession is established in the descendants of either sex of the House of Hapsburg, who at their coronation must take an oath in the presence of the diet, to preserve and maintain inviolate the liberties, privileges, rights, laws, and usages of the kingdom at present existing, or which may hereafter be decreed during their reign; never to carry the Hungarian diadem out of the kingdom, but to entrust it to two lay guardians elected by the diet for the purpose; to unite to the crown of Hungary all the countries which it formerly possessed, should they be reconquered; to restore to the estates of the realm the right of electing a king after the extinction of the line of the descendants of Charles VI., Joseph I., and Leopold I.; and that each of their successors shall be bound to sanction this conservative act at the diet of his coronation within six months after his accession.

The prerogatives of the monarch consist in his exercising the executive power in its full extent; but the legislative power he holds only in conjunction with the diet, whose decrees alone have the force of laws; the nomination to all bishoprics and abbeys, and ecclesiastical dignities, as also to all civil and military appointments, (the Palatine, and the two keepers of the crown excepted, who are chosen by the diet from a list of candidates presented by the king); the power of creating nobles, of making peace and war, and of calling out the personal levy; the right to the revenues of all vacant benefices, as also to the properties of all deceased nobles who have died without heirs, or who have been convicted of treason or rebellion; the immediate superintendance and direction of all establishments of public instruction, whether religious or temporal, whether Catholic or Protestant; and the right of convoking the diet, of pointing out the matters that are to be there discussed, and of proroguing or dismissing it.

The privileges of the nobility, by an act of the diet in 1741, were formed into a fundamental law of the kingdom, and consist in the right of assisting at the deliberations of the legal assemblies of the county, wherein they dwell or possess property, whatever be the subject under consideration; the inviolability of their persons from arrest, unless in the cases of felony, high-way robbery, and some other crimes; the sole right of possessing lands with the seignorial power over their vassals; and the exemption from all contributions and imposts.

The royal free cities enjoy the same rights as the nobles without exception, and are subject to the same laws and usages. They are considered as domains of the crown, which can neither be alienated nor mortgaged. They constitute the fourth order of the diet, and are represented by two members each; and the citizens elect their own burgomasters, judges, and magistrates. Besides the royal free cities, there are others which possess particular privileges; the most considerable of which are the sixteen cities of Zips, which were mortgaged to Poland by King Sigismund, but restored to Hungary in 1772. Their jurisdiction, civil and military, is independent of the county; and they enjoy the right of appeal from their own tribunals to the supreme courts of the kingdom. Their population is 45,000. The six cities of Heidukes, in the county of Saboltsch, which possess nearly the same privileges, and send two deputies to the diet. They contain about 27.500 inhabitants; and the districts of Jazyg, of Great and Little Cumania, which form a population of 112,723 souls. They are under the immediate jurisdiction of the palatine, and form, like the royal free cities, a domain of the crown. They pay neither duty nor tithe, and send two representatives to the diet. All these, however, are subject, like the other cities, to the general contributions.

The peasants, since 1791, by an act of the diet, are no longer attached to the soil, but are at liberty to leave their habitations at the proper term, and seek another lord. Formerly it was not permitted for plebeians to plead in law against a noble; but the free cities pleaded for their individual burghers, and one noble defended the rights of his vassals against another. By the diet of 1802, however, it was decreed, that, for the future, citizens and peasants should be permitted, in certain cases, to prosecute for themselves. Plebeians, also, as such, may fill the highest situations in the church; and it is not unfrequent, that, on account of their learning and good conduct, they obtain letters of nobility. When once ennobled, the career of honours is open to them, and they may then aspire to the first offices of the kingdom.

The principal officers of state are the *palatine*, who, besides other duties, presides at the assembly of the diet, is viceroy in the absence of the king, and generalissimo of the Hungarian troops; the grand judge of the kingdom; the *bann* of Croatia, Dalmatia, and Sclavonia; and the grand treasurer.

The *Diet* of the states is composed of four orders, viz. the prelates; the lay-barons and the magnats; the representatives of the counties, each county sending two members; and the representatives of free cities. They are invited to the diet, in the name of the king, by letters of convocation dispatched by the chancery; and these letters often contain a statement of the different points that are to be there discussed, that the counties and free cities may give proper instructions and powers to their deputies. According to the constitution, no one but a noble, that is, one who possesses landed property, can sit and deliberate in the diet. When assembled, all the members are considered as upon an equality, neither baron nor bishop having any privileges more than a simple gentleman. They meet in separate chambers: the chamber of *magnats*, where the palatine presides, and which is composed of the prelates, the barons of the kingdom, the governors of counties, and all the counts and barons who may be members of the diet; the other deputies, who are the most numerous body, constitute the chamber of *states*, where the grand judge presides. When a motion has passed both chambers, the king has the power of confirming or rejecting it, his approbation being necessary to give it the force of a law.

The internal police of the kingdom is administered by the supreme aulic chancery, the council of government, and other subordinate courts. The first sits at Vienna, and is composed of an aulic chancellor, vice-chancellor, and ten aulic counsellors, all chosen by the king. Of the counsellors, two are bishops, two magnats, and six nobles. It is the organ by which the king exercises his royal authority, and directs the political affairs of the interior. It expedites all letters-patent, granting favours and privileges, and also all diplomas, nominating to vacant bishoprics, ecclesiastical benefices, and other offices. The *council of government* sits at Buda, and consists of the palatine, who is president, and 24 counsellors. It has the superintendance of all inferior courts, and of all matters regarding general police and public safety, and the inspection of churches, universities, &c.; it encourages agriculture, industry, and commerce; and decides in all matters of litigation respecting the services of peasants towards their lords, &c.

The subordinate courts are those of the counties and free cities. Each county has its governor and two vice-governors, a procurator, and vice-procurator-fiscal, a receiver-general and assistant, a notary, &c. The governors are appointed by the king, except in the cases of the palatine, the primate, the princes Esterhazy and Bathyany, the counts Kobari, Illeshazy, Palfy, Nadasdy, Schonhorn, Csaky, Erdody, and baron Revay, who are hereditary governors of counties; the other magistrates are appointed by the county, and are renewed every three years. The governor convokes the county whenever he thinks it necessary, and all the nobility within its bounds have a right to deliberate and vote. The subjects which are there discussed, regard the police and agriculture of the county; the election of their deputies and magistrates; the levying of contributions and imposts; and the publication of the decrees of the diet, and of the council of government.

The magistracy of a free city consists of a judge, a burgomaster, a counsel, a notary, &c. to whom are entrusted the administration of justice and police within the royalty.

The tribunals of justice, which possess general jurisdiction throughout the kingdom, are the septemviral table, and the royal table. The *septemviral table* consisted formerly only of seven members, but it is now augmented to twenty-two, of whom the palatine is president. It is only a court of cassation, and receives processes by appeal from the royal table and inferior tribunals. The *royal table*, where the grand judge presides, is composed of seventeen members, nine of whom must be present, in order to constitute its decisions valid. It pronounces on all disputes respecting property, the maiming or murdering of nobles, and crimes of high treason. It is also a court of appeal, and holds four sessions during the year.

The inferior and special judicatories are the four tribunals of the circles, which decide only in civil cases, having no criminal jurisdiction; the county tribunals, which have also four sessions, and take cognizance of all matters civil and criminal, except in cases of high treason; the district tribunals; the city tribunals; and the tribunals of individual nobles. Croatia has also a court of appeal, called *tabula banalis*, which sits at Agram, and of which the ban of Croatia and Sclavonia is president. It has the same jurisdiction within these provinces as the royal table at Pesth, with this difference, that an appeal may be carried from the *tabula banalis* to the royal table.

The bases of Hungarian jurisprudence are the *corpus juris Hungarici; decretum tripartitum Verboeczianum*, and *decisiones curiales*. The *corpus juris Hung.* is a collection of all the decrees passed by the diet from the commencement of the monarchy, and was first formed in 1584. Since that time it has received so many additions, that it is increased one half; but, latterly, these laws have been so ill digested, and so intermixed with other matters, that the confusion which is thus occasioned renders the study of them both difficult and laborious. The *decretum tripartitum Verboeczianum*, is a collection of customs introduced into the administration of justice, which, by long usage, have received the force of laws. This collection was made by Verboecz, the grand judge in the reign of Ladislaus II.; and though it has been rejected as a national code by several diets, yet, through the course of time, it has acquired such reputation, that it is actually acknowledged throughout the kingdom, as forming a legitimate part of Hungarian law. The *decisiones curiales* are the decisions of the judges of the royal table on certain questions to which no existing law could be directly applied. They were collected by order of Maria Theresa in 1769; and, after having been revised by the septemviral and royal tables, were published under the title of *planum curiale*.

The revenue of Hungary arises from three sources; the royal domains, the legal duties, and the contributions or imposts. The *royal domains* consist of the *kron-güter*, or such property as is attached to the crown, and is unalienable; and the *kammer-güter*, that which belongs to the king personally, and which he can dispose of at his pleasure. The annual value of both amounts to 6,000,000 of florins. The *regal duties* comprehend the management of the salt, which is supposed to yield nearly 6,800,000 florins; the mines, which, after deducting all expences, produce 1,097,000 florins; the duties upon exports and imports, valued at 1,300,000 florins; the quit-rents of the royal free cities, and of the sixteen cities of the Zips, amounting to 34,000 florins; the royal exchequer, which brings 94,000 florins; the toleration tax paid by the Jews, producing 100,000 florins; the tax of 5 per cent. upon all employments, to which is attached a retiring pension, yielding 37,000 florins; the ecclesiastical subsidy, which, in 1781, was 71,000 florins. To these may be added the post-office, the tolls upon the bridges, the tax of 10 per cent. which all must pay who carry their fortune out of the country; the lottery; and the banks, of which there are two, one at Presbourg, and the other at Buda. The contributions or imposts are levied upon the counties and cities. The total amount is fixed by the diet, and is divided into *porten* or portions, each of which is valued at 688 florins, 50 kreutzers. Every county and city is then burdened with so many *porten*, according to its population and resources, which they collect from the citizens and peasants. The sources of this branch of the revenue arises from the poll-tax, tax upon cattle, &c.; the land-tax paid by the farmer; and a tax upon trades, &c. The total amount of the contributions in 1802 was $6210\frac{2}{8}$ *porten*, making 4,277,827 florins, $12\frac{4}{8}$ kreutzers; to which may be added 113,615 florins, $58\frac{2}{8}$ kreutzers for Croatia. The total revenue of Hungary cannot be well ascertained, as the different items given above are not for the same year, and authors are also much divided in opinion respecting it. Schloezer makes it 13,500,000 florins; Busching, 18,000,000; De Lucca, 15,000,000; Schwartner, 11,750,000; and Demian, who is the latest author, fixes it at between 15 and 16 millions of florins. After deducting the public expenditure, the surplus, according to Schwartner, amounts to 1,002,296 florins.

The management of the finances is entrusted to the royal chamber of Buda, which is independent of all other authority within the kingdom, and corresponds with the royal treasury at Vienna. It administers all the royal revenues, except the contributions which are lodged in the government chest, and the mines and mint, which are entrusted to a particular council.

Since 1802, the Hungarian army, exclusive of the frontier regiments, is formed of twelve regiments of infantry and ten regiments of cavalry, making an armed force of 64,000 men. The military cordon, which extends along the frontiers from the Adriatic to the county of Marmarosch, is formed of seventeen regiments of armed peasants, each regiment having its particular district; viz. eight in Croatia, three in Sclavonia, two in the Bannat, and four in Transylvania. Each regiment has two battalions, and in time of war a battalion of reserve; the whole, exclusive of the reserve, amounting to 49,402 men. There is also a regiment of hussars, whose complement, in time of peace, is 1364 men and 1212 horses. The Hungarian army is maintained by an annual contribution, fixed by the diet in 1715, which is levied upon the citizens and peasants, and amounts to nearly three millions of florins. The country is also obliged to furnish bread and forage necessary for the troops at a fixed price, whatever be the price of these necessaries in the public markets; and the loss which is thus sustained by the counties, is computed at about a million of florins. The extraordinary contributions, however, which were required during the late wars with France, were paid almost entirely by the nobility.

In addition to the permanent army establishment, the diet, in urgent cases, grants a levy at the request of the king. During the middle ages, every Hungarian noble, by a law of the kingdom, was obliged to arm himself and his vassals in defence of the country when threatened by an enemy; and in cases of imminent danger, the whole nation took up arms. The levy now, however, is confined to a certain additional force, furnished and paid by the counties and cities. The first levy of this description was raised in 1741, for the war of the succession; and in the first coalitions against France, regular levies were decreed by the diet; but they were always too late of being brought into the field, to be of any service to the common cause. The levy of 1797, 40,000 strong, was scarcely assembled before the peace of Campo Formio was concluded; that of 1800 was stopped in their march by the peace of Luneville; and that of 1805 was withdrawn on account of the peace of Presbourg.

All religious sects enjoy full toleration and security in this kingdom, as well as in other parts of the Austrian dominions. The Roman Catholic is the established religion, and is under the jurisdiction of three arch-bishops, Gran, Kolotcha, and Erlau; 14 diocesan bishops, and 16 titular bishops; 16 metropolitan chapters, and two others of collegiate churches; 178 beneficed canons, and 79 honorary canons; 1 archabbot, and 146 abbots; 19 grand provosts, and 89 provosts. The revenues of the bishops and chapters are very considerable; and, according to Schwartner, that of the former, in his time, amounted to 864,776 florins, and of the latter to 530,668; but, according to Demian, they may now be valued, when taken together, at above two millions of florins. The inferior clergy are composed of pastors and monks. Of the former, there are 4189, including 2298 rectors, 402 chaplains, and 1489 curates; and of the latter are 3059, including 2236 priests, 214 novices, and 609 lay brethren. The Emperor Joseph II. increased the number of the pastors, so that every *commune*, containing a certain number of parishioners, should have one; and fixed their allowance at 300 florins for each rector, and 240 for each chaplain or curate. According to Grellmann, the Roman Catholic pastors, comprehending those of Croatia and Sclavonia, receive 1,379,500 florins. But, while the Emperor Joseph augmented the number of pastors, he at the same time suppressed 134 monasteries, containing 1209 priests and 275 lay brethren. There are still 136 remaining, of different orders: the *Piaristes*, who have two residences and 23 colleges; the *Benedictines*, four abbeys and three residences; the *Premontres*, five abbeys; the *Citeaux*, two abbeys and three monasteries; the fathers of *Charity*, ten monasteries; the *Cordeliers*, 61; the *Minimes*, eleven; the *Capuchins*, seven; the *Dominicans*, four; the *Carmes*, one; the *Servites*, three; and the *Augustines*, one. The support of these religious beggars, since they were precluded from seeking alms, costs the chest of religion 75,000 florins a year. There are also ten convents, containing 274 nuns and 116 lay-sisters; six of the order of *Sta. Ursula*, two of *Sta. Elizabeth*, one of *Notre Dame*, and one for English ladies at Buda. Six convents had been suppressed by the Emperor Joseph, containing 152 nuns and 39 lay-sisters. In 1802 there were 500 monks and nuns of the suppressed convents still living, who received pensions from the chest of religion; the priests and nuns from 300 to 200 florins, and the lay-brethren and sisters 150 florins. The number of Roman Catholics in the kingdom is calculated at about 4,000,000.

The Greek Catholic church, whose members amount to nearly 500,000, is under the direction of two bishops, who are suffragans to the Roman Catholic archbishop of Gran; two chapters composed of two grand provosts; eleven beneficed canons and six titular canons, and 820 pastors. The revenue of the two bishops is 28,000 florins, that of the chapters 9150, and that of the pastors 78,000 florins. Belonging to this church are eight monasteries of the order of *St Basil*, containing 68 monks, 21 novices, and 17 lay brethren.

The Greek Schismatic Church has five bishops, all suffragans of the metropolitan archbishop of Carlowitz in Sclavonia, whose dioceses contain 1120 parishes. There are ten monasteries of this religion, having a revenue of about 17,000 florins, and are inhabited by 82 monks. This sect amounts to 1,877,587 souls.

The Protestant Evangelical, or Lutheran Church, consisting of 700,000 souls, has 445 places of worship, and 478 ministers, who are chosen and supported entirely by their congregations.

The Reformed Evangelical Church is under a similar constitution, and includes 1324 churches, 1361 ministers, and 1,300,000 members.

There are 75,128 Jews, who have 42 synagogues, and 56 rabbies. This sect is excluded from all the cities which are near the mines; and some other cities consider the prohibiting of Jews to settle within their walls among the number of their privileges. The Anabaptists are inconsiderable in number, and are to be found only in a few cities.

The establishments for public instruction in Hungary, may be distinguished into General and Particular. Of the former, there is an elementary school, with two masters, established in every Catholic commune, where are taught, reading, writing, arithmetic, and religion. In addition to these, there are also 73 principal schools, to which are attached 234 teachers; 9 normal schools, with 51 masters; 43 gymnasia, with 88 professors; and 5 arch-gymnasia, with 26 professors. In all these establishments, education is gratuitous, and costs the state about 90,000 florins. For the higher sciences, there are four academies, at Presbourg, Kaschau, Grosswardein, and Raab; a lyceum at Erlau; two schools of philosophy at Stein-am-Anger and Szegedin; and a university at Pesth. Besides a school in each of their parishes, the Lutherans have several other establishments for the education of their youth. In all of them, however, the sciences are very imperfectly taught, and the masters very poorly paid. The Reformed, in addition to their parish-schools, have two colleges at Debretzin and Saros-Patak, which are intended chiefly for the education of their ministers. The Greek Schismatics have very few schools, except in the military frontiers of the Bannat, where there are 130, with 3615 scholars; and those of this persuasion who wish to study the higher branches of science attend the Catholic or Protestant academies.

The Special Schools consist of the practical schools for rural economy in all its branches, of which there are four, at Szarwasch, Kessthely, St Miklosch, and Hradek; a school for the deaf and dumb at Waitzen, and the royal school of mines at Schemnitz. To the school of mines at Schemnitz are attached two professors, one for metallurgy and chemistry, and the other for mathematics and other subjects connected with the mines. It is of great repute on the continent, and is generally attended by 90 students of different nations.

Notwithstanding the number of public establishments for education in this country, the state of the sciences and literature is still very low. The Latin language is in general use among the inhabitants, and indeed there are few parts of the country where it is not understood even by the lower orders. At Schemnitz, "the most prevailing tongue is the Sclavonian; next to this the Hungarian; then the German; and lastly the Latin." "Some conjecture," says Dr Clarke, "respecting the state of literature in any nation, may perhaps be formed by examining the booksellers' shops belonging to its capital; and with this view we eagerly inspected those of Presbourg, but no prospect could be more barren: there was not a single volume worth a moment's notice either upon sale in the town, or mentioned in any of their catalogues." The public library at Pesth, however, contains all the best editions of the classics, and some manuscripts, but these are of little value. The Hungarian language cannot boast of one work of merit; and even its Latin writers are very little known. The most voluminous and celebrated authors of this nation are Pray and Windisch. The researches of the former, who wrote in Latin, were confined chiefly to the history of his country; and those of Windisch, in German, to its geography.

See Gibbon's *Roman Empire*, 4to. vol. ii. p. 577, vol. iii. p. 362, and vol. v. p. 143, 548. *Anc. Un. Hist.* vol. xix. p. 204. *Mod. Un. Hist.* vol. xxxii. p. 99. Demian *Tableau Geographique et Politique des Royaumes de Hongrie*, &c. translated from the German. Clarke's *Travels*, vol. iv. p. 627—700. Pray's *Historia regum Hungariæ*, &c. Windisch's *Political, Geographical, and Historical Description of the Kingdom of Hungary*, in German; also his *Geography of Hungary*. Schwartner's *Statistics of the Kingdom of Hungary*. Sacy's *History of Hungary*. Townson's *Travels in Hungary*. Born's *Travels in Hungary*, &c. (*p*)

HUNGER. See ABSTINENCE and FASTING.

HUNS. See HUNGARY.

HUNTER, WILLIAM, M. D. celebrated as a physician and author, and as the collector of the Hunterian museum now in Glasgow, was born on the 23d of May, 1718, at Long Calderwood, his father's estate, in the parish of Kilbride. At the age of 15 he was sent to the university of Glasgow, where he passed five winters, being destined by his father for the church. This pursuit, however, did not accord with some modes of thinking which he had adopted; and an acquaintance which he formed with Dr Cullen, then a practitioner at Hamilton, inspired him with a taste for the medical profession, to which accordingly he attached himself. He resided three years with Dr Cullen as his pupil; after which it was agreed that he should study in Edinburgh and London, and afterwards return to Hamilton, to settle in partnership with Dr Cullen. In pursuance of this plan, he studied in Edinburgh in the winter of 1740 and 1741; and in the summer of 1741 he went to London, where he lived in the house of Dr Smellie; and prospects gradually opened on him, which induced him to remain in the metropolis. He brought with him a letter of recommendation to Dr Douglas from Mr Foulis of Glasgow, (the well-known printer of excellent editions of several of the classics,) who had formed a connection with that physician, by procuring for him various editions of Horace, of which the enthusiastic admiration of Dr Douglas made him anxious to possess himself of every existing edition. Dr Douglas, entertaining a favourable opinion of Mr Hunter's talents, proposed to engage him as his assistant in performing dissections for a splendid work on the bones, which he was then preparing for publication. Mr Hunter, obtaining his father's consent, accepted of this offer. His father died soon after, and in a few months he also lost his patron, Dr Douglas, who died, leaving a widow and two children. Mr Hunter continued to reside in the family, superintending the education of the children, and prosecuting his own studies. In 1743, he communicated to the Royal Society his observations on the structure of the cartilages of the joints, in which he shewed that, contrary to the ideas previously entertained, they were formed of short perpendicular fibres, like the enamel of the teeth. Meeting with applause in his anatomical pursuits, he wished to lecture on anatomy; and an opportunity was soon afforded him by Mr Sharpe, who had for some years lectured to a society of naval surgeons, and declined this task in favour of Mr Hunter. In commencing his first course, he felt great solicitude; but he soon met with applause which encouraged him. He had little difficulty to encounter, compared to one who commences such an undertaking without previous introduction to public notice. His eminent talents were in the first instance exercised in a field in which they were sure to be recognised. He therefore proceeded, not merely with confidence, but with enthusiastic zeal, in the pursuits in which he so much delighted. The profits of the first winter put him in possession of a larger sum than he had ever before possessed, 70 guineas; but as his generosity led him to supply the wants of different friends, his fund was completely exhausted before next winter, and he was even obliged to delay his lectures for a fortnight, for want of money to pay for advertising. This incident, together with the ultimate inutility of some of his generous acts to those who were the objects of them, impressed on him a lesson of prudence, which preserved him ever after from similar inconveniences, and laid in part the foundation of that fortune, which he expended in a public-spirited manner.

In 1747, he became a member of the college of surgeons; and in the spring of the following year he made a tour with the son of Dr Douglas through Holland to Paris. The beautiful anatomical preparations of Albinus, which he saw in Holland, inspired him with admiration, and an ambition to emulate their excellence. He returned to resume his lectures; and in the mean time he practised both surgery and midwifery. But he soon gave up the former of these branches, and attached himself to midwifery, in which his late preceptor Dr Douglas had been eminent. He was elected, in 1748, surgeon accoucheur to the Middlesex hospital, and the following year to the British lying-in hospital. These appointments, together with his agreeable person and address, in which he furnished a favourable contrast to Dr Smellie, who at that time enjoyed a high reputation, promoted greatly the extension of his practice, which was rendered still greater by the death of Sir Richard Manningham, and the retirement of Dr Sandys.

In 1750, he obtained the degree of M. D. from the university of Glasgow. At this time, he quitted the family of Mrs Douglas, and took a house for himself in Jermyn Street. In the summer of 1751, he paid a visit to his mother and other relations in Scotland, where he had an opportunity of exchanging congratulations with Dr Cullen, who was now, like himself, rising into eminence, and was established as a physician and professor in Glasgow.

In 1755, he was made physician to the British lying-in hospital on the resignation of Dr Layard, was admitted licentiate of the college of physicians, and soon after became a member of the medical society of London. He published, in the *Observations and Inquiries* of this body, a history of an aneurism of the aorta.

Dr Hunter turned his extensive practice to very eminent account, by adding to the pathological and medical knowledge of the age. He had the merit of first explaining the nature of the disease called *retroversio uteri*, and distinguishing it from other diseases with which it had been confounded; he explained the texture of the cellular membrane, and the pathology of anasarca and emphysema; he also threw much light on the subjects of ovarian dropsy, diseases of the heart and stomach, and hernia. For his papers on these and many other subjects, we refer to his *Medical Commentaries*.

In 1762, he was consulted during the pregnancy of the queen, and in two years after was appointed physician-extraordinary to her Majesty. In 1767, he became a fellow of the Royal Society, and enriched their Transactions with his learned observations on the bones of animals found on the banks of the river Ohio, and on the rock of Gibraltar.

He, after this, became engaged in some personal disputes with the present Dr Monro, senior, of Edinburgh, on their contending claims to priority in anatomical discoveries. This contest became keen, and was enlivened with wit and pleasantry; but probably more was lost by the irritation which it created, than was in any respect gained by either party. A man, in defending his own claims, is tempted to expose every defect which tends to shake the general credit due to his adversary, and the feelings which are most profitable and becoming for men of liberal pursuits are extinguished. Those are happiest who feel no temptation to enter on such controversies, or who, if accidentally betrayed into them, soon perceive their pernicious tendency, and in good time relinquish them. The subjects of dispute were indebted to both of these celebrated anatomists, but they both had been anticipated in some of their boasted discoveries by Haller, in others by Nouguez. The principal of them were the origin and uses of the lymphatics; the possibility of injecting the epididymis, and the excretory ducts of the lacrymal gland.

In 1768, Dr Hunter was elected a member of the Society of Arts, and was appointed anatomical professor to the Royal Academy of Arts. By now applying his anatomical knowledge to the elucidation of painting and statuary, he displayed in a new field the versatility and extent of his genius. In 1781, he was unanimously elected to succeed Dr John Fothergill as president of the London Medical Society. In the same year, the Royal Medical Society of Paris elected him one of their foreign associates; and, in 1782, he received a similar mark of honour from the Royal Academy of Sciences of Paris.

Dr Hunter's most distinguished publication was his *Anatomy of the Gravid Uterus*, which he began in 1751; but, from his great ambition to give it in the most complete state, he delayed to publish it till 1775.

In consequence of a memoir read by Mr John Hunter in 1780 to the Royal Society on the functions of the placenta, Dr Hunter was led into another keen dispute with this eminent man and near relation, in which he claimed, with considerable warmth, the share of merit which belonged to himself in the discovery. He seems to have perceived that he carried these disputes too far. They promoted an irritability of temper, which must have created to him much uneasiness; and it was remarked by those who occasionally conversed with him on professional subjects, that sometimes, when an organ or function was barely mentioned which had been the subject of a dispute, he broke out into a torrent of abuse of the knavery of his adversary. In the supplement to the first part of his *Commentaries*, he excuses his polemical appearances by representing *enthusiasm* as necessary to promote the sciences, and observing, that no man had ever been a great anatomist who had not been engaged in some violent dispute.

Dr Hunter was long employed in collecting and arranging materials for a history of morbid concretions formed in the human body. This design, however, was left imperfect, along with others contained in different manuscripts.

The magnificent museum, which we have already mentioned, is a monument which will perpetuate the name of Dr Hunter. The systematic manner in which he planned and conducted that undertaking, was characteristic of a strict philosophic prudence. He did not follow the occupation of a collector under the influence of a passion, the effects of which might afterwards interfere with his private happiness. He first laid aside a sum which he reckoned an adequate provision for himself whenever he should be obliged to retire from practice, and resolved to dedicate the remainder of his fortune to some plan of public utility. In 1765, he projected an anatomical school on a grand scale, proposing to expend 7000*l.* on the building, and to endow a professorship of anatomy. He did not, however, receive the encouragement from government which he expected; and, though afterwards the Earl of Sherburne entered so much into the scheme as to offer 1000 guineas to encourage the execution of it by means of subscription, the doctor's delicacy would not allow him to accede to this plan, and he chose to execute it at his own expense: for which purpose he purchased a house in Great Windmill Street, to which he removed in 1770, in which he had an amphitheatre and apartments for dissection, besides a magnificent room for a museum. Previously to this time he had confined his collection to human, comparative and morbid anatomy; but he now extended his views to the formation of a general museum, including fossils, antique medals, and rare books in the Greek and Latin languages. In an account of a part of this collection published by his friend Mr Combe, the expence of it was estimated at 20,000*l.* In 1761, he added to it the collection of Dr Fothergill, consisting of shells, corals, and other curious objects in natural history, which were purchased for 1200*l.*

About the year 1773 he had experienced so much injury to his health from gout, that he thought of giving up practice, and returning to Scotland; but prudential considerations, and his attachment to his favourite pursuits, determined him to remain in London. The returns of his disease became more frequent; and at last, on Saturday, the 15th of March, 1783, after having experienced a return of wandering gout, he complained of great head ach and nausea, and was confined for a few days to bed. He then thought himself so well, that he gave his introductory lecture to an intended course of surgery; but, towards the conclusion of the lecture, he fainted away, and was carried to bed. This happened on a Thursday. On the Saturday morning he told his friends, that he had a paralytic stroke in the night, though no symptom of it then appeared about him. He suffered little or no pain; and at one time, turning to his friend Mr Combe, he said, "If I had strength enough to hold a pen, I would write how easy and pleasant a thing it is to die." His death happened in ten days after his last lecture, viz. on the 30th of March, 1783. His figure was small and slender, but symmetrical and becoming. He was an agreeable, lively companion. The chief blemish in his character was an irritability on some subjects, which gave his manner an air of imperiousness. He will long be held in high estimation as a man, who, when the limited extent of his means is considered, contributed in a singular degree to the promotion of science. His nephew, the present celebrated Dr Baillie, was left the use of his museum for life, to be succeeded by Mr Cruickshanks, Dr Hunter's assistant, who was to enjoy it for thirty years, and then it was to become the perpetual property of the university of Glasgow. The right of reversion of Mr Cruickshanks was extinguished by the death of this gentleman; after which Dr Baillie generously gave up his claim, and the museum was removed to Glasgow, where magnificent apartments have been built for it, and the annual interest of 8000*l.* left by Dr Hunter, is appropriated to the preservation and augmentation of it. It has already been enriched with many additional articles; and, on the whole, adds a new lustre to that seminary, and tends to promote the resort to it which it has so long and so deservedly attracted. (*H. D.*)

HUNTER, John, an eminent surgeon and author, and brother to the subject of the preceding article, was born at Long Calderwood on the 14th of July, 1728. He was about ten years old when he lost his father; and, being the youngest child, was so much indulged by his mother, that, though sent to the grammar school in Glasgow, he made no proficiency in his studies, and, at last leaving them, lived for some time idle in the country. Tiring of this mode of life, he wrote to his brother Dr Hunter in London, proposing to become his assistant in his dissections; or, if that would not suit him, to go into the army. The doctor gave him a kind invitation to London, and he went up to him in September, 1748. The doctor found, on a very short trial, that he promised to become an expert dissector; and, entertaining great hopes of him, gave him every encouragement to persevere in professional pursuits. The following summer he attended Chelsea hospital, where he learned the first rudiments of practical surgery. By the succeeding winter he had made such proficiency, that his brother left in a great measure to him the superintendence of his public dissecting room. In the following summer he renewed his attendance at Chelsea hospital, and the summer after that he attended at St Bartholomew's. In 1753, he entered as a gentleman commoner at St Mary's Hall, Oxford. In 1756, he was appointed house surgeon to St George's hospital, where he had attended as a pupil the two preceding summers. In 1755, he was admitted to a partnership in his brother's lectures. His uncommon dexterity in making anatomical preparations, and some distinguished discoveries which he made in anatomical science, gradually raised him to great celebrity. He traced the ramifications of the olfactory nerves on the Schneiderian membrane; he demonstrated the mode of termination of the arteries of the uterus in the placenta; and he was the first who discovered the lymphatic vessels of birds. By directing his labours extensively to comparative anatomy, he laid the foundation of his splendid anatomical museum. These labours were not conducted with the design of exhibiting preparations of the entire bodies of different animals, but for the more useful purpose of illustrating, in a regular series, the varieties of organization subservient to each function in the different classes of animals. He applied to the keeper of the Tower, and other persons who kept wild beasts, to procure the bodies of those that died; and he had generally in his possession living animals of different species, for the purpose of observing their manners and instincts. Two anecdotes are related by his brother-in-law Sir Everard Home, that are very characteristic of his enthusiasm in this amusement. Two leopards which he kept broke loose on one occasion from their den, and the howling of his dogs in the same yard, alarmed the whole neighbourhood. Mr Hunter ran into the yard, and found one leopard scrambling over the wall, while the other was surrounded by the dogs. He without reflection seized both the leopards, and led them back into their den; but immediately after, when he thought of the risk which he had run, as an unlucky irritation on their part might have terminated in his immediate destruction, he was so much agitated that he almost fainted away. On another occasion, while he was struggling with a young bull, a species of amusement in which he had delighted, the animal got him down on the ground, and would have proceeded to the utmost extremities, if a person luckily coming to the spot had not rescued him.

In 1767, he was made fellow of the Royal Society, and formed a party of friends, who met at a coffee-house to discuss points of science after the meetings of the Society, which he soon found to increase, and to consist of some of the most eminent men of the age. It contained Sir Joseph Banks, Dr Solander, Sir Charles Blagden, Sir Harry Englefield, Mr Watt of Birmingham, and several others. An accident which he suffered, the rupture of the tendo achillis of one leg, in dancing, led him to study particularly the surgical pathology of that part, which he illustrated by experiments on animals. In 1768, Mr Hunter went to the house which had been occupied by his brother in Jermyn-street, as the latter moved to his house in Windmill-street, which he had just completed, and adapted on an extensive scale to his learned pursuits. Mr Hunter was thus placed in a favourable situation for private practice, and he now became a member of the College of Surgeons. In May, 1771, he published his celebrated work on the natural history of the teeth. In the following July he married Miss Home, of whom the present Sir Everard Home was a younger brother. The latter was then at Westminster school, and was brought up by Mr Hunter to the profession of surgery. It is to this gentleman that we are indebted for the interesting life of Mr Hunter, prefixed to a posthumous edition of his book on Inflammation. Mr Hunter's progress in acquiring practice was at first slow, as he was not possessed of those winning manners, and did not study those superficial arts, by which many rise in this respect to distinction. But the weight of his character for genius and professional industry at last brought him into the highest repute. His income was greatly augmented; but it was chiefly expended on his museum, to which he also regularly devoted his mornings, from sun-rise to the hour of breakfast. He continually laboured to turn his physiological discoveries and observations to account, in improving the art of surgery. To enumerate his improvements would far exceed our limits, and they are only to be learned by perusing his valuable works. He always delighted in making acute discoveries, and striking out new views. It is in explaining the phenomena of inflammation in its various forms, and the principles on which the healing process under various circumstances is conducted, that Mr Hunter's genius is most usefully displayed. Some of his opinions cannot be easily admitted as well-founded; such as his doctrine of the life of the blood, and of the identity of syphilis and gonorrhœa. In the winter of 1773, he began to give lectures on surgery, in which he delivered a full account of his practical improvements, as well as his pathological views. His first two courses were given gratis. He continued to improve comparative anatomy by the dissection of various animals, some of which were rare and curious, such as the torpedo and the gymnotus electricus, the electrical organs of which he described. He repeatedly dissected the elephant; he discovered those receptacles in the bodies of birds, to which the air passes through the lungs, which threw a new light on the function of respiration, as performed by that class of animals. He engaged an artist to live with him, for the purpose of making drawings of such parts as did not admit of being preserved. In 1776, he was appointed surgeon extraordinary to his Majesty. In the autumn of that year, however, he was taken dangerously ill, and began to reflect seriously on his situation and that of his family. As he had expended his fortune in his museum, he was desirous of making it appear to advantage, that it might bring its value after his death. Accordingly, as soon as his health permitted, he arranged it, and made out a systematic catalogue of its contents. He afterwards regained sufficient health to prosecute his physiological and surgical investigations; and numerous ingenious papers, written by him after this period, appeared in the Transactions of the Royal Society. In 1783, he had the honour of being admitted into the Royal Society of Medicine, and the Royal Academy of Surgery, of Paris. The lease of his house in Jermyn-street having at this time expired, he purchased one of a large house in Leicester Square, on which he was tempted to expend above 3000*l.* which sum was in a great measure lost to his family by the shortness of the lease. Here he had ample accommodation for his museum. The eclat which this great object gave to him, however, was very great; and the services of his friends and the public were always readily furnished, when they could contribute to adorn it with new articles in comparative anatomy. In 1786, he published his work *On the Venereal*, and his *Observations on certain parts of the Animal Economy*, consisting of a collection of papers which had appeared in the Philosophical Transactions. About this time his health began to decline, and he was obliged to resign much of his laborious duty to his brother-in-law Mr Home; but we find him still active in adding to the stock of professional information. He wrote some physiological papers, for which he obtained the Coplcian medal. In 1792, he gave up his course of lectures entirely to Mr Home. But he continued to receive splendid marks of public respect; he was appointed inspector-general of hospitals, and surgeon-general to the army; he was made a member of the College of Surgeons of Dublin, and one of the vice-presidents of the Veterinary College, then first established in London. He continued to write various papers, which appeared in the Transactions of the Society for promoting medical and chirurgical knowledge.

His health during the last twenty years of his life was greatly impaired. The symptoms of his disease, which was *angina pectoris*, are minutely described by Sir Everard Home in the account of his life. The first attack was brought on by mental irritation, and, though he was liable afterwards to slight affections from causes of different kinds, every severe attack arose from some mental cause. Unfortunately his mind was easily provoked by trifles, while matters of real importance produced no effect. He died suddenly under an accidental irritation at St George's hospital, while he laudably attempted to controul it till he obtained information of the circumstances by which it was occasioned. This event took place on the 16th of October, 1793, in the 65th year of his age.

He was a man of uncommon originality of thought, which he displayed under considerable deficiencies of general erudition. In this respect he was a contrast to his brother, who united genius with erudition in an eminent degree. This circumstance seems, however, to have had the effect of concentrating his attention more completely in his favourite objects of pursuit, and to have given a character of more obvious originality to all his writings. Though ambitious of a high name in his own line of investigation, he was not envious of the well merited honours of others. But he was liable to strong indignation at the presumption of ignorant mediocrity or indolence. He was prone to undervalue too much those professional men, who were his inferiors in merit, and who, while they paid no homage to his doctrines, made feeble attempts to shine by their own light. He was frank in his manners and conversation, a decided enemy to all deceit and intrigue, but on the whole too apt to speak harshly of his cotemporaries.

The museum which he left was purchased by the British government, was by them committed to the charge of the college of surgeons, and is now contained in a splendid hall fitted up for the purpose, where a professorship of comparative anatomy is attached to it; and it is open to the inspection of the public on certain days of the week for the greater part of the year. This museum affords a brilliant proof of the comprehensive views and persevering assiduity of the collector. It presents a very extensive collection of anatomical facts, arranged in such a manner as to illustrate, in a beautiful series, the various functions, as performed in the gradations of organized nature, from vegetables to animals, and from the lowest tribes of animals to the beautiful complication exhibited in the fabric of the human body. It is divided into four parts, corresponding to a fourfold division of the functions. 1. The parts adapted to motion; 2. The parts essential to the internal economy of the different tribes; 3. The parts which connect living beings with surrounding objects; and 4. The parts subservient to the propagation of the species. We understand that the arrangement has undergone some modifications since the appointment of Mr Lawrence, the present professor of comparative anatomy. In this museum, the eye surveys, as in one vast landscape, all that is interesting in the sublime science of physiology. It furnishes even to the most ignorant a pleasing and rapid view of the subject, which could not be obtained from books without much study. To those who are already well informed, a visit to this museum affords an opportunity of giving form and body to their knowledge, and adds a permanence to their impressions which they could not have otherwise obtained. It is indeed now imitated on a smaller scale, by the laudable industry of many other professional men; but it is still an object of the highest interest, both for its own merits, and when considered as one of the earliest of those vast efforts which have been made, to give an intellectual celebrity to the whole seminaries of our native country. (*H. D.*)

HUNTING, or the pursuit of wild animals, in its most comprehensive signification, includes those of every denomination, and all the different means by which their capture is accomplished; but, in its more restricted sense, it chiefly denotes the pursuit of terrestrial and amphibious quadrupeds.

Mankind, in establishing themselves in uncultivated regions, find it alike essential to destroy those creatures, whose ferocity may endanger their life, or to seek subsistence from the flesh, and clothing from the skin of others, from which no danger is to be dreaded. Originally a measure of necessity, hunting becomes an enterprise, wherein all the strength and activity of the human frame is called forth; or it is converted into an amusement, in which equal skill and ingenuity must be exercised, to combat the power and instinct of animals. Savage nations, during their repose from war, are principally occupied in the chace; and there are some, to whose country nature has been so sparing of vegetation, that, without the resources obtained by hunting, a famine would infallibly ensue. Hunting has enabled us to bring the most useful animals into a state of domestication. While employed to subdue the horse, the ox, and the elephant, in their native climates, it is elsewhere followed to procure those precious furs, which pay the tribute of entire countries, and are so highly valued, as to be the emblem of royalty itself. Hence have resulted various expedients and stratagems to ensure the capture of wild animals. But it is to his faithful ally, the dog, that man is chiefly indebted for their possession. This invaluable creature is trained, not only to rouse the game in the forests, to pursue it on the plain, and after a successful chace, instead of devouring its prey, to watch until the approach of its master, or to lay it uninjured at his feet. What substitute could the huntsman find for his dog? Deprived of its aid, those excursions, which enable him to return laden with spoils, would terminate in fatigue and disappointment.

Hunting is prosecuted after a great variety of fashions, according to the nature of the country and the description of the game. 1. Wild animals are hunted by means of others specially trained for that purpose. 2. They are caught by various stratagems; as by nets and pitfalls, or in traps formed either for the purpose of destroying them, or of taking them alive. 3. They are shot by fire-arms or arrows, or destroyed by the same weapons set in their paths. 4. They are taken by intoxicating substances, which they are induced to swallow, or killed by poisons. These are the principal methods employed throughout the world in destroying wild animals.

Man is engaged in incessant warfare against the rest of the animated creation: the numbers sacrificed by him exceed all credibility; for scarcely has he come into the world, and gained the use of his members, when he begins to think of destruction. But animals have opponents equalyl formidable among each other, and frigthful havoc is committed among the weaker by the stronger and more carnivorous tribes. Endowed with natural antipathies, they hunt each other down for the purpose of extirpation, not for the sake of prey. The ancients have told us of an invincible antipathy entertained by the ichneumon against the crocodile; and although this singular property has not been witnessed by the moderns, it indubitably exists in respect to snakes. The rhinoceros, a herbivorous animal, is said constantly to seek the elephant, when the most furious combats ensue between them; and it is affirmed to delight in the destruction of all other animals. Dogs incessantly endeavour to destroy cats, on which they are not known to feed; and horned cattle will frequently make an attack, and gore the object to death, from rage and antipathy combined. But it is less for the indulgence of such antipathies, than to satisfy the cravings of nature, that animals hunt each other in their wild state, and have thus taught men to avail themselves of their properties. Yet, as they carefully shun our presence on those ocassions, we are acquainted only with some of the methods which they pursue. Animals of the canine species seem to hunt in troops; those of the feline race are in general solitary. The nature of the wild-dog, which we can so materially improve by education, is little known; but it appears to hunt in packs of eight, ten, or twelve, in India and Persia; and in this way it does not dread to attack the most ferocious of beasts of prey, the tiger. In Africa, it has been observed, that wild-dogs hunt with much sagacity, always acting in concert, while each in particular does its best to overtake or meet the game, until at length it becomes their joint victim. Not content, however, with merely satisfying their hunger, they are said to wound and destroy every thing that comes in their way, and prove the greatest enemies of the herds which are kept among the colonists or natives of Southern Africa. The wolf, the fox, and jackal, all hunt in troops, though each may be seen alone in quest of prey. But many animals are by nature solitary in their pursuits, and seem jealous of the presence of each other. The lion never hunts in company, and is said to chace its prey at full speed by the eye, from its sense of smelling being obtuse. It makes a spring when within reach of the object; but, if foiled by distance, skulks away, as if ashamed of the disappointment. The tiger, a cruel and terrible destroyer, is generally single in its immediate attack; and instead of trusting to speed, like the lion, it lies in wait in some thicket, whence, with an astonishing leap, it pounces on its victim in an instant. Immediate death follows a blow from its tremendous paw, and the prey is then dragged off to be devoured at leisure. Nothing can restrain the ferocity of the tiger; not even fire, the dread of all wild animals. It is the terror of the forest; it attacks man as readily as beasts, and even pursues boats while navigating rivers. As the fatal blow is always inflicted by the paw of this animal, in like manner others evince the same uniformity in the mode of hunting and killing their prey. The wolf bites it in the throat; the jackal invariably seizes a cow by the udder; and the crocodile, fixing its teeth in the nostrils, draws its prey into the water to be drowned.

Man, in every country, has availed himself of the instincts evinced by certain animals in hunting their prey, to aid him in the chace. Dogs of many different kinds are trained to it, and in every possible fashion; either running down the game by speed, conquering it by absolute strength, or dislodging it from its haunts, or merely pointing out its position. In the East, a species of panther, there named *cheeta*, but more commonly the hunting tiger, is taught to pursue the antelope; but if caught young, and brought up among mankind, so much of its activity and fierceness are lost, that it proves unserviceable. Therefore the cheeta is always taken old in pits, and soon becomes familiar with its keeper. The cheeta is carried hoodwinked on a cart to the vicinity of the game; and being then unhooded, steals from bush to bush, until approaching within 70 yards of it. Rushing forwards with surprising swiftness, by a dexterous use of its paw it throws the animal down, and seizes it firmly by the throat, until it feels that respiration has ceased. Sometimes the cheeta cannot be induced to run; but, if it is forward to the chace, it seldom continues longer than for 300 or 400 yards, within which space the antelope is either caught, or escapes. If disappointed in its original spring, should it get near enough, or be foiled in the course, it lies down, testifying much disappointment; and in its resentment will sometimes, though rarely, turn on its keeper. On the day of hunting, the cheeta is kept without food, at other times it is allowed 4lb. of flesh daily. The lion is said to be taught by the Africans to hunt for them, as is also reported to have been practised by the ancient Romans. In this country, we teach the ferret to hunt after rabbits; and, considering that many animals are susceptible of this education, it is not unlikely that more would be trained to hunt, were not their use superceded by the universal employment of the dog. There is hardly a situation in which the dog is not serviceable. There is scarcely an animal which it will not venture to attack, when encouraged by the voice and presence of its master; and it equally promotes the capture of the terrestrial and the feathered tribes.

The most general mode of pursuing game is by a small and select company of huntsmen, and then, perhaps, the greatest success attends their exertions; but in some countries vast multitudes assemble, surrounding a great extent of territory, and driving numbers of wild animals into a narrow space, where their destruction is accomplished at will. Some of the sovereigns of China have carried an army of people into Tartary, and occupied themselves several months uninterruptedly in the chace, while the monarch himself, unable to use fire arms, dexterously shot the animals with arrows. The modern princes of Hindostan were wont to advance with 400 or 500 elephants, besides horses, and all the necessary equipment of several hundred dogs, nets, and weapons, to the country where the game was sought. Even in Scotland, we read of hunting matches conducted on a great scale, where 12,000 men were present, and when "thirty score of wild beasts" were killed. But the real hunting for profit and utility, in which many thousands engage for subsistence, is conducted by small parties, or by individuals only. It appears that in Britain it was very common for ladies anciently to participate in the pleasures of the chace.

The lion is a large and powerful animal, less ferocious, and not equally dreaded as the tiger, perhaps from an imaginary attribute of generosity, and from the belief that it never wantonly kills its prey. Nevertheless, the lion is also a terrible enemy, and its roar inspires all other animals with fear. Shaw, the eastern traveller, affirms, that the wild boar is principally its prey; but sometimes after so courageous a defence, that victory has inclined to neither, or both have been found lying dead together, and torn in pieces. We have said that the lion never hunts in company, and on this head M. Golberry relates, that a lion and a lioness having discovered a wild boar on the skirts of a forest, the latter sprung forward to the attack. Having furiously seized the boar by the throat, she lashed its sides with her tail, while the lion sat a silent spectator of the combat, which lasted five minutes, seemingly indifferent to the struggles of both. At length the boar, yielding to the force of its opponent, fell with horrible cries; and only when dead, the lion leisurely advanced to participate in the repast of his mate. It is supposed that the lion will not attack women, but the number of victims evince the fallacy of this hypothesis. However, it is confidently affirmed, that no person is in danger who has courage to look the lion stedfastly in the face. An African colonist of the Cape of Good Hope having unexpectedly met a lion, levelled his gun, but the ball fell short, as the piece hung fire; and, apprehensive of the consequences, he immediately fled. The lion closely pursued him, when the colonist, leaping on a small heap of stones, resolved to defend his life with the butt end of his gun, being precluded from loading it again, as he had unfortunately dropped his powder flask in his flight. At this moment the lion made a sudden stand also; and then lay down, at the distance of a few paces, quite unconcerned. Meantime the colonist durst not move; but the lion, after remaining before him completely half an hour, slowly retired. The fleetness of this animal enables him to keep up with a horse galloping, and its strength is such that it can drag away a heifer with perfect facility. In general, it is said to lie in ambush, whence it springs upon its prey; but should the object be missed, no second attempt is made; the lion returns silently to the spot, to practise more address on the next occasion. Probably animals are more usually preferred, but there are instances of a single lion attacking a whole caravan. The lion is hunted by horsemen on the plains, and large dogs, but not of any particular species, are used to dislodge him from his haunts. At the first sight of the huntsmen, he always endeavours to escape by speed; but if they and the dogs get near, he either shakes his head with a terrible roar and slackens his pace, or quietly sits down to wait their attack. The dogs immediately rush on; and he has time only to destroy two or three, each with a blow of his paw, until they tear him in pieces. Twelve or sixteen are, in this manner, a sufficient match. Huntsmen going on the enterprize keep together in pairs. If they they have not the requisite number of dogs, one, when within reach of the lion, leaps off his horse, and aims at the animal's heart; but he must instantly remount, in order to fly from its rage if wounded. Should he miss, the same is done by his companion, who must also give full reins to his horse; and then the third of the party follows. This mode of hunting is represented as quite free from danger, there being no example of its being attended with fatal consequences. In the northern parts of Africa, where lions are not so numerous, the whole surrounding district is raised when one is discovered to infest it. A circle of three, four, or five miles in compass is formed, according as circumstances require, and dogs of large size are employed to rouse the game. Horses are here trained for the purpose, and the party proceeds, always narrowing the circle until the lion appears. But this is a moment of danger, as he will readily spring on the person nearest to him. The expert huntsman, however, is generally prepared to terminate his career by a musket-ball. The lion is likewise killed by spring guns set in the path by which it returns to commit its ravages; or the Moors and Arabs dig a pit, which, being slightly covered with reeds and branches, the animal falls in, and is taken.

One of the noblest sports of the East is the hunting of the tiger; and indeed, considering the size, the strength, and the ferocity of the game, no inconsiderable gratification must arise from the conquest. The tiger is sometimes so large as to measure 13 feet from the nose to the tip of the tail. It is active, bold, and cunning; it is one of the most destructive beasts of prey: flocks and herds are its usual pursuit, but it is the mortal enemy of man; and, having once tasted his blood, it is said to reject ever after the blood of other animals. The immense and extensive thickets of Asiatic countries are so many retreats where it can lurk in concealment, and spring forth upon its victim, which it does with a horrible growl; or if the prey is in motion, where this cannot be accomplished, the tiger creeps along parallel to it and unperceived, until it gains the favourable position for its spring. A deadly blow from the paw precedes the seizure of its victim, and the prey is then dragged away. An instance occurred of a Sepoy on a march acquainting his comrades that he observed a tiger, "which had set him," as it is called, stealing along through a jungle. Divesting himself of all incumbrances, he drew a broad sword, and intrepidly watching the moment of the spring, with dexterity, as singular as his courage, immediately disabled his assailant. Sometimes a tiger takes possession of a pass, whence it has, for a length of time, carried off a man daily. This animal is hunted in various fashions, but chiefly by a numerous party of sportsmen, and elephants trained for the chace: those males having long tusks are preferred, but few females are fit to be employed in it. Indeed the elephant and the dog are the only auxiliaries of man on this occasion. Horses become fractious and ungovernable; camels offer an insecure position to their riders, independent of their natural dread of the game; and even the elephant can with difficulty be urged onward with due preparation. When the retreat of a tiger is discovered, which is generally in a jungle near the carcase of a mangled animal, a line of elephants is formed, and every exertion made for its dislodgment. The jungle, however, may contain more than one; and as the tiger becomes lethargic when satiated, and does not remove far from the spot of its depredations, the jungle is entered with much precaution. Here the search is made with the largest and best trained elephants; and it is they that first disclose the presence of the tiger by a peculiar kind of snorting and trumpeting, and likewise an uncommon agitation. The tiger is prone to spring on an approaching object; but if skulking off, the whole covert becomes impregnated with its smell, and the elephants, uncertain of its distance, and always dreading an attack, frequently become perfectly ungovernable, nor can some be restrained from flight. A certain emanation from the body of the lion and the tiger, even when unseen, has a powerful effect on other animals: and men themselves have experienced a kind of shuddering sensation solely from that cause. The huntsmen who, mounted on their elephants, are not above ten yards asunder, immediately on discovering the tiger, fire from a piece of large calibre; but should the shot not prove instantly fatal, the tiger springs up with a furious roar, and endeavours to attack its enemy. Particular danger may thence ensue, and both skill and dexterity are required in the hunter expeditiously repeating his discharge for his own preservation. The elephant may then be brought forward to crush the fallen animal, and gore it with its tusks; which, although quite dead, it often testifies a repugnance to do. Horses shew the most decided antipathy, and dogs take a tour around the carcase. Sometimes the tiger will spring upon the elephant, and put the hunter in the most perilous situation. Notwithstanding its intimate resemblance to the cat in every thing, the tiger takes the water without hesitation, and it has been known to force its way into a boat in spite of all opposition. It does not appear that hunting this ferocious creature solely with dogs is ever attempted: indeed it could not be accomplished without great loss to the huntsman. It is taken in nets, however; but the sport is dangerous, for the game is apt to recoil on its pursuers; and besides, the nets are not always of sufficient strength, nor is the tiger so perfectly enveloped and secured, as to be deprived of the power of doing mischief. Tigers are caught, but very rarely, in traps and pits, the former constructed like a large cage, and baited with a live dog or goat, which is confined in an interior division. They are likewise shot by a single sportsman, who, having discovered a carcase half devoured, promptly constructs a platform of bamboos, 15 or 20 feet high, and there awaits the depredator's return. The natives of the hills of Bengal set poisoned arrows in their path to be discharged from a bow of extraordinary strength, sometimes so great, that the weapon penetrates to the heart. It is difficult, however, to give it the proper direction from the step of the tiger, which effects the discharge. Even though the arrow does not touch a vital part, the poison speedily begins to operate, and never fails to destroy the animal within an hour. The same apparatus is used with an arrow free of poison. By means of the vigorous warfare carried on against tigers, many places of India, formerly almost uninhabitable, are completely cleared of them. In other parts they are still common, and the appearance of one inspires the whole neighbourhood with alarm.

The panther, leopard, ounce, and lynx, all of the feline tribes, are closely allied in habits and disposition to the lion and tiger. But none readily attack man. Their depredations, nevertheless, are not confined to smaller animals, as some of them are endowed with considerable strength. The leopard is particularly expert in climbing trees, whence it drops or springs on its prey. It greedily devours dogs ; but seldom prowling about by day, it chiefly commits nocturnal ravages. All animals of prey, of every tribe, are for the most part occupied in seeking their sustenance at dawn and twilight. Leopards are roused by by dogs, and shot with fire-arms or arrows. The natives of the East also capture them in deep pits, which are baited with the carcases of beasts.

Animals of the canine species are endowed by nature with the most remarkable sagacity. Almost all, with suitable treatment, may be rendered tractable, while those of the feline tribes seem absolutely indocile and void of attachment. The hyæna is one of the fiercest of the canine kind ; its strength enables it to resist the lion, and encourages it to attack the panther. It overpowers the bear, and readily assails mankind. Acting as a decoy, it is said to imitate the cries of other animals, or, by a frightful howl, to scare a whole herd, that it may then seize some one of the stragglers. It is a solitary animal, inhabiting the clefts of rocks and caverns in mountains, whence it issues forth on its prey at night. Hyænas are hunted by dogs, and traps are set for them, but few are taken. One of the most remarkable methods of capturing these animals is practised by the gypsies of Aleppo ; who, according to M. Olivier, enter with torches in the day-time into the grottos known as the haunt of hyænas, and, on perceiving one, make a great outcry, or boldly approach, speaking aloud, in order to intimidate the animal. The hyæna, which is terrible by night, does no injury by day ; and the effect of the light and clamour are such, that it retires farther and farther to the extremity of the cavern, where no sooner do the gypsies reach it, than it is bound, muzzled, and led out. When taken after other methods by the Arabs, they carefully bury the head, lest the brain should be employed against them in sorcery and enchantment.

Hunting the wolf, an animal the type of destruction, and the enemy of the shepherd, has been every where and in every age an ardent pursuit. But its sagacity is so great, that while others run headlong into danger, it carefully avoids the snare. When roused by hunger, the ferocity of the wolf is great. It attacks man, and runs down creatures far larger than itself. It boldly leaps inclosures, and steals into cottages to carry away children, which are always seized by the throat. A wolf suddenly appeared in a district of France, which it ravaged a whole year about 1765, proving so crafty, that an association of 63 parishes provided a band of 40,000 men for its destruction. At length 40 huntsmen and their dogs accomplished its destruction. Hunting the wolf was anxiously enjoined by the laws of this country, particularly in Scotland, formerly a wild and mountainous country, whence it could not be easily extirpated. King Edgar is said to have effected the utter destruction of wolves in England, by commuting the tribute of money into an annual tribute of the heads or skins of these animals. They still subsisted in Ireland in the reign of Elizabeth, and were not extirpated from Scotland until the year 1670. The means which have been devised of destroying this redoubtable enemy are not few ; but owing to the habits and sagacity of the animal, they are of very uncertain success. Its haunts are exceedingly diversified : It sometimes seeks the recesses of the woods, sometimes the bottom of the cavern ; it hunts by day and also by night, first assuming one path for its exit, and then another for its return. In certain seasons of the year it has no fixed abode. In Tartary, and other parts of the East, the wolf is hunted by eagles trained specially for the purpose. In Europe, the strongest greyhounds and other dogs are employed, and the chace is prosecuted either on foot or on horseback. Much difficulty, however, is experienced in running down the wolf; nay, it frequently proves impracticable, for the full grown animal is infinitely stronger than any dog. An old wolf is able to run 20 miles easily, which, added to the nature of the ground to which it resorts, often renders the pursuit abortive. The wolf, besides, has recourse to many stratagems for deceiving both the dogs and the huntsman. When one is known to infest a district, the first attempt is to dislodge it from the covert, and to bring it to an open chace. But hunting the whelps is more interesting sport, because they have fewer means of defence, nor are they so capable of foiling the hunter as the old and experienced animals. Independent of the constant use of fire arms, it becomes necessary to recur to various stratagems, as nets, traps, and pitfalls. If an animal of large size, as a horse or an ox, is discovered to have become the prey of a wolf, to which it will return for the purpose of satisfying its appetite, the huntsman drags the carcase above a mile from the spot, always proceeding against the wind. Then leaving it in a place exposed to view, as the wolf will follow, he takes his station in concealment by moonlight, in a spot whence he may pierce the animal with a ball. It is said that the wolf never passes through by a door where it can leap a wall ; whence the position of traps is regulated, so as to deceive its watchfulness. Sometimes the traps are constructed with springs and iron teeth ; sometimes with a wicket, which yields to gentle pressure, but refuses an exit to the captive. Some years ago, during a terrible famine in India, where the miserable sufferers were devoured half alive by wolves, these creatures, emboldened by the want of resistance, continued their ravages after its cessation. They openly attached men and women, and children at the breast seemed to be their favourite prey. An ingenious and simple apparatus was devised for their destruction. Two bamboos eight or nine feet high, were erected at the opposite sides of an old well, and their tops being brought together, a basket, containing a kid, was suspended from the junction. A pot of water with a hole in the bottom, loosely stopped by a rag, was hung over the animal, which was kept bleating and in constant agitation by the dripping upon it. Brushwood and thorns disguised the edge of the well, and the wolves in stretching over or leaping up to reach the bait, readily tumbled in. On another occasion, they were successfully smoked out of burrows in the earth, which they had chose for a retreat, or were killed in attempting to escape suffocation. In digging up the burrows, an incredible quantity of trinkets, not less than ten pounds weight, was found belonging to children they had carried away and devoured. The affliction of the unfortunate parents at recognising the different ornaments that had decorated their offspring, presented a most impressive scene. At present packs of wolves are said to infest a district of France, where the inability of the inhabitants to resist them has led to extraordinary instances of their attacks in open day, and on every opportunity.

Similar address, though demonstrated in a less conspicuous manner, is displayed by the jackal and the fox, both of the canine species. The former is hunted by greyhounds, which it will so harass by its extreme cunning in incessantly crossing the haunts of its fellows, that it can seldom be taken in this manner. Likewise the dogs, while in full pursuit, are sometimes attacked with great fury by another troop of jackals attempting to rescue the fugitive, and beaten off with severe injuries. The jackal itself hunts in packs of 30 or 40 together.

As fox-hunting is so common a sport in Great Britain, and of so much consequence to other nations which traffic in the fur of animals, we shall lay before our readers a pretty full account of it. Though the total number of foxes in this island may not exceed a few hundreds, yet in the north of Europe and America, and in the north-eastern parts of Asia, they are more numerous. There they are frequently to be found in vast multitudes, and of various species, called the black, blue, grey, and arctic fox, some of them changing their colour according to the season of the year. Two islands, St George and St Paul, were discovered in 1786 in the Northern Pacific Ocean; the first does not exceed 30 miles in length, nor the second 19; yet, in the course of only two years, 8000 blue foxes were taken upon them. But to enable the huntsman to conduct the chace successfully, he must always render himself intimately acquainted with the nature of the game: it is by this means that he can ascertain its haunts, defeat its stratagems, and avail himself of those particular circumstances which will lead to its capture. The instincts and propensities of the fox are exhibited in the most decided manner; though they receive strong modifications from the circumstances under which the animal is placed. In populous and civilized countries, it is shy and watchful: in those seldom trodden by the foot of man, it exhibits no apprehensions at his presence, and may easily be led to destruction. In one country it will devour nothing except what has been killed by itself; in another, where scarcity usually prevails, every kind of animal food is acceptable. It is highly carnivorous in many places; yet in some it fattens on grapes, and is noxious to vineyards. The craftiness of the fox is proverbial. Without the strength of the wolf, it possesses equal sagacity, which is similarly exercised in destroying creatures weaker and more timid than itself. In addition to the smaller quadrupeds, its ravages are considerable among birds which nestle on the ground, and also among poultry of the domesticated kinds. The day is the period of repose; while the dawn and twilight are industriously employed in quest of prey. The fox is a bold and a cunning animal, adventurously approaching the object it has singled out, and waiting a favourable opportunity of accomplishing its ends; but, not content with satisfying the cravings of hunger, it often destroys many more victims than it can devour; which are either left behind, or carried away and stuffed into a hole, or buried in the ground, to provide for future necessity. It is said to feign sleep, in order to betray its prey into security; and a tame fox has been known to spurt its food around it, for the purpose of attracting poultry within the length of its chain. Foxes burrow in the earth, or inhabit the clefts and cavities of rocks, and also dwell in thick coverts, or among furze. As swallows testify their antipathy to the hawk, the common enemy of their tribe, so does the clamour of crows and magpies disclose the retreat of the fox, when unseen by his enemies; and during pursuit the latter will scream from tree to tree, according to the course which the animal takes. By the northern nations, where the preservation of the fur is an object, the fox is captured in traps, by bows set in its path, discharging arrows against it, and it is also destroyed by poisons. Sometimes a net is used. The natives observe, as a remarkable circumstance, that the more valuable foxes are the most cunning: and Krascheninikow mentions, that the Cossacks of Kamtschatka tried unsuccessfully during two years to catch a black fox frequenting the Great River. But it is likely that this arises from such animals becoming more sagacious in endeavouring to avoid danger, than those which have none to apprehend. In Britain and some other countries, foxes are hunted almost exclusively by packs of hounds trained to the sport; and the chief source of entertainment arises from the nature of the animal itself. A rank odour, peculiar to its species, of which it can never be divested, constantly escapes from its body, and is distinguishable by the hounds from that which emanates from other animals, whereby they are enabled to follow the same course without once obtaining a view of the game. The manner in which this effluvia is conveyed, is a point of exceedingly difficult explanation; but, like all odorous emanations, it is of very unequal intensity at different times. Our ancestors were certainly acquainted with the properties of hounds, as "sharp-scented dogs fit for hunting wild beasts," are mentioned at a very early period of English history; and the aborigines of every nation are addicted to the chace. But we are unacquainted with the particular species which were employed. Much attention is requisite both for the breeding and training of hounds; and no where has the art been more studied than in Great Britain. When the dogs are bred and trained, then the selection is to be made. Hounds are prized for colour, figure, voice, and especially for staunchness, without which the rest of their qualities are of little avail. In respect to the first, there can be no absolute rule; and the huntsman who has had a few excellent hounds of a certain colour, will be prejudiced in its favour; but we must admit, that the properties depending on colour are very uncertain, particularly when we reflect that a total change takes place in several animals according to the alternation of the seasons, and that it is again restored without having occasioned any extraordinary effects. Naturalists have not yet determined the inseparable concomitants of colour. Hounds of a uniform colour seem to rank highest in the estimation of sportsmen; next, those spotted with red, and white hounds with black ears and a black spot at the root of the tail. Those spotted with dun are conceived to be defective in courage, and therefore bear an inferior value. Properties which would require the most undoubted confirmation by repeated trials, are ascribed to some external characters. Thus it is said, that the black tanned, the uniform white, the true Talbots, are the best for string or line; that the grizzled, if the hair is shaggy, are the best runners, and that a couple of these should always belong to a pack. Those uniformly dun are thought fit for all kinds of the chace; their sagacity is great; they are more sensible of their master's voice or his horn, and less liable to be influenced by the unsteadiness of other hounds. The figure of the hound is probably more essential than his colour, being more decisive of pure descent. A small head, very pendulous ears, a thin neck, broad back, deep chest, straight legs, and round feet, not too large, are esteemed prominent characteristics. Defective proportions indicate that little can be expected from exertion. Hounds of middle size are the strongest, and most capable of protracted fatigue: and here it is necessary to regulate the equality of the pack. There should be complete uniformity in speed; for, though the fleetest hound is commonly esteemed the best, yet he may do much injury among his companions in the chace. Speed and vigour are indispensible qualities, and these are likely to be promoted by having hounds of the same family. Both are conspicuous in those of English breed. A hound has been known to run seven miles in four minutes; and a fox chace is said, on one occasion, to have been continued for about 120 miles, calculating, as nearly as possible, from the places where the hounds were seen. The ardour of the hounds is so great, that they sometimes actually die in the course of pursuit. A prejudice formerly prevailed in France against British hounds, which probably arose from their having degenerated on being transported from their native climate. Most animals degenerate under great transitions, whereas, were they carried to moderate distances, they might easily be habituated to the change of climate and of circumstances. The breed of all the useful animals ought to be anxiously studied, because real quality can be obtained in no other way than by selection from the offspring of parents who are themselves of the genuine stock. On both sides those alone should be chosen which demonstrate the properties of the fox hound in a superior manner: age must be avoided; and, as both sexes reach maturity nearly about the same period, there ought not to be a great disparity between them. General rules nevertheless admit of many exceptions, as the origin and properties of animals are but little known. The breeder will often be disappointed of his expectations, and he will sometimes have to admire the offspring of parents from whose union nothing was expected. In both cases, good qualities and defects may lurk in concealment during one generation, and be unfolded in the next. Some persons who have paid strict attention to this subject, maintain, that, in the course of numerous experiments, they succeeded in obtaining excellent hounds. The whelps must be kept very clean, both before and after leaving the mother. When they cease to obtain subsistence from her, it is recommended that they should be fed with wheat bread, to improve their strength; but in France, it is said that bread made of barley-meal is universally admitted to be better feeding, and is given at the rate of two pounds and a half or three quarters daily, in two portions. The whelps should be well aired, and have sufficient exercise, until they attain their full strength, or arrive at an age a little beyond it, when their active powers are to be called forth. It is supposed that dogs continue to grow during eleven months. Something probably depends on climate; for a much longer time frequently elapses before some of them have acquired all their vigour. Numerous specific rules are given regarding the entrance or initiation of hounds to the chace, on which head there are hunters who advance extraordinary, and apparently inconsistent, opinions; such as, that the first object of pursuit ought to be different from that for which the dog is ultimately destined. But it has been judiciously remarked, that "*nature* will instruct hounds how to hunt; *art* only is necessary to prevent them from hunting what they ought not to hunt." Instinct is incessantly operating; and if it is to be modified, we must always keep in remembrance, that early habits have a great preponderance; and that animals will probably be most eager in the pursuit of that game which they have been taught to hunt originally. One of the primary qualities of a dog is, to addict itself exclusively to the specific object of pursuit, and to abstain from every other; whence it would appear as inconsistent to enter pointers with larks, as fox hounds with rabbits. If hounds are accustomed, at an early age, to woods, or hills and vallies, it is likely that they may not be equally successful when there is a complete transposition of circumstances, whence a considerable variety of surface seems beneficial in exercising those which are young. These necessary preliminaries having been attended to, hounds are to be assorted in packs, the extent of which is quite arbitrary. Experienced hunters affirm, that 25 couple are sufficient at any time to be taken into the field; and this is the ordinary number. Forty couple will admit of hunting three times a-week; but if packs are very numerous, each hound will have too little occupation in the chace: hence it is essential that the qualities of hounds should be frequently brought into action, in order that they may be preserved by practice. Although instinctive habits may be permanent, yet artificial acquirements are soon forgotten. A pack of good hounds is a valuable property, and has been sold in England for a thousand guineas. With respect to the actual practice of fox-hunting, it is a subject susceptible of so much detail, that we must chiefly refer those who are desirous of becoming masters of it, either to certain districts of England and Ireland, where gentlemen of fortune follow it as a kind of profession, in preference to more useful pursuits of agriculture, and more delicate and refined amusements, or to the modern authors Beckford and Daniel, who treat copiously of the subject. They have not only exhausted the observations of their predecessors, but have embellished their writings with new and entertaining illustrations. As the fox leaves his burrow in quest of prey before the day breaks, all the earths are to be stopped at a very early hour in the morning; and the huntsmen having met at the appointed covert, it is to be carefully drawn for the game. A bad or windy day is always to be avoided, as the scent is so much affected and so precarious, that the hounds may be disappointed, which is injurious to their nature. It is not necessary that the fox should ever be seen by the dogs; when once roused, they pursue him by the scent alone, continuing the chace through many miles. But this animal neither possesses much speed, nor apparently entertains great dread of the hounds. His principal object is gaining the earth; and he trusts by wiles and stratagems to deceive his pursuers. If he is foiled, many turnings, doublings, and crossings, are resorted to: when fatigued, he will either lie down in a field, should one be in his way, or run amidst a flock of sheep, or a herd of cattle. In the course of the chace, sometimes, the scent becomes quite imperceptible, especially when confounded with the emanations of other animals, as in the latter case, when the hounds are said to be *checked* or *at fault*; and the recovery of it becomes most interesting to hunters. Silence is then to be observed, as the dogs will be industrious enough themselves in endeavouring to regain the scent. If they are successful, which does not invariably happen, they rapidly renew the pursuit, and gaining distance as the strength of the fox declines, they at length come up, and tear him to pieces. "Then," say sportsmen, "they should be allowed to eat him ravenously." It frequently occurs, that amidst a number of earths all are not stopped, and the fox, having taken shelter, is dug out or dislodged by terriers; sometimes the hounds pursue him thither, and are themselves suffocated within. It is difficult to kill the female while breeding, from her never wandering far from the burrow, and retreating into it on the slightest alarm. A modern author remarks, that "the whole art of fox-hunting is to keep hounds well in blood; therefore every advantage of the fox is taken. Sport is but a secondary consideration with the true fox hunter; his first motive is the killing of the fox, by which he makes his hounds. Present success is almost a sure forerunner of future sport; and he is better pleased with an indifferent chace, with death at the close of it, than with the best chace possible, if it terminates with the loss of the fox." This kind of amusement has been practised a considerable time in Great Britain. That King James I. had its commendation in view, when treating of the education of a prince, we shall not affirm; but he says, "I cannot omit here the hunting with running hounds, which is the most honourable and noblest sort thereof; for it is a thievish form of hunting to shoot with guns and bows; and greyhound hunting is not so martial a game." Fox-hunting is certainly no inconsiderable enterprise, when we hear of horses running themselves blind, or dying of fatigue under the lash of their riders; of dogs perishing during the chace, and of men breaking their limbs, or dislocating their necks. But whether it is an amusement either humane, or attended with any utility, might admit of some discussion.

Wild cattle are numerous on the southern continent of America, and herd together in great flocks; and the same may be said of horses. Both are hunted by the Indians in two different ways. A lash or belt is made of skin or leather, about fifty feet in length and two inches broad, with a running noose at one end. The huntsman holds the noose in his right hand, and being well mounted, on approaching within a few yards of the wild animal, throws the noose over its head, though running at full speed, whereby it is easily taken. By the second method, an iron ball, of about two pounds weight, is fastened to each end of a leather strap about twelve feet long, and the huntsman, when within the necessary distance, having swung one of the balls several times around his head to give it an impetus, throws it at the animal's legs, also parting with the other whereby they are entangled. Hunting the buffalo, which is a powerful, fierce, and intractable animal, is attended with great danger; for it readily attacks its pursuers, who must trust to the swiftness of their horses for escape. It entertains the utmost antipathy to every thing coloured red; and it is said that if a piece of red cloth is thrown in its way, it will be so much occupied in venting its rage upon it, that the huntsman has sufficient opportunity to advance or to retire.

A valuable animal, the deer, has been liberally dispersed by nature throughout the world, especially in the colder regions. In Siberia, vast herds of reindeer shift their abode at certain seasons, leaving the woods to seek for better pasture, and swim across wide rivers, always having a leader at their head. Then they become an easy prey; but if the leader suspects danger and returns, he is invariably followed by the rest, and the sportsman is disappointed of his game. The elk or moose deer north of Hudson's Bay, is hunted in a singular manner; for there the Indians themselves absolutely run it down. This is attempted only when the earth is covered by snow, and especially when the surface is encrusted over; then it sinks with the weight of the animal, while the snow shoes of the huntsman bear him up. A good runner will generally tire a moose in less than a day, and very often in six or eight hours; though it sometimes happens, that the hunters continue the pursuit two days before they can come up with and kill the game. They are very lightly clothed on such occasions, and carry only a bow with two or three arrows, and a small bag with implements for striking fire. Dogs are trained for this sport by the southern Indians, which renders it easier and more expeditious; and they are likewise used in Europe and other countries inhabited by the deer. In Britain, stag hunting is followed with hounds, and the strength and swiftness of the animal renders this description of the chase particularly interesting. Its agility surmounts every obstacle; the plains vanish under its feet; rivers are no barrier; and it seeks for shelter alike in the woods and mountains. Thence the pursuit is generally long and difficult, and the stag can be wearied down only by the strongest and most sturdy hounds. When the stag despairs of escaping, it sometimes stands at bay; and, presenting its antlers to the pursuers, seems resolved to sell its life as dearly as possible. The huntsman, however, is always the victor, and his precautions most commonly secure him from injury. But a more treacherous method is generally followed in stalking or approaching in disguise to shoot this fine animal, at least in those parts of the north and western parts of Scotland where it still runs wild. In the northern climates deer are shot with arrows, by means of a spring bow set in their path.

The antelope is a gregarious animal, very shy, and of great speed. Besides the use of the cheeta, it is hunted by numbers of men forming a circle, which, gradually closing, brings it within reach of the sportsman; or it is pursued by dogs, while hawks, trained for the purpose, being let fly, retard its swiftness by striking it on the head, and fluttering before its eyes.

There are various species of bears, which are hunted after different fashions both in the warmer and colder climates. The white bear, an enormous animal of the polar regions, is never seen but on ice and snow. Winterers on Nova Zembla remark, that it retreats from their abode as the sun sinks below the horizon in November, and returns with his appearance in January; meanwhile, they are visited by the arctic fox, which retires as the bear approaches. White bears attack man, and swim around ships as if to get on board. They are hunted by the northern savages, on the ice and snow, with pikes, swords, bows and arrows; but the bear makes a vigorous defence, turning on its assailants, whose victory is sometimes dearly purchased. However, a single man has been known to engage intrepidly in combat with a very fierce bear, without any other weapon than a knife, and to destroy his antagonist. The black bear never attacks man unless when provoked; it then rises upright, and, clasping him in its fore paws, endeavours to crush him to death. Before any encounter, it is said to make its young ascend trees. This animal can be dislodged with difficulty from its retreats by dogs; but when once roused, it is pursued, and shot. It is likewise taken by a great number of stratagems, of which we have already given an account under the article Bear, Vol. III. page 365. Hunting the badger, which pertains to the same genus, is followed in another shape. It burrows in the earth, and is also difficult to dislodge. When driven out by terriers, it fights boldly, inflicting severe lacerations on its pursuers. However, it is generally overpowered. Though covered with a strong hide and long hair, which render it tenacious of life, a slight blow on the nose occasions inevitable death. The badger is caught alive in sacks covering the mouth of its burrow, into which it is driven by the terriers.

After speaking of all these powerful, ferocious, and crafty animals, it is painful to treat of the hunting of the timid hare—a weak, harmless, and defenceless creature, which the very sight of man renders breathless with alarm. Yet, in Britain, whole troops of men, horses, and dogs, col-ject, to enjoy the gratification of running it down; a feat which is accomplished either by grey-hounds surpassing its utmost speed, or by slow hounds wearing it out with fatigue. But these are not the only means devised for its destruction, as numberless traps and snares besides fire-arms are always ready to bereave it of life. The hare is the ordinary prey of other animals; yet it feeds on none: its subsistence is derived exclusively from vegetable productions, and in few instances does it appear in sufficient numbers to occasion injury. Many fables are interwoven with the history of this animal, and the prejudices of mankind have determined its presence to be ominous on certain times and occasions. In general the hare shuns the haunts of men: it is abroad chiefly at dawn and twilight, and during the night troops of this animal meet to sport in the fields. Its vigilance is incessant: the eyes, which are not closed while it sleeps, are so constructed, that it can see farther around in the same position than other animals: its ears are adapted for the reception of the faintest sounds, and its foot is particularly fashioned for protection against different substances that cover the ground. As if aware that safety is to be found in concealment, it remains closely squatted in its form, even though its enemies be near; but when once roused, no bounds are set to its flight. Unlike the fox, which is regardless of distance, the hare feels confidence only when beyond the voice of its pursuers; but it is nevertheless full of stratagems. In the first outset a circular figure is described: all the subsequent course will approximate to the original line: but doubles are repeated after doubles, and the point of departure will frequently be approached during the chace. Hares are hunted either by harriers, a species of slow hound, or by greyhounds, the latter sport being technically designed *coursing*. Under a few modifications, nearly the same rules and principles are applicable here as before, regarding the choice, breeding, treatment, and entrance of hounds; but it is invariably to be observed, that the best harriers are those that never pursue any other game than hares. There is a very diminutive species called beagles, which are in much request for this kind of sport, and some of them are so small, that ten or eleven couple are said to have been carried to the field in a pair of panniers slung across a horse. Twenty couple of harriers are estimated a sufficient number in any pack. The hare, though swift, and endowed with considerable strength, is weaker than the fox, and the chace is rarely of equal duration; yet there is an instance of a hare, after having been chased sixteen miles, taking to the sea, and swimming nearly a quarter of a mile before it was caught, and also of one running above twenty miles in about two hours. The chace is followed by the scent, which is lost and recovered as in fox-hunting; and this peculiar emanation is thought to depend on the motion of the animal, because it is seldom perceptible while the hare remains quiet in its form. When it is first started, strict silence should be preserved by the hunters, as the hare is so timid, it is very readily headed back; whereby the hounds pushing forward lose the scent. Coursing is more generally practised in different countries, from requiring less of the apparatus of hunting, and because every master is in this case his own huntsman. Whether the shaggy or the smooth greyhound should be preferred, is not decided; but a greater portion of strength is usually ascribed to the former. Contrary to the nature of the harriers, greyhounds hunt entirely by the view, and while the others remain intent on recovering the scent, they very soon become bewildered on losing sight of the game. They should attain their full vigour before they are initiated into the chace, and in the meantime they should have abundance of air and exercise; but sportsmen are commonly too impatient to wait for the proper period. The qualities of the greyhound are often to be discovered almost entirely from their figure; and some have instinctively the property of carrying the game to the hunter's feet. Coursing can be traced to a very early period: it is said, however, that the Britons anciently abstained from eating the flesh of hares. Grants of land were obtained from several of the earlier sovereigns, for an annual tribute in horses, hawks, or hounds; and as greyhounds are used in stag-hunting, it is not to be supposed that they would be omitted. In the reign of King John, two charters were granted in 1203 and 1210, in consideration of which a certain number of greyhounds should be delivered, in addition to other obligations. Coursing is a favourite amusement in many countries besides Britain; and a good greyhound is so highly prized by some tribes in the eastern parts of Persia, that, according to a recent traveller, Lieut. Pottinger, the natives sometimes pay fifty pounds for one of acknowledged quality; a very high sum, considering their narrow finances. But sportsmen go farther still among ourselves, as, under the article Dog, it will be seen that 152*l*. has been paid for a greyhound. The greyhounds of Cyprus interrupt the chace by the huntsman merely throwing a pole before them, which indicates singular docility. It is said that a huntsman should acquire so much knowledge of the stratagems of the hare, as to be able to defeat the whole in two or three seasons; and he will also find his greyhounds improve by experience. The speed of the hare is great, and so are the speed and strength of the greyhound. Two are reported to have coursed a hare seven miles, though they were then so completely exhausted, that medical aid could scarcely preserve them; and there are examples of their dying in the very act of seizing the game. Whether the hare can see distinctly during the rapidity of its flight, or how its vision is then directed, is doubtful. It runs against obstacles with great violence; and we are told of a terrier eagerly coming up to join the chase having been met by the hare, when the latter was killed on the spot by the concussion, and its skull broken to pieces. When hard pressed, the hare will run to earth like a fox or rabbit: it often takes the water; seeks shelter in a house; or even leaps on the breast of a spectator. Thus do we behold the effect of terror and the love of self-preservation conquer its almost invincible timidity. But the devoted victim seldom essapes its merciless pursuers. Compared with that description of the chace, where the power, the ferocity, and the craftiness of animals, are to be combated by the strength and ingenuity of man, it may be questioned whether hare-hunting should be ranked among the more elevated kinds of sport.

We shall now say a few words of hunting animals which are sought only for the value of their furs, without any regard to the species to which they belong. These are more particularly of the weasel tribe, the *Mustela* of naturalists. The fur of some of these, as the ermine sable and sea otter, are of the finest quality, and always bear a very high price. A large portion of the revenue derived by Russia from her Siberian possession consists in the skin of the sable only. But hunting it is a more tedious occupation than the capture of any of the animals hitherto named, as it occupies the hunters a whole year at a time. Companies of from 6 to 40 men agree to hunt together, and they ascend the river Witim and two subsidiary streams, dragging boats capable of containing 3 or 4 people, and their provisions along with them, as far as the Lake Oronne. There they erect huts, and constitute a leader, to whom the whole promise implicit obedience. The party subdivides to hunt in different districts, and in this second excursion small huts banked up with snow are built, while all are occupied in constructing traps. As the sable is a carnivorous animal, they are suitably baited and set; and being so devised that the slightest touch ensures its capture, they are seldom long empty: but should the huntsman be unsuccessful in this manner, he is conducted by the tract of the sable in the snow to its burrow, from which being dislodged by a piece of smoking wood, it falls into a net spread for it, and there the huntsman kills it with his dog. Smoke is never used where there is only one hole to the burrow, as the sable would rather perish than come forth. Sometimes it runs up a tree, which is then cut down, the huntsman again spreading his toils in the direction in which it is to fall; or he employs blunt arrows to shoot the sable, whereby its skin is preserved from injury. Hunting being closed as the ice begins to melt, the whole produce is collected, the skins properly prepared, and when the rivers are open, carried down in the boats. Many superstitious ceremonies are practised by the hunters: they never articulate while skinning the sable; nor must any thing hang on the stakes around them. The carcase is laid on dry sticks, which are set on fire, and afterwards carried round it, previous to its being buried in the earth or snow. A portion of the spoils called God's sables, is always devoted as an offering to some church, in honour of which each leader also builds his hut.

However arduous and tedious a task it may be to hunt the sable, the pursuit of the sea otter, combined with that of several other animals, exceeds it infinitely in duration. Parties of huntsmen, consisting of from only a few to many hundreds together, engage in it, and ten years sometimes elapse before their return home. Far from being a pursuit of sport or pleasure, it is an occupation of dire necessity: the hunters are sparingly subsisted, they are scantily clothed, and, exposed to all the inclemency of a rigorous climate, they lead the most miserable lives. Such is particularly the case with the Russians in Siberia, and the natives of the continent, or the islanders under their controul. The sea otter is of an amphibious nature. It inhabits the shores of the Northern Pacific Ocean, and is found, though not in plenty, as far as Japan, or even the Yellow Sea. It is exceedingly pacific, and seeks safety only in flight; but it is unceasingly persecuted, and destroyed for the sake of the beautiful jet black fur that covers it. The hunters having obtained a vessel, to which the Russian government appoints a steersman, they sail from Okhotsk, or the harbours of Kamtschatka, with a small cargo of what will prove most acceptable to the savages of the distant islands which they mean to visit. Taking possession of some of these, they either compel the natives to depart alone in quest of game, (and in this way a fleet of canoes, carrying 300 Aleutans, went out some years ago, which was never after heard of,) or they are themselves of the party. Hunting the sea otter is in other respects attended both with danger and difficulty. Two very small canoes, each containing two expert hunters, are prepared with bows and arrows, and a small harpoon, to which last is attached a line a few fathoms in length. Though the animal is hunted also on ice, it is more commonly captured by pursuit in the water, continued during several hours. From the necessity of respiration, it can dive but for a few minutes; the principal skill to be displayed is in the canoes taking the same direction which it does in its course. They separate, therefore, as the sea otter goes down, in order to inflict a mortal wound either with the arrows or harpoon at the moment it rises. If hunted on a larger scale, the mode adopted renders the animal so sure a prey, that scarcely one in a hundred can escape. A number of hunters being engaged, when one observes a sea otter he endeavours to pierce it, and at all events rows to the spot where it plunges. Here he stations his canoe, and raises his oar as a signal, on which the rest of the hunters form a surrounding circle. The moment of reappearance, he discharges his arrows, or throws another harpoon, and hastening to the place where the otter dives, makes a signal by again raising his oar. A second circle is then formed, and the chace protracted, until the animal is exhausted. The first plunge exceeds a quarter of an hour, the next is of shorter duration, and thus the intervals diminish until the animal can plunge no more. When the female sea otter is overtaken with its young, parental affection is manifested in the most interesting manner; it supersedes all sense of danger. Taking the cub in her paws, she dives to save it; but obliged to rise for breath, she is exposed to the hunter's weapons. Should it be taken first, she becomes regardless of her own safety, and, approaching the boat, falls an easy sacrifice. But both parents sometimes defend their young furiously, tearing out with their teeth the arrows that have pierced them, and even attacking the canoes. Incessant pursuit of this animal has almost totally extirpated it from places where it was common formerly.

It would require a long enumeration to specify all the different modes of hunting, and the various stratagems employed for the capture of wild animals. Some are exceedingly ingenious, and others require continual alteration, according as the game becomes more wary of the designs of its pursuers. The skill of the huntsman, which an ordinary spectator is ready to undervalue, is the result of long continued experience only: the footstep, the track, the pasture of the animal, and other indications, are all studied, to discover its age, its sex, and its haunts; and it cannot be denied, that much of the naturalist's knowledge is deduced from the information of huntsmen alone. The whole geographical discoveries of the Russians in the north-east of Siberia originated exclusively with their hunters, to whom also they were indebted for the discovery of the Kurile and Aleutan islands, the promontory of Alaksa, and the island Kadiak. Hunting, when directed to the more important game, is an interesting, manly, and athletic exercise. Yet, if prosecuted for no other object than to deprive an innocent animal of life, or merely for the pleasure of witnessing its speed, and beholding the vigour of its defence for self-preservation, it is a cruel and hateful pastime. Men familiarised with the torture of animals, whose flesh is needlessly torn from their bones, will soon behold with indifference the pain of their fellow creatures. See *Chasse au fusil*. Williamson's *Field Sports of the East*. Daniel's *Rural Sports*. Beckford *On Fox and Hare Hunting*. *Sportsman's Dictionary*. *La Chasse Encyclop. Method*. Krascheninikow's *History of Kamtschatka*. Meare's *Voyage*. Lisianky's *Voyage*. Krusenstern's *Voyage*. Hearne's *Journey*. Cartwright's *Journal*. See Beaver, Bear, and Elephant, for an account of the method of hunting these animals. (*c*)

HUNTINGDON, is a town of England, and the principal town in Huntingdonshire. It is situated on a gently rising ground on the northern side of the river Ouse. It consists principally of one street, stretching in a north-west direction from the Ouse to nearly a mile from it, with several lanes branching off at right angles. The houses, which are built of brick, are genteel and commodious, and the streets are well paved and lighted. The town is nearly connected, by a causeway and three bridges, with the village of Godmanchester.

The principal public buildings and establishments are St Mary's church, All Saints church, and the town-hall. St Mary's, which is the corporation church, was rebuilt between the years 1600 and 1620. It has an elegant embattled tower at the west end, with nave, chancel, and aisles. All Saints church stands on the north of the market-place, and appears to have been built in the time of Henry VII. It is an embattled edifice, with nave, chancel, and aisles, and a small tower at the north-west angle. The town-hall, which stands on the south side of the market-place, is a good modern brick building, with a piazza at the front and sides, and butchers' shambles behind. In the lower part of the building are the civil and criminal courts, where the assizes are held. Above is a spacious assembly-room, adorned with the portraits of George II. and III. and their respective Queens, and of Lord Sandwich, who died in April 1792. The Free Grammar School is well endowed, and well conducted. There is also a greencoat school, called Walden's Charity, where 24 poor boys are clothed and educated. The county gaol, which stands at one end of the town, has recently been repaired and rendered more commodious. There are two places of worship here belonging to the dissenters, one for the Quakers, and the other for the sect patronised by the Countess of Huntingdon.

As Huntingdon is situated on the great north road, it has several good inns. The brewing trade is carried on here, though less extensively than formerly. It has also a small vinegar manufactory. Coals, wood, &c. are brought to the town by barges, which come up the river from Lynn in Norfolk, and return with the corn of the surrounding country.

This borough returns two members to Parliament, the right of election being vested in about 200 of the freemen and inhabitants. It is governed by a mayor, 12 aldermen, and a number of burgesses. The following is the population of the borough of Huntingdon in 1811:

| | |
|---|---|
| Number of houses | 450 |
| Number of families | 522 |
| Families employed in trade and manufactures | 291 |
| Males | 1085 |
| Females | 1312 |
| Total population | 2397 |

See the *Beauties of England and Wales*, vol. vii. p. 345.

HUNTINGDON. See PENNSYLVANIA.

HUNTINGDONSHIRE, an inland county of England, is almost inclosed by Cambridgeshire and Northamptonshire; by the former it is bounded on the north-east, and part of the south; by the latter, on the north and west. Bedfordshire bounds it also partly on the south-west. Its limits are nearly artificial. The river Nen, and the canals which join it to the Ouse, form its limits on the north and north-east, on the Northamptonshire and Cambridgeshire borders. The Ouse, at its entrance, separates for a short space from Bedfordshire, and at its exit from Cambridgeshire. The figure of this county is so irregular as scarcely to afford a proper measurement; but reckoning from its furthest projection, it does not exceed 24 miles each way, and in general is of much less extent. In fact, it is the smallest county in England except Rutland, and is very nearly the size of Middlesex; Huntingdon containing, according to the best accounts, about 210,000 acres; Rutland, 110,000; and Middlesex about 200,000 acres. The whole upland part in ancient times was a forest, and particularly adapted to the chace, whence the name of the county took its rise. It was disafforested by Henry II., III., and Edward I., the last of whom left no more of it a forest than what covers his own ground.

It is divided into four hundreds, namely, Normancross towards the north; Toseland towards the south; Hurstingstone towards the east; and Leightonstone towards the west. It contains one county-town, Huntingdon; six market towns, of which the principal are Kimbolton, St Neots, St Ives, and Godmanchester. The number of parishes is 104. It is in the province of Canterbury, and diocese of Lincoln. The ecclesiastical government is managed by the archdeacon of Huntingdon, and it is divided into five deaneries. It is in the Norfolk circuit, and returns four members to Parliament, viz. two for the county, and two for Huntingdon. This county and Cambridgeshire are joined together under one civil administration, there being but one high-sheriff for both, who is alternately chosen one year out of Cambridgeshire, the second year out of the isle of Ely, and the third year out of this county. It is one of the seven counties, Bedford, Huntingdon, Bucks, Berks, Hertford, Essex, and Suffolk, that are contiguous without a city.

The fenny part of it lies in the Bedford level on the north-east, and joining the fens of Ely. There are besides three distinct varieties of surface in this county. The borders of the Ouse, flowing across the south-east part, consist of a tract of most beautiful and fertile meadows, of which Portsholme Mead, near Huntingdon, is particularly celebrated. The middle and western parts are finely varied in their surface, fruitful in corn, and sprinkled with woods. The upland parts still bear the appearance of ancient forest lands.

The soils are various. In the upland parts, they are chiefly a strong deep clay, more or less intermingled with loam, or a deep gravelly soil, with loam. Of what are called the deep stapled lands, by far the greatest part are still in an open-field state. Indeed, there is a larger proportion of this most unproductive land in Huntingdonshire than perhaps in any other county of England; upwards of one-third of the high lands being still uninclosed. The more anciently inclosed parts are, generally speaking, in the possession of a few proprietors; but in the new inclosures, and in the open fields, property is divided among a much greater number of persons. The woodlands are but of inconsiderable extent, and the county is thin of timber. This is attributed to the very great demand for it in the fens, underwood being sold at a higher price than in most other counties. The meadow lands consist of about 1200 or 1400 acres, bordering on the rivers Nen and Ouse, but chiefly on the latter. They are extremely productive, but the produce is frequently damaged or carried away by the floods.

The fens consist of about 44,000 acres, besides nearly 5000 acres of what are provincially called skirty lands. The fens of Huntingdonshire constitute nearly a seventh part of what is called Bedford Level. About 8000 or 10,000 acres of them are productive; but the expence of preserving them from inundation amounts to almost one-third of the rents, in consequence of the drainage having been undertaken on an erroneous and imperfect plan. It is effected by engines, which throw the water out of the lands into the rivers, without having a proper out-fall near the sea. In consequence of this, the embankments are frequently broken through by the immense pressure of the weight which they contain. The mode of management of the fen lands has been much improved of late years, and the fen-men are very expert at the plough; no such thing as a driver being known, though they frequently plough with three horses abreast. The *skirty* lands, in general, afford luxuriant grazing.

The climate is rather mild, and by no means so unhealthy as might be anticipated from the fenny nature of a large portion of the county. The most unhealthy parts are the low moorish tracts near Huntingdon, Godmanchester, Ramsey, and Yaxley; for in the other parts about Kimbolton, and indeed through the whole of the hundred of Leightonstone, the air is remarkably good.

The principal rivers connected with Huntingdonshire are the Ouse and the Nen. The Ouse, which is generally called the Lesser Ouse, to distinguish it from a river of the same name in Yorkshire, enters this county from Bedfordshire between St Neots and Little Paxton, and, in its course southwards to Huntingdon, is increased by a number of small streams from the north-west. After passing that town, it flows eastward, and passing the west end of St Ives, becomes, near Holywell, the boundary between this county and Cambridgeshire, till it enters the great level of the fens near Erith. It is navigable along its whole line across this county. The Nen rises in Northamptonshire, and reaches Huntingdonshire near Elton, where it becomes the boundary between the two counties. It afterwards flows to Peterborough, below which it sinks into the fens. Some smaller streams water the north-east side of the county, together with several large meres or pools of water. Of these, Whittlesea Mere is by far the largest. In the time of Camden, it was six miles long and three broad; but its limits are now much contracted, so that the water is said at present to cover only an area of 1570 acres. It affords excellent sailing and fishing; and is, in the summer season, much frequented by parties of pleasure. Anciently, there was a navigation from Peterborough by the river to this Mere, and from thence to Ramsey.

Though this county has long been celebrated for its wealthy farmers, particularly in the vicinity of Godmanchester, yet its agriculture presents very little that is interesting or important. In Camden's time, Godmanchester was reckoned the largest village in England; and at that period, no place employed so many ploughs; and, according to that author, no people had so much advanced in agriculture, either by their purse or their genius. When James I. came through it on his journey from Scotland to take possession of the throne of England, the inhabitants met him with 70 new ploughs, drawn by as many teams of horses; for they hold their lands by this tenure, that, whenever the sovereign took this place in their progress, the farmers should make the most pompous appearance with ploughs and horses, adorned like triumphal cars with rustic trophies. King James was so pleased with the sight, that he granted them a charter constituting Godmanchester a borough, at the same time condescending to partake of a collation prepared under a bush, still known by the name of the King's Bush, and the Beggar's Bush. But Huntingdonshire is no longer remarkable for the excellence of its agriculture; nor, indeed, could improvement in this most useful art be excited in a county where so large a proportion of the land is still in the barbarous state of open field. Besides the common produce of wheat, barley, oats, hemp, and rape in the fens, turnips on the drier soils, and a few hops, this county grows a considerable quantity of mustard: it is cultivated on various soils, chiefly rich loam, good old pasture land, rich clay, and the best fen soils. The ground is ploughed only once for it: it is sown any time between Candlemas and Lady Day. There are two kinds, the black and white; the former is most esteemed. The weeding is performed by sheep, which will not eat the mustard. The produce is from 28 to 44 bushels per acre.

The breed of sheep upon the enclosed lands is of a mixed description, nearly approaching to the Leicestershire and Lincolnshire kinds, with which the native breeds have been much crossed. Those bred on the open fields and commons are much inferior. The cattle are for the most part the refuse of the Lancashire, Leicestershire, and Derbyshire breeds: oxen are purchased for grazing generally without any attention to the breed, and are never used in husbandry. From the open state of the county, dairy farming is not much followed; and the cows are used for suckling calves in the southern parts, to supply the London market. The rich and celebrated cheese, called Stilton cheese, takes its name from a village in Huntingdonshire; but it is made in the vicinity of Melton Mowbray in Leicestershire; and it is generally supposed never to have been made at Stilton, but always to have been sent there for sale: of this, however, there seems some doubt. Mr Nicholls, in his History and Antiquities of the County of Leicester, says, that it began to be made in the parish of Little Dalby, in that county, about the year 1730; but, on the other hand, there is the evidence of a very old inhabitant of Stilton, who died there about the year 1777, aged 80 years, that, when he was a boy, the cream used to be collected in the neighbouring villages for the purpose of making Stilton cheese: this of course fixes the making of this famous cheese at Stilton long before, according to Mr Nicholls' evidence, it was made in Leicestershire. In the fens of Huntingdonshire, mares are used for all the purposes of agriculture; and every farmer breeds from them as many foals as he can, selling the colts off at two years old, and as many of the fillies as can be spared, with proper attention to the team. The high roads in this county, in general, are tolerably good; the cross roads are but indifferent, and in the winter season many of them are nearly impassable.

No manufactures of note are carried on in Huntingdonshire, except wool, stapling, and spinning yarn: the latter is the chief business of the women and children in the winter season; in the summer they find more profitable employment in the fields. There is a small manufacture of lace at Kimbolton; and at St Neots, there is a very large paper mill worked by patent machinery. At Standground, there are two manufactures for sacking. The markets and fairs of St Ives for live cattle are some of the greatest in England.

In the year 1803, the poor's rates amounted to 30,952*l.*: in the year ending the 25th of March, 1815, it amounted to 40,625*l.*

There are few remarkable antiquities in this county. Dornford, in the north-west part of it, formerly called Deorm-ceaster and Caer Dorm, is probably the *Durobrivæ*, a passage of the Nen mentioned in the Itinerary of Antoninus. A little above Stilton, a Roman pathway, leading from Dornford to Huntingdon, appears with a very high bank, which, in an old Saxon charter, is called Ermingstreet. From Ramsey, which stands on an isle of the same name, formed by the fens, there runs a causeway, called Kings-delf, for ten miles, to Peterborough. It appears upon record in King Edgar's time. At Ramsey, was formerly a very rich abbey, built in the midst of a bog. There is little left of it, beside a part of the old gate-house, and a statue of its founder Alwyn, who was called alderman of all England, and cousin to King Edgar. The keys and ragged staff in his hand denote his offices. This is reckoned one of the most ancient pieces of English sculpture extant.

This county, under the Saxon heptarchy, formed part of the kingdom of Mercia, or the middle Angles. Mr Speed mentions an observation of Sir Robert Cotton, that the families of this county were so worn out even in his time, (about the beginning of the 17th century,) that, though it was formerly very rich in gentry, yet few surnames of any note were then remaining that could be traced higher than

Henry VIII. Mr Camden remarks, that, in the civil wars, there were more actions in this than in much larger counties, because it was the native county of Oliver Cromwell.

According to the returns made in the year 1800, the population of this county was 37,568. In the year 1811, the returns afford the following results.

| | |
|---|---|
| Houses inhabited | 7,566 |
| Families occupying them | 8,808 |
| Houses building | 23 |
| ——— uninhabited | 153 |
| Families employed in agriculture | 5,361 |
| ——— in trade and manufactures | 2,205 |
| ——— not comprised in these classes | 1,242 |
| Males | 20,402 |
| Females | 21,806 |
| Total | 42,208 |
| Square statute miles | 370 |
| Rental of land | *l* 202,076 |
| Amount of tithe | *l* 10,166 |
| Annual value of square mile | *l* 574 |
| Persons in a square mile | 114 |
| Agricultural population | 61 |
| Net product per family | *l* 40 |

(W. S.)

HUNTLY is a small town of Scotland, in the county of Aberdeen. It is pleasantly situated on a point of land at the confluence of the rivers Bogie and Deveron. It consists of two principal streets, crossing each other at right angles, and forming a spacious market-place at their junction. The town contains some good houses, and has of late years increased considerably. In 1792, it contained 52 flax-dressers, the annual value of whose manufactures was 16,224*l.*; and 209 weavers, who produced yearly 73,150 yards of cloth. Huntly Lodge, the seat of the Marquis of Huntly, stands near the town, on the banks of the Deveron; and near the bridge over the same river are the remains of Huntly Castle.

The town and parish contained, in 1811,

| | |
|---|---|
| Inhabited houses | 608 |
| Number of families | 720 |
| Ditto employed in agriculture | 190 |
| Ditto employed in trade and manufactures | 510 |
| Males | 1186 |
| Females | 1578 |
| Total population | 2764 |

HUSS, John, the celebrated reformer and founder of the sect called Hussites, was born at Hussinez, a village in Bohemia, about the year 1376, and received his education at the university of Prague, where he took his degrees of M. A. and B. D. and at length became minister of a church in that city. In the year 1400 he was chosen confessor to the queen Sophia; and at this early period, he already began to distinguish himself by his freedom and zeal in reprehending the corrupt morals of the laity, as well as the vices of the clergy. The monks, under the protection of some of the nobles, complained of him to the king Winceslaus; but this prince, who was no friend to the clergy, declined to interfere.

About this period, in consequence of the marriage of Ann of Bohemia with Richard II. of England, a communication and intercourse were opened between these two countries; and several young Bohemians repaired to England, where they became acquainted with the writings of Wickliffe. Among these was Jerome of Prague, who had formerly been a pupil of Huss, and after spending some time at the university of Oxford, returned to his native country, bringing along with him several of the works of the English reformer. Huss perused these writings, and having found that many of the opinions which they contained coincided with those which he himself had been led to entertain, he continued to preach openly and zealously against the errors and corruptions of the reigning church. His eloquence was powerfully directed against the sale of indulgences; he inveighed against this system of Papal extortion with uncommon warmth; and his arguments received countenance both from the monarch and the people. By this conduct, however, he rendered himself greatly obnoxious to Subinco, the archbishop of Prague, a violent, bigotted, and illiterate prelate, who from thenceforth became his irreconcileable enemy. Being aware that Huss was secretly attached to the doctrines of Wickliffe, he obtained a decree of the university, in which the opinions of the English reformer were condemned as heretical, and those who should in future attempt to disseminate these opinions were threatened with the punishment of burning. Huss perceived at once that this decree was levelled at his person, rather than the opinions of Wickliffe; but he relied upon the protection of the queen, and the acknowledged purity of his life and conversation.

Meanwhile, two young Englishmen, and zealous disciples of Wickliffe, having arrived at Prague, contributed to strengthen his attachment to the doctrines of that reformer; and Wickliffe's treatise *De realibus Universalibus* having fallen into his hands, he relished it so much, that he adopted the opinions of the author, and became a decided *realist*. The whole university was at this time divided into two parties, the German and the Bohemian, or the *nominalists* and *realists*, whose contests were carried on with great animosity, and not without bloodshed. The German, or foreign party, possessed most influence in the university, as the original constitution allowed them three votes in all elections and deliberations; while the native Bohemians had only one. This constitution conferred upon the former a superiority, which the latter could not contemplate without jealousy, especially as the Germans conducted themselves with great arrogance towards the natives. Huss took upon himself to contest the right of the Germans to this superiority, and demonstrated, that although, by the original constitution of the university, the German masters had been allowed three votes, while the Bohemians had only one, as the latter were then inconsiderable in point of number; yet that, by a later act of Charles IV. it was expressly declared, that in all matters they should be governed by the constitution of the university of Paris, according to which foreigners had but one vote, and the natives three. Through his great influence at court, Huss actually succeeded in carrying this measure, the consequence of which was, that almost all the Germans withdrew from Prague, and repaired to Leipsic, where a new university was soon after founded.

No sooner did the Bohemians find themselves in full possession of the university, than they proceeded to elect Huss for their rector. He now exerted his eloquence more powerfully than ever in declaiming against the scandalous corruption of morals among the clergy; and, among other doctrines, he strongly recommended a diminution of the superfluous revenues of the church, as the best means of producing a moral reformation. He even ventured to attack the supreme power of the pope, in whom he would acknowledge no superiority over other bishops.

As soon as the conduct of Huss was represented to Pope Alexander V. he gave the Archbishop Subinco a commission to take measures for repressing these dangerous doctrines. The archbishop accordingly not only prohibited all preaching in chapels, but ordered all the writings of Wickliffe, which he could collect, to be publicly burnt. Huss, however, entirely disregarded the prohibition, and continued to preach, as zealously as ever, in favour of the condemned doctrines. At length, in the year 1410, he was summoned to appear before the papal tribunal by John XXIII.; but Huss, under the protection of the king and queen, several powerful nobles, and the university, declined appearing in person, but sent three deputies to excuse his absence, and to answer all that should be alledged against him. In the mean time an event occurred, which made the breach between Huss and the court of Rome utterly irreparable. In the autumn of 1411, Pope John caused a general indulgence to be proclaimed for all those who should assist him in his crusade against the excommunicated king, Ladislaus of Naples; and for this purpose he sent his commissaries to Prague. Huss, who had formerly opposed the sale of indulgences, now raised his voice boldly against this papal traffic; while his friend Jerome of Prague, even went so far as to burn the papal bull in the market-place under the gallows. This was sufficient to call forth the vengeance of the Roman pontiff. Huss was now excommunicated for his contumacy in declining to appear personally at the papal tribunal; and the town of Prague was laid under an interdict. The number of his friends and adherents would probably have enabled Huss to set at nought this sentence; but, in order to remove every pretext for tumult and disorder, he resolved to withdraw from Prague, and accordingly retired to his birth-place, Hussinez. Here, and at Cracowitz, to which place he soon after repaired, Huss continued to disseminate his doctrines by preaching, and composed several treatises, with a view to expose the most objectionable tenets of the Romish church.

Matters were in this situation, when the emperor Sigismund agreed with Pope John to assemble a general council at Constance. To this general council Huss was summoned, in order to defend himself publicly against the accusation of heresy. His friends having procured for him a safe-conduct from the emperor, and being likewise provided with attestations of his orthodoxy and innocence from the university and the papal inquisitor at Prague, he set out upon his journey to Constance, where he arrived shortly before the opening of the council. The pope treated him with kindness, assured him of his protection, and even removed the sentence of excommunication. But shortly afterwards, some of his most violent persecutors having arrived at Constance, they used their utmost influence to procure his condemnation; and Huss himself having had the imprudence to promulgate the doctrines of Wickliffe at Constance, he was summoned before the pope and the cardinals, and, notwithstanding the emperor's safe-conduct, thrown into prison.

Upon receiving intelligence of these proceedings, the emperor, who had not yet arrived, sent an order to his ambassador to insist with the pope and the cardinals upon the liberation of John Huss, and to threaten, if they refused to comply, that the prison would be opened by force. The pope and the cardinals, however, disregarded the command of the king, and caused the prisoner to be more strictly confined. When Sigismund arrived at Constance, he allowed himself to be persuaded by the theologians and canonists, that he was not bound to keep faith with a notorious heretic; and he issued a declaration that the council should have free power in all matters of faith, and should be allowed to proceed as judges against all those who were accused of heresy. Some of the most considerable among the Bohemian nobles, indignant at the perfidious conduct of the emperor, repeatedly requested, in pretty bold language, that John Huss, who had received a safe-conduct from the monarch himself, and otherwise would certainly not have repaired to Constance, should be set at liberty, and publicly heard in his defence before the whole council. But Sigismund excused himself in evasive terms, and thereby drew upon himself the mortal hatred of the Bohemians, which, in the sequel, proved highly dangerous to his power.

After Huss had remained more than six months in prison, he was, for the first time, allowed a public hearing, in a general congregation, in which, however, the proceedings were so irregular and tumultuous, that he found it impossible to speak. In the following audience, three points of accusation were read; to which Huss answered in a manner so satisfactory, that no charge of heresy could be fixed upon him, and every impartial judge must have acquitted him. In the third diet, thirty-nine articles were read to him, which had been drawn up by his enemies, and were alleged to have been extracted from his writings. Huss acknowledged such of these as contained opinions which he had really held; but with regard to the greater number, he utterly denied them, declaring that they were either garbled and distorted, or altogether forged by his enemies. Some of the prelates, and even the emperor himself, now urged him to retract and abjure the whole of these articles; but Huss required that he should first be convicted of error; for so long as this was not done, it was impossible for him to retract any of his opinions. And to this determination he adhered, with immoveable firmness, as often as the council endeavoured to induce him to retract, and even threatened to bring him to the stake.

At length, in the 15th session, which Sigismund attended in person, the final sentence was pronounced, that the writings of Huss should be publicly burnt; and that he himself, as a manifest heretic, who openly taught, and refused to retract doctrines which had long been condemned as dangerous to the Catholic faith, should be deprived of his ecclesiastical dignity, and delivered over for punishment, to the temporal arm. Huss, who was obliged to listen on his knees while this sentence was publicly read, repeatedly attempted to complain, and to vindicate himself in regard to several offences which were falsely laid to his charge; but he was always interrupted, and compelled to keep silence. The unfortunate victim was now forced to submit to the punishment of degradation, which was performed with several absurd ceremonies, by seven bishops commissioned for that purpose. He was then delivered over, by the emperor, to the elector palatine, who was commanded to execute upon him the usual punishment of heretics.

Immediately after the termination of the session, Huss was conducted under a strong escort, to the square in front of the episcopal palace, where he was compelled to witness the public burning of his writings; and from thence to the place of execution before the city gate. While he was preparing for the stake, several fruitless attempts were made to extort from him a recantation; but his fortitude remained unshaken to the last. When he was fastened to the stake, and fire was laid to the faggots around him, he continued his devotional exercises until the vital spark became extinct within him. His ashes were gathered up and thrown into the Rhine.

Such was the fate of John Huss, who fell a victim to the most abominable persecution. His talents and acquirements, although not of the first order, were highly respectable; and his moral character was universally acknowledged to be irreproachable. In his manners he was gentle and condescending. Strict in his principles, and virtuous in his conduct, he looked more to the practice than to the opinions of others. His piety was calm, rational, and manly; and his zeal in the cause of Christianity was untainted with fanaticism. The events of his life sufficiently prove, that his fortitude was not to be shaken by any human power.

It is difficult to conceive how such a character as that of Huss should have been exposed to such unrelenting animosity and furious persecution. His creed, it is true, did not exactly square with the tenets of the established orthodox faith; yet several of his persecutors had publicly maintained almost all the offensive doctrines which he was charged with disseminating. It seems most probable, according to the opinion of some authors, that the violent animosity excited against him, is to be ascribed chiefly to the zeal with which he declaimed against the dissolute morals of the ecclesiastics, the usurpations of the Roman court, and the temporalities of the clergy. These principles were naturally considered as dangerous to the power and influence of the priesthood; and his brethren, who dreaded the effects of his eloquence and example, were glad to have recourse to an accusation of heresy, as the best and least unpopular means of destroying the enemy of their corruptions, and of crushing those principles which appeared subversive of their privileges and pretensions.

Jerome of Prague, the friend and pupil of Huss, underwent the same fate with his companion. He, indeed, was at first terrified into a temporary submission; but he afterwards resumed his fortitude; and, at length, on the 30th of May, 1416, sealed by martyrdom, his belief in the principles he professed.

The memory of John Huss was long cherished by his countrymen, the Bohemians; the sixth of July was for many years held sacred, as the anniversary of his martyrdom, and medals were struck in honour of the martyr. The Bohemian and Moravian nobles addressed a spirited protest to the council of Constance, in answer to the intimation of his sentence and execution; and the zeal of his indignant disciples afterwards broke out into an open war against the emperor, which was conducted, on both sides, with a savage spirit of barbarity, and gave rise to acts of atrocity at which humanity shudders. These troubles were at length fortunately terminated by the interference of the council of Basil, in the year 1433. See Zitte *Lebens beschreibung des Mag. Johan. Huss*, Prague, 1799; Æn. Sylvii *Hist. Bohem.* in Freheri *Script. rer. Bohem.*; Wil. Hist.* vol. iii.; Gilpin's Lives, *Life of John Huss*; and the *Gen. Biog. Dict.* (*z*)

HUSUM is a sea-port town of Denmark, situated on the west coast of the duchy of Sleswick, about two miles from the small river Ow, and about four from Sleswick. It was formerly celebrated for the great quantities of malt which it exported. At one time 40 large vessels belonged to this town, and the oyster trade was almost confined to its inhabitants.

HUTCHESON, Francis, an ingenious philosopher and elegant writer, was the son of a dissenting minister in the north of Ireland, and was born on the 8th of August, 1694. From his childhood he discovered a superior capacity, and an ardent thirst after knowledge; and having received the usual elementary instruction at a grammar-school, he was sent to an academy to begin his course of philosophy. In the year 1710, he was entered a student in the university of Glasgow; where he renewed his application to the study of the Latin and Greek languages, and explored every province of literature; but devoted himself chiefly to divinity, which he proposed to make the peculiar study and profession of his life.

After spending six years at Glasgow, he returned to his native country; and having entered into the ministry, he was just about to be settled in a small congregation of Dissenters in the north of Ireland, when some gentlemen about Dublin, who were acquainted with his great talents and virtues, invited him to undertake the charge of a private academy in that city. With this invitation he complied; and he had resided but a short time in Dublin, when his talents and accomplishments attracted general notice, and procured him the acquaintance of persons of all ranks, who had any taste for literature. Lord Molesworth is said to have taken great delight in his conversation, and to have assisted him with his criticisms and observations upon his *Enquiry into the Ideas of Beauty and Virtue*, before it was committed to the press. He experienced the same favour from Dr Synge, Bishop of Elphin, with whom he cultivated an intimate friendship. The first edition of the work to which we have just alluded, was published anonymously; but its great merit did not allow the author to remain long concealed. Lord Granville, who was then lord-lieutenant of Ireland, sent his private secretary to enquire at the booksellers for the author; and when he could not learn his name, he left a letter to be conveyed to him, in consequence of which he soon became acquainted with his excellency, and was ever after treated by him with distinguished marks of familiarity and esteem.

From this period, his acquaintance began to be still more courted by men of distinction, either for station or literature, in Ireland. The celebrated Archbishop King held him in great esteem; and the friendship of that prelate was highly useful in screening him from two attempts which were made to prosecute him, for venturing to take upon himself the education of youth, without having subscribed the ecclesiastical canons, and obtained a regular license from the bishop. He also enjoyed a large share of the esteem of the Primate Boulter; who, through his influence, made a donation to the university of Glasgow of a yearly fund for an exhibitioner to be bred to any of the learned professions.

In the year 1728, Mr Hutchinson published his *Treatise on the Passions*; and about the same time he wrote some philosophical papers, inserted in the collection called *Hibernicus's Letters*, in which he accounted for laughter in a manner different from the theory of Hobbes, and more honourable to human nature. Some letters having appeared in the "*London Journal*, 1728," subscribed Philaretus, containing objections to some parts of the doctrine contained in the *Enquiry*, he was induced to give answers to them in those public papers. Both the letters and answers were afterwards published in a separate pamphlet.

After he had conducted his private academy at Dublin for several years with great reputation and success, he was invited to Scotland in 1729, to fill the chair of moral philosophy in the University of Glasgow. In this situation he spent the remainder of his life, in a manner highly honourable to himself, and useful to the university of which he was a member. About this time, the degree of Doctor of Laws was conferred upon him. A firm constitution, and a pretty uniform state of good health, with the exception of some slight attacks of the gout, seemed to promise his friends a long enjoyment of his valuable life; which, however, was terminated by a sudden attack, in the year 1747, when he had only attained the age of 53.

He was married, soon after his settlement in Dublin, to Mrs Mary Wilson, the daughter of a gentleman in the county of Longford; by whom he left one son, Francis, Hutcheson, M. D. who published from the original MS. of his father, *A System of Moral Philosophy*, Glasgow, 1755, 2 vols. 4to.

Dr Hutcheson was a man of considerable learning, and various acquirements. He was not only acquainted with those subjects most intimately connected with his profession, but was also well versed in mathematics and natural philosophy. His works have been frequently reprinted, and have been universally admired, both for the sentiments and language, even by those who have not assented to the author's principles. He belonged to that class of philosophers, who deduce all our notions of right or wrong from a moral sense or faculty implanted in our constitution, which leads us to perform good actions ourselves, and to approve of them when performed by others, independently of any reasoning with regard to their utility or fitness. He was a decided antagonist of the doctrines of Hobbes; entertaining high notions of the dignity of human nature, and being persuaded that, even in this corrupt state, it is capable of great improvement, by proper instruction and assiduous culture. See Dr Leichman's *Account of the Life, Writings, and Character of Dr Hutcheson*, prefixed to the *System of Moral Philosophy*; and the *Gen. Biog. Dict.* (z)

HUTTON, James, M D. well known as the author of an ingenious Theory of the Earth, was the son of a respectable merchant in Edinburgh, and was born on the 3d of June 1726. He received at the high school and the university the rudiments of a liberal education, during which his curiosity was powerfully excited by various facts in chemistry which came under his knowledge, and he acquired a taste for chemical pursuits, which distinguished him through life. His friends, however, placed him as an apprentice with Mr Chalmers, Writer to the Signet. But this gentleman soon perceiving that he disliked his employment, and occupied much of his time with chemical experiments, liberally released him from his engagements, and advised him to turn his attention to more congenial pursuits. He now entered on a course of medical studies, which he prosecuted first in Edinburgh, from the year 1744 to 1747. He next studied at Paris; and in 1749, he took the degree of M. D. at Leyden. Having thus completed his education, however, he perceived serious difficulties opposed to his views of success in obtaining practice. He also apprehended that the labours of a professional life might interfere with the gratification of his taste for chemistry; and in 1750 he resolved to apply himself to agriculture. For the purpose of learning that art, he went to Norfolk, where he resided two years in the house of an intelligent farmer. During this residence, he made pedestrian excursions to different parts of England for his improvement in agricultural knowledge; in the course of which he contracted an attachment to mineralogy and the kindred speculations of geology.

In 1754, he extended his agricultural knowledge, by making a tour in Holland and Flanders. During all these peregrinations, he made a collection of facts, which were afterwards made to contribute to his theory of the earth. He returned to Scotland, and reduced his agricultural knowledge to practice, by improving his patrimonial property in Berwickshire. In this occupation he was engaged for 14 years. He had the honour of being among the first who introduced good husbandry into our country, where it has since been so successfully cultivated. In 1768 he let his farm, which he had now brought to a high state of improvement. He had been for several years concerned in a manufactory of sal ammoniac, conducted in Edinburgh under the name of Mr James Davie, who was one of his early and constant friends; and in 1765, a regular partnership had been formed, after which the work was conducted in the name of both. When he gave up his farm, he took up his residence in Edinburgh, and devoted his attention to the pursuits of science, in which he was assisted and animated by his learned friends, whose company he enjoyed in this metropolis. In the course of his chemical pursuits, he discovered that soda was contained in zeolite; the first time an alkali had been found in a stony mineral. He continued to make tours to various parts of the island, in prosecution of his geological enquiries, which assumed greater and greater consistency. In 1777, Dr Hutton published a pamphlet, entitled *Considerations on the Nature, Qualities, and Distinctions of Coal and Culm*, with a view to throw light on a disputed point, whether the small coal of Scotland was liable to the duty on English coal, or to that on English culm. On this subject he displayed great accuracy of observation, and his discussion led to a satisfactory decision of the question. From the time of fixing his residence in Edinburgh, Dr Hutton had been a member of the Philosophical Society, known by the three volumes of literary and physical essays which it published. In that Society he read several papers, none of which have been published, with the exception of one which appeared in the second volume of the Transactions of the Royal Society of Edinburgh, "On certain natural appearances of the ground on the hill of Arthur's Seat." The institution of the Royal Society, which happened in 1783, called forth from Dr Hutton the first sketch of his Theory of the Earth, which he had matured in his own mind, but communicated only to his friends Dr Black and Mr Clerk of Eldin, both of whom approved of it. For an account of this theory, see the article Mineralogy. The distinguishing feature of it was, the universal agency of heat in consolidating the rocky strata, after the materials of which they were formed had been collected by the subsiding of loose earthy materials at the bottom of the sea. This heat he conceived to be seated in the central parts of the earth. To the expansive power of this agent, acting on water or other bodies, he ascribed the elevation of the strata from the bottom of the sea to the higher situations which they have since occupied. He thus accounted for the present appearances. He supposes the earth to have undergone many revolutions at very distant intervals of time, and to be subjected to a law, which produces a general and sudden convulsion as a stage in certain cycles of changes, which at all other times are slowly yet incessantly advancing. This theory has been defended by the author and his followers with much learning and ingenuity; and in a particular manner by his zealous and enlightened admirer Professor Playfair. It has, however, met with a formidable competitor in that of Werner; the leading feature of which is, to account for consolidation by crystallization from a state of aqueous solution, rejecting the hypothesis of a central heat, whether as concerned in the fusion of the rocks, or in the elevation of the strata. It supposes the materials of the strata to have subsided at their present elevation; and its chief embarrassment consists in the difficulty of accounting for the retiring of the waters. The illustration of these opposite general views includes a vast variety of discussion on the constitution of the rocky strata. The controversy has eminently promoted the investigation of the mineral kingdom. A great part of the world content themselves with a smile bordering on contempt, when they casually listen to these speculations; and a superficial observer is generally struck with the character of extravagance, which appears so prominent in the hypotheses assumed. No hypothesis, however, within the limits of possibility, is too extravagant for the subject. The disposition of the strata is itself an extravagant fact, if we may be allowed to apply this epithet to any thing in nature. It points to causes so different in their general character from any that we see in actual operation, that no hypothesis is to be rejected for its strangeness; and hypotheses of this kind are unavoidable to those who attempt to explain the phenomena before them. A wish of this sort cannot be reasonably condemned. There can scarcely be a more sublime speculation in physics, than to attempt the resolution of problems which nature suggests on so magnificent a scale. We may indeed sometimes wonder to see a particular theory so tenaciously adhered to; and it may be regarded as a curious fact, that in the present age the one or the other of the theories now mentioned should be adopted by all geologists. It might be supposed, that the subject would afford several others equally plausible; but it is probably not so much a satisfaction with their own theory as a simple preference of it to its opponent, that is indulged in by the greater part of geologists. The unexplained phenomena of magnetism, particularly the fluctuating variations of the needle, and the supposition of interchanges of materials among the different planets, (countenanced in some measure by the well authenticated instances of stones which have fallen from the atmosphere,) will perhaps at some future period lead to a modification of our geological theories, or to the formation of others.

A paper of Dr Hutton "On the Theory of Rain," was published in the first volume of the Edinburgh Transactions. It forms the only scientific explanation of the phenomena that we have. The discovery of it evinced profound genius and accurate information, and it will probably always be retained by meteorologists. Two portions of air of different temperatures, both saturated with humidity when mixed, and thus reduced to a medium temperature, have not the power of retaining the same quantity in a state of vapour. The reason of this is, that the quantities of humidity retained in this state proceed in a geometrical ratio, while those of temperature increase arithmetically. A larger quantity of water is retained by that heat which had kept the one portion of air above the resulting medium, than when the same heat is employed in raising to that medium the temperature of the coldest portion. The consequence of this is, that a part of the water is precipitated. This theory was opposed by Monsieur de Luc, who maintained, that the heat was communicated from one part of the atmosphere to another without the actual intermixture of different portions of air. Dr Hutton made several other acute improvements in meteorology, which were afterwards published in his "Physical Dissertations," in which his theory of rain was again given. It was by the theory of the earth, however, that the greatest portion of his interest was absorbed. The journeys which he made to Glen Tilt, to Galloway, the isle of Arran and St Abb's Head, supplied him with facts which afforded him exquisite delight, especially those which elucidated his peculiar views of the nature of granite, and the circumstances under which it assumed its present situation in relation to the other rocks. He supposed it to have been forced up in a state of igneous fusion by the expansive power of the central heat, and injected in that state into the rents produced in the superincumbent strata, which had previously formed the exterior crust of the globe. It was the continuation of the granite upward into these rents or veins that so much delighted Dr Hutton. This is a fact which still furnishes one of the strong points of the Huttonian theory.

This philosopher also turned his attention to another subject suggested by his chemical pursuits, viz. the general nature of matter. His doctrines on this subject are given in his "Dissertations on different subjects in Natural Philosophy." They bore some resemblance to those of Boscovich, though somewhat different, and seem to have been with Dr Hutton altogether original. After this he published a more voluminous work, entitled "An Investigation of the Principles of Knowledge and the Progress of Reason from Sense to Science and Philosophy," in three 4to volumes. His leading idea was, that matter is an assemblage of powers; that our ideas of external substances have no resemblance to the causes which produce them; and consequently that the world, as conceived by us, is entirely the creation of the mind itself, acted on by unknown external causes.

In 1793, Dr Hutton was seized with a severe and dangerous illness from a retention of urine. When he recovered from its severest symptoms, he continued his literary occupations. It was then that he prepared the work last mentioned for publication. He was also now called on to defend his doctrine on the theory of the earth, from the arguments of Mr Kirwan, published in the Transactions of the Irish Academy, especially as these were accompanied by some misrepresentations which it was incumbent on him to expose, and some charges of an odious tendency which it was necessary to repel. It was only now that he began to publish his theory of the earth in a separate state, as it had hitherto been but partially unfolded in a variety of papers. He published two octavo volumes in 1795, and a third was left behind in manuscript.

After this he published his "Elements of Agriculture," and eminently contributed by this publication, as he had done by his former example, to give an impulse to the progress of that important art.

After this he suffered under a renewed and very severe attack of his complaint; and in 1796 and 1797, his strength was greatly reduced, and his constitution broken. Still, however, he employed himself in reading and writing. Saussure's Travels among the Alps, which at this time were newly published, furnished him with high entertainment, congenial with the favourite scientific amusements of his life. On Saturday the 26th of March 1797 he suffered much pain, but continued to make some efforts in study. In the evening of that day, his complaint increased in a most rapid manner, and carried him off before time was allowed for his medical attendant to arrive.

He was undoubtedly a man powerfully qualified to advance science. It is reckoned by some persons a reflection on the memory of any philosopher, to have been the author of a theory of the earth. But we have already observed, that such persons are not aware of the engaging nature of such speculations to a philosophical and attentive mind, to which it is a natural object of ambition, to throw a consistent light on the stupendous and mysterious appearances exhibited in the mineral kingdom. Some who have studied this subject profoundly, and have embraced conclusions very different from those of Hutton, have betrayed too great proneness to throw reflections on the degree of soundness attached to this author's general philosophical discernment. They show themselves little sensible of the uncertain nature of all such speculations, and thus furnish greater evidence of their own deficiencies than of those of their opponents. The theory of the earth should be acknowledged to be as yet an enigmatic department of science; and the various attempts which have been made to solve its difficulties, both those of old and those of recent date should be allowed their respective share of plausibility, while the defects of each should be equally kept in view. It is a mistaken idea to suppose, that enthusiasm in favour of one system is in any degree necessary to keep up the spirit of science. Such an enthusiasm partakes of intemperance; the activity to which it gives birth is of a spurious complection, and is not of that kind which promises greatest durability. Dr. Hutton's private character was highly amiable. His manners were simple, but his conversation was animated. A combination of sincerity and ardour gave a charm to his company in the eyes of all his learned friends, though he was not formed on such a model as to fit him for gay or general society, which he did not relish or in any degree cultivate. His expressions in explaining his views of points of science were remakably clear and forcible, and would not have led his friends to expect so much obscurity as is found in some of his writings. For an interesting view of his character and pursuits, we refer to the account of him published in the 5th volume of the *Transactions of the Royal Society of Edinburgh*, from the pen of his friend Professor Playfair. From that source the present short abstract has been chiefly taken. (*H. D.*)

HUYGENS, Christian, a celebrated mathematician and natural philosopher, was born at the Hague on the 14th April 1629. He was the son of Constantine Huygens, Lord of Zelem and Zuylichem, who had acted as secretary and counsellor to three successive princes of the house of Orange. Constantine Huygens was not only a poet, but a good mathematician, and took particular pleasure in the instruction of his son, who, at the early age of thirteen, exhibited an ardent passion for mathematical learning, and was constantly occupied in examining all the machines and pieces of mechanism that accident threw in his way. In the sixteenth year of his age he went to the university of Leyden, to study law, under Professor Vinnius; but he still pursued his mathematical studies, in which he was assisted by the learned Professor Schooten, the commentator of Descartes. After remaining a year at Leyden, he prosecuted his studies at the university of Breda, which had been newly established, and placed under the direction of his father. In the year 1649, he travelled into Holstein and Denmark, in the suit of Henry, Count of Nassau; but on account of the short stay which that prince was to make in Denmark, he was prevented from visiting Descartes in Sweden, an object which he was very anxious to accomplish.

In the year 1651, he began his career as an author, by publishing a refutation of the famous work of Gregory St Vincent, entitled *Opus Geometricum quadraturæ circuli et sectionum Coni.* Huygens' reply, which is considered as a model of distinctness and precision, was entitled *Exetasis quadraturæ circuli P. Greg. à sancto Vincentio*, 4to. He published, in the same year, his *Theoremata de circuli et hyperbolæ Quadratura;* and in 1654 appeared his ingenious work, entitled *De circuli magnitudine inventa nova, accedunt problematum quorundam illustrium constructiones.* In 1656, he travelled into France, and took out his degree of Doctor of Laws at the university of Angers. The new subject of the calculation of probabilities, which had been successfully begun by Pascal and Fermat, and which has recently been so much advanced by La Place, now occupied the attention of Huygens, who developed the principles of the science in his treatise *De Ratiociniis in Ludo Aleæ*, which appeared in 1657. In the same year he printed his *Brevis institutio de Usu Horologiorum ad inveniendas Longitudines*, in which he described the model of a newly invented pendulum. In 1659, Huygens published his *Systema Saturninum, sive de causis mirandorum Saturni phenomenon, et comite ejus Planeta novo*, which contains the various important discoveries relative to the planet Saturn, of which we have already given a full account. See Astronomy.

In the year 1660, Huygens travelled into France; and in the following year he came to England, where he made known his method of grinding the lenses of telescopes. In the year 1663, he paid a second visit to this country, and was one of the hundred individuals who were declared members of the Royal Society at a meeting of the council held on the 20th May 1663. At this time the Royal Society had requested its members to apply themselves to the consideration of the laws of motion, and Huygens resolved several of the cases which were proposed to him. On the 15th November 1668, Dr Wallis communicated to the Society his principle of the collision of bodies. Doctor, afterwards Sir Christopher, Wren made a similar communication on the 17th of December; and on the 5th January 1669, Huygens wrote a letter to Mr Oldenburgh, containing his first four rules, with their demonstration, concerning the motion of bodies after impact. The method of Wallis was the most direct, but related only to bodies absolutely hard. Wren's method was founded on the same principle, but related only to elastic bodies; and the method of Huygens was the very same as that of Wren.

Huygens had now acquired such a reputation, that, in the year 1663, he was invited by Colbert to settle in France. He accepted of the honourable and advantageous conditions which were offered to him, and took up his residence in Paris in 1666, when he was admitted into the Academy of Sciences. In 1668, he published, in the *Journal des Sçavans*, and also in the Memoirs of the Academy, a paper entitled *Examen du livre intitulé Vera Circuli et Hyperboles quadratura a Jacobo Gregorio*, which led to the dispute of which we have already given some account in our life of Gregory. In the year 1673, he published his great work, entitled *Horologium oscillatorium; sive de motu pendulorum ad horologia aptato demonstrationes geometricæ*, in which he published his great discovery of applying pendulums to clocks, and rendering all their vibrations isochronous, by causing them to vibrate between cycloidal cheeks. This discovery was made about the year 1656; and about the middle of 1657, he presented to the States of Holland a clock constructed on this new prienciple. In our article Horology,* we have given a description and a drawing of this machine. The contrivance of cycloidal cheeks, however, though exceedingly beautiful in theory, was found in practice to be of no advantage.

About this time our author invented the spiral spring for regulating the balances of watches, without knowing what had been done by Dr Hooke; and he applied to the French government for the exclusive privilege of employing it. The Abbé Hautefeuille had, however, conceived the first idea of this invention, and communicated to the Academy of Sciences, in 1674, the secret of regulating the balances of watches " by a small straight spring made of steel." He therefore disputed Huygens' right to the exclusive privilege, and the affair was accommodated in consequence of Huygens renouncing his claim. The observations of Montucla on this subject are certainly unjust towards the Abbé Hautefeuille, when he characterises his invention as rude and clumsey, and claims all the merit for Huygens. The idea of regulating the balance by a spring was certainly the principal part of the invention, which is unquestionably due to the Abbé Hautefeuille; while Huygens is entitled to the credit of having perfected the invention, by giving a spiral form to the spring.

Huygens would probably have continued in France during the remainder of his life, had it not been for the revocation of the edict of Nantz. He resolved to remain no longer in a country where his religion was proscribed, and

* See Horology, and Plate CCC. Fig. 4.

its professors persecuted; and, anticipating the fatal edict, he returned to his native country in 1681.

After his return to Holland, he continued to prosecute his favourite studies with his usual zeal. In 1684, he published his *Astroscopia Compendiaria tubi Optici molimine liberata*, in which he gives an account of a method of using telescopes of great focal length, without the incumbrance of a tube. He published also in 1690, at Leyden, his *Traité de la Lumiere*, and his *Tractatus de Gravitate*. The first of these works contains his Theory of Light, which he supposes to be propagated like sound, by the undulation of an elastic medium,* and the beautiful law by which he represented all the phenomena of double refraction, as exhibited in Iceland spar. The remainder of our author's life was occupied in composing a work on the plurality of worlds, entitled Κοσμοθεωρος. *sive de terris celestibus, eorumque ornatu conjecturæ*. While this work was in the printer's hands, Huygens was seized with an illness, which proved fatal on the 5th of June 1695.

All his papers were bequeathed by his will to the Library of Leyden, with a request that Burcher de Volder and Fullenius, two excellent mathematicians, should print such of them as seemed of most importance. In the year 1700, this posthumous volume was published. The *Cosmotheorios* had appeared in 1698, and was speedily translated into French, English, German, and Dutch. In 1703, there appeared another posthumous volume, entitled Christiani Hugenii *Dioptrica, Descriptio Automati planetarii; de parheliis, Opuscula Posthuma*. This work contains Huygens' interesting dissertation on coronæ, and mock suns, of which we have given a short account in our article Halo. And which was reprinted by Dr Smith in his *Complete System of Optics*. A complete edition of the works of Huygens was published, in four volumes, by M. S'Gravesende. The two first appeared at Leyden in 1724, in 4to. entitled *Opera Varia*, and the two last at Amsterdam in 1728, entitled *Opera Reliqua*. He published also several papers in the early volumes of the *Philosophical Transactions*, and in the *Memoirs of the Academy of Sciences*. In the *Machines Approuvées par l'Academie*, tom. i. p. 71 and 72, he has published two papers, one of which is entitled *Machine pour Mesurer la force mouvante de l'air*; and the other, *Maniere d'empecher les vaisseaux de se briser lorsqu'il echouent*. He also published a letter on a new microscope, in the *Collections Academiques*, tom. i p. 281; and another on the Toricellian experiment, in the second volume of the same work.

Christian Huygens was unquestionably one of the most eminent mathematicians and natural philosophers of the age in which he lived. His application of the pendulum to regulate the motion of clocks; his beautiful investigation of the isochronism produced by making pendulums swing between cycloidal cheeks; his discovery of the ring and satellites of Saturn; his application of the spiral spring to regulate the balances of watches, (in which, however, he was anticipated by Dr Hooke;) his discovery of the law of collision, which he shares with Dr Wallis and Sir Christopher Wren; his theory of the centre of oscillation; his investigations respecting central forces; and the beautiful law, by which he has represented the phenomena of double refraction, exhibit the depth and variety of his attainments, and entitle him to a very high rank among those illustrious men who have done honour to their species. In our articles Astronomy, Halo, Horology, Mechanics, and Optics, the reader will find an ample account of his various labours.

HUYGEN's Temperament of the musical scale. In 1682, M. Christian Huygens published his *Cyclus Harmonicus*, or commensurate system, of thirty-one equal divisions in the octave; of which his mean tone is five, and major limma 3, of these divisions. The temperaments calculated by Mr Farey's 12th scholium, in the *Philosophical Magazine*, vol. xxxvi. p. 52, are as follows, viz. V—2.651765Σ, III+0.400802Σ, and VI—3 05256Σ. In p. 224. of the second edition of Dr Smith's *Harmonics*, he gives the monochord lengths of strings for each of the notes of this system; and at p. 207. he mentions a method by which the beats of its concords may nearly be obtained: but this being neither sufficiently easy of application, or exact enough, we have calculated them anew, as follows, viz.

| 1. | 2. | | | 3. | 4. | 5. | 6 | 7. | 8. | 9. |
|---|---|---|---|---|---|---|---|---|---|---|
| C | 612.000000 | 12 | 53 | 480.0000 | | | | | | |
| B | 552.741175 | 11 | 49 | 448.8583 | 9.2608 | 51.7853 | 5.3810 | 4.0233 | 1.6234 | 7 7449 |
| ♭B | 513.303530 | 10 | 44 | 429.2280 | 65 6060 | .9712 | 5.1456 | 3 8480 | 77.4450 | 7.4058 |
| A | 454.044705 | 9 | 40 | 401.3804 | 8.2824 | .9076 | 4.8118 | 3 5984 | 1.4532 | 6.9254 |
| ♯G | 394.785880 | 8 | 36 | 375.3394 | 7.7449 | 43.3030 | 4 4996 | ♯22.0202 | 1 3582 | 49 0570 |
| G | 355.348235 | 7 | 31 | 358 9243 | 7.4058 | .8117 | 4.3028 | 3.2173 | 1.2984 | 6 1927 |
| ♯F | 296.089410 | 6 | 27 | 335.6379 | 6.9254 | 38.7225 | 5.3810 | 3 0089 | 1 2142 | 43.8681 |
| F | 256.651765 | 5 | 22 | 320.9590 | 49.0570 | .7266 | 4.0233 | 2 8770 | 57 9100 | 5.5384 |

| C | 0. | 0 | 0 | 240.0000 | 4.9520 | .5428 | 2.8770 | 2.1514 | 43.3030 | 4.1412 |
| Notes. | Σ Value of the Notes. | +f | +m | Vibrations in 1″ of time. | *Sharp* of 3ds on | *Sharp* of IIIds on | *Sharp* of 4ths on | *Flat* of Vths on | *Flat* of 6ths on | *Flat* of VIths on |
| | | | | | Beats in 1 Second of Time. | | | | | |

* This doctrine has found an able supporter in Dr Thomas Young; but recent discoveries respecting the polarisation of light seem to give a new degree of probability to the doctrine of the emanation of material particles.

In column 2. the values of the notes are given as they arise in calculating by the series of tempered fifths, as above, its wolf fifth ♯G ♭E being V+17.161553Σ. Col. 3. is as usual, adapted to the octave above the tenor cliff C. All the beatings in columes 5. to 9. are *sharp* or *flat*, as marked at the bottom of each column, except the 4th and Vth wolves, which are contrary to all the others of these concords.

Mr Ambrose Warren, in a thin quarto work, called *The Tonometer*, published in 1725, gave the lengths of strings for this system, without any intimation of its having been before published by M. Huygens. (ϱ)

HYÆNA. See Hunting, and our article Mammalia.

# HYBERNATION OF ANIMALS.

The changes which take place in the condition of Plants at the approach of winter are familiar to all of us. In the course of a few weeks in autumn, the fields exchange their dress of summer green for the harvest yellow, while the forests acquiring an orange hue, speedily become leafless. While these alterations are taking place, the vital principle retires to the roots, or is in part condensed in the buds. In this state of preparation, the various tribes of perennial plants await the approach of winter,—a state which is termed their *hybernation*. As this department of vegetable physiology has been already illustrated in the article Botany, and may be found fully explained in the elementary works on that science, we refrain from farther discussion on the subject.

In the *Animal Kingdom*, changes equally remarkable precede the rigours of winter. The swallow forsakes the windows of the altar, the landrail retires from the fields, and the cuckoo deserts the hedges. The nightingale ceases to pour fourth her evening song, and in the grove all the warblers are silent. The lost or broken feathers of birds are renewed, to complete their covering, and to enable them, if necessary, to retire to warmer regions. Quadrupeds, and other animals, obtain an additional supply of clothing, collect a stock of provisions, or peacefully fall into a temporary lethargy. In these various conditions, animals prepare to pass the winter, or are said to *hybernate*.

This subject is still involved in much obscurity. It does not immediately interest us, as being but remotely connected with the ordinary concerns of life. Hence we possess few well established facts, and even those which have been ascertained, are still widely scattered in various publications; as naturalists in general are more anxious to establish the nomenclature of animals, than to investigate their habits and instincts.

Naturalists are in the practice of restricting the term *hybernation*, to that condition of animals during the winter season more familiarly expressed by the term *torpidity*. We are not aware of any reason to induce us thus to limit the original meaning of the word; and therefore, in this article, we use it as expressing the various conditions in which animals are found during the winter season, and the circumstances by which these conditions are distinguished.

The subject naturally divides itself into four branches, corresponding with the different states of hybernation which animals exhibit. The first includes those animals which obtain a change of dress;—the second, those which provide for themselves a store of food;—the third, those which migrate; and the fourth, those that become torpid.

## CHAP. I.

### Hybernating Animals which obtain a Supply of Clothing.

"Ante omnia (says Pliny when comparing the condition of man with that of the inferior animals) unum animantium cunctorum alienis velat opibus: cæteris varia tegumenta tribuit, testas, cortices, coria, spinas, villos, setas, pilos, plumam, pennas, squamas, vellera. Truncos etiam arboresque cortice, interdum gemino, a frigoribus et calore tuata est. Hominem tantum nudum, et in nuda humo, natali die abjicit ad vagitus statim et ploratum, nullumque tot animalium aliud ad lacrymas, et has protinus vitæ principio." But this condition of man is most agreeable to his nature, as he can provide for himself a suitable covering, and accommodate his dress to all climates, seasons, and occupations.

As the inferior animals do not possess such powers of contrivance, we find that nature has furnished them with clothing suited to their situations and habits. Hence those animals, whose appointed residence is in the warm regions of the earth, are in possession of the thinnest coverings; while those which are destined to dwell in the arctic regions, are enveloped in fur. Thus in the climate of Spain and Syria, the dog and the sheep have fine tufty and silky hair; while in the Siberian dog and Iceland ram, the hair is long and rigid. In still warmer regions than those which we have mentioned, the fur becomes so very thin, that the animals may be considered as naked. This is strikingly illustrated in the dogs of Guinea, and in the African and Indian sheep.

The clothing of animals living in cold countries, is essentially different from that of the animals of warm regions in another respect. If we examine the fur of the swine of warm countries, it consists entirely of bristles or hair of the same form and consistency; but those which live in colder districts possess not only common bristles or strong hair, but a fine frizzled wool next the skin, over which the long hairs project. This statement may easily be verified, by a comparison of the fur of the swine of the south of England with that which is found on those of the Scottish Highland breed. The same observation may be made on the sheep of warm and cold countries. The fleece of those of England consists entirely of wool; while those of Zetland, Iceland, and other northern regions, besides the wool, contains a number of long hairs, which at first sight give to the fleece while on the back of the animal, the appearance of great coarseness. The living races of rhinoceros and elephant of southern regions have scarcely any fur on their bodies; while those which have formerly resided in the middle and northern parts of Europe, now only found in a fossil state, have been covered with long hair, and a thick coating of short frizzled wool.

Climate in this case exercises a powerful influence over the secretions of these animals, in the increase or diminution of their clothing. Were such changes not to take place, the inhabitants of cold countries would perish by the inclemency of the weather, while those of warmer regions would be exhausted by a profuse perspiration.

The effects which climate is here represented as producing on the clothing of animals, are also observable as the annual result of the season of the year in all the temperate and cold regions of the earth. There is always an increase in the quantity of covering during the winter season, and not unfrequently a change in its colour. Let us now attend to each of these changes.

Increase in the quantity of clothing.—If we attend to the condition of the clothing of our domestic animals previous to winter, we shall witness the changes which take place. The fur is not merely renewed, but it is increased in quantity and length. This is very plainly exhibited in those quadrupeds which are kept out of doors, and exposed to the vicissitudes of the weather. But even with those animals kept in houses during the winter, the length and thickness of the fur vary according to the warmth of their habitations; and as the temperature of these habitations depends in part on the elevation, so we find the cattle living on farms near the level of the sea, covered with a shorter and thinner fur than those which inhabit districts of a higher level. Hence if we look at the horses, for example, of the farmers in a market day in winter, we might determine the relative temperature of their respective farms, from the relative quantity of clothing provided by nature for the animals which live on them.

This winter covering, if continued during the summer, would prove inconveniently warm. It is, therefore, thrown off by degrees as the summer advances; so that the animals which were shaggy during the cold months become sleek in the hot season.

This process of *casting the hair* takes place at different seasons, according to the constitution of the animal with respect to heat. The mole has, in general, finished this operation before the end of May. The fleece of the sheep, when suffered to fall, is seldom cast before the end of June. In the northern islands of Scotland, where the *shears* are never used, the inhabitants watch the time when the fleece is ready to fall, and pull it off with their fingers. The long hairs, which likewise form a part of the covering, remain for several weeks, as they are not ripe for casting at the same time with the fine wool. This operation of pulling off the wool, provincially called *rooing*, is represented by some writers, more humane than well-informed, as a painful process to the animal. That it is not even disagreeable, is evident from the quiet manner in which the sheep lie during the pulling, and from the ease with which the fleece separates from the skin.

We are in general inattentive with respect to the annual changes in the clothing of our domestic animals; but when in search of those beasts which yield us our most valuable *furs*, we are compelled to watch these operations of the seasons. During the summer months the fur is thin and short, and is scarcely ever an object of pursuit; while during the winter, it possesses in perfection all its valuable qualities. When the beginning of winter is remarkable for its mildness, the fur is longer in *ripening*, as the animal stands in no need of the additional quantity for a covering; but as soon as the rigours of the season commence, the fleece speedily increases in the quantity and length of hair. This increase is sometimes very rapid in the hare and the rabbit, whose skins are seldom ripe in the fur until there is a fall of snow, or a few days of frosty weather; the growth of the hair in such instances being dependent on the temperature of the atmosphere.

The *moulting* of birds is another preparation for winter, which is analogous to the casting of the hair in quadrupeds. During summer, the feathers of birds are exposed to many accidents. Some of them are torn off during their amorous quarrels; others are broken or damaged; while in many species they are pulled from their bodies to line their nests. Previous to winter, however, and immediately after the process of incubation and rearing of the young is finished, the old feathers are pushed off by the new ones, and in this manner the whole plumage of the bird is renewed. During this process of moulting, the bird seems much enfeebled, and, if previously in a weak state, is in danger of dying during the process. In consequence of this complete renewal of the feathers, the winter covering is rendered perfect, and the birds prepared for withstanding all the rigours of the season.

Change in the colour of the clothing.—The difference in point of colour between the summer and winter dress of animals is very conspicuously displayed both among the quadrupeds and birds. We are not aware that it has been observed among the cold-blooded animals.

Among quadrupeds, the Alpine hare (*Lepus variabilis*) is a very remarkable example. It is found, in this country, on the high mountains of the Grampian range. Its summer dress is of a tawny grey colour; but, about the month of September, its fur gradually changes to a snowy whiteness. It continues in this state during the winter, and resumes its plainer covering again in the month of April or May, according to the season. The *ermine* is another of our native quadrupeds, which exhibits in its dress similar changes of colour according to the season. It frequents the outskirts of woods and thickets. During the summer months its hair is of a pale reddish brown colour; in harvest it becomes clouded with pale yellow; and in the month of November, with us, it is of a snow white colour. Its winter dress furnishes the valuable fur called ermine. Early in spring, the white becomes freckled with brown, and in the month of May it completely resumes its summer garb.

Among the feathered tribes such instances of change of colour in the plumage during winter are numerous. They greatly perplex the ornithologist, and have been the means of introducing into the system several spurious species. The white grous or ptarmigan (*Tetrao lagopus*) may be produced as a familiar example of this kind of hybernation. This bird, like the Alpine hare, inhabits the higher Grampians, and is never found at a great distance from the limits of the snow. In summer its plumage is of an ash colour, mottled with small dusky spots and bars. At the approach of winter the dark colours disappear, and its feathers are then found to be pure white. In remarkably mild winters the change is sometimes incomplete, a few dusky spots of the summer dress remaining. In spring its winter garb becomes again mottled, and the bird loses much of its beauty. Even the young birds in their first dress resemble their parents in their mottled plumage, and like them become white at the approach of winter.

Among the aquatic birds similar changes in the colour of the plumage have been observed. The black guillemot (*Uria grylle*), so common on our coasts, is of a sooty black colour during the summer, with a white patch on the wings. During winter, however, the black colour disappears, and its plumage is then clouded with ash-coloured spots on a white ground. In the winter dress, it has been described by some as a distinct species, under the name of the *spotted guillemot*. In the more northern regions, as in

Greenland, for example, this bird, in winter, becomes of a pure white colour. This is a decided proof of the influence of temperature in producing this change of colour. There is a fine example of this bird in its white winter dress in the collection of the Dublin Society, where we saw it a few months ago. It was brought from Greenland by that intelligent and enterprising naturalist Sir Charles Giesecké.

These changes of colour, which we have already mentioned, extend throughout the whole plumage of the bird; but in other instances, the change extends to only a small part of the plumage. Thus the little auk (*Alca alle*) during summer has its cheeks and throat of a black colour, but in winter these parts become dirty white. In this its winter garb, it is often shot on our coasts. Its summer dress induced Pennant to consider it as a variety, and as such to figure it. The black headed gull (*Larus ridibundus*) has a black head during summer, as its trivial English name intimates. During the winter, however, the black colour on the head disappears; and, when in this dress, it has been regarded by many as a distinct species, under the name of the *red-legged gull*.

In many other birds there is a remarkable difference in point of colour between the summer and the winter plumage, although not so striking as those which we have noticed. The colours of the summer feathers are rich and vivid; those of the winter obscure and dull. This is well illustrated in the Dunlin, (*Tringa alpina*,) whose summer plumage has much black and rufous colour, but whose winter plumage is dull and cinereous. In its winter dress it has been described as a distinct species, under the trivial name of *T. cinclus*, or Purre. Similar instances might be produced in the case of the Wagtails, Linnets, and Plovers, and a great many other birds.

From the preceding statements, we are naturally led to inquire, in what manner these changes in the colour of the dress are produced? It has been supposed by some, that those quadrupeds, which, like the alpine hare and ermine, become white in winter, cast their hair twice in the course of the year; at harvest, when they part with their summer dress, and in spring, when they throw off their winter fur. This opinion does not appear to be supported by any direct observations, nor is it countenanced by any analogical reasonings. If we attend to the mode in which the hair on the human head becomes grey as we advance in years, it will not be difficult to perceive, that the change is not produced by the growth of new hair of a white colour, but by a change in the colour of the old hair. Hence there will be found some hairs pale towards the middle, and white towards the extremity, while the base is of a dark colour. Now, in ordinary cases, the hair of the human head, unlike that of the inferior animals, is always dark at the base, and still continues so during the change to grey; hence we are disposed to conclude from analogy, that the change of colour, in those animals which become white in winter, is effected, not by a renewal of the hair, but by a change in the colour of the secretions of the rete mucosum, by which the hair is nourished, or perhaps by that secretion of the colouring matter being diminished, or totally suspended.

As analogy is a dangerous instrument of investigation in those departments of knowledge which ultimately rest on experiment or observation, so we are not disposed to lay much stress on the preceding argument which it has furnished. The appearances exhibited by a specimen of the ermine now before us are more satisfactory and convincing. It was shot on the 9th May, (1814,) in a garb intermediate between its winter and summer dress. In the belly, and all the under parts, the white colour had nearly disappeared, in exchange for the primrose yellow, the ordinary tinge of these parts in summer. The upper parts had not fully acquired their ordinary summer colour, which is a deep yellowish brown. There were still several white spots, and not a few with a tinge of yellow. Upon examining those white and yellow spots, not a trace of interspersed new short brown hair could be discerned. This would certainly not have been the case, if the change of colour is effected by a change of fur. Besides, while some parts of the fur on the back had acquired their proper colour, even in those parts numerous hairs could be observed of a wax yellow, and in all the intermediate stages from yellowish brown, through yellow, to white.

These observations leave little room to doubt, that the change of colour takes place in the old hair, and that the change from white to brown passes through yellow. If this conclusion is not admitted, then we must suppose that this animal casts its hair at least seven times in the year. In spring, it must produce primrose yellow hair; then hair of a wax yellow; and, lastly, of a yellowish brown. The same process must be gone through in autumn, only reversed, and with the addition of a suit of white. The absurdity of this supposition is too apparent to be farther exposed.

With respect to the opinion which we have advanced, it seems to be attended with few difficulties. We urge not in support of it, the accounts which have been published of the human hair changing its colour in the course of a single night; but we think the particular observations on the ermine warrant us in believing that the change of colour in the alpine hair is effected by a similar process. But how is the change accomplished in birds?

The young ptarmigans are mottled in their first plumage similar to their parents. They become white in winter, and again mottled in spring. These young birds, provided the change of colour is effected by moulting, must produce three different coverings of feathers in the course of ten months. This is a waste of vital energy, which we do not suppose any bird in its wild state capable of sustaining; as moulting is the most debilitating process which they undergo. In other birds of full age, two moultings must be necessary. In these changes, the range of colour is from blackish grey, through grey, to white, an arrangement so nearly resembling that which prevails in the ermine, that we are disposed to consider the change of colour to take place in the old feathers, and not by the growth of new plumage; this change of colour being independent of the ordinary annual moultings of the birds.

Independent of the support from analogy which the ermine furnishes, we may observe that the colours of other parts of a bird vary according to the season. This is frequently observable in the feet, legs, and bill. Now, since a change takes place in the colouring secretions of these organs, what prevents us from supposing that similar changes take place in the feathers? But even in the case of birds, we have before us an example as convincing as the ermine already mentioned. It is a specimen of the little auk, (*Alca alle*,) which was shot in Zetland in the end of February, 1810. The chin is still in its winter dress of white, but the feathers on the lower part of the throat have assumed a dusky hue. Both the shafts and webs have become of a blackish grey colour at the base and in the centre, while the extremities of both still continue white. The change from black to white is here effected by passing through grey. If we suppose that in this bird the changes of the colour of the plumage are accomplished by moulting, or a change of feathers, we must admit the existence of three such moultings in the course of the year—one by which the white winter dress is produced, another for the dusky spring dress, and a third for the black garb of summer. It is surely unnecessary to point out any other examples in support of our opinion on this subject. We have followed nature, and our conclusions appear to be justified by the appearances which we have described.

Having endeavoured to ascertain the manner in which this change of colour takes place, we are now ready to investigate the causes by which it is produced. As this change of colour in winter is peculiar to the animals which inhabit cold countries, we may safely conclude, that temperature exercises over it a powerful influence. This supposition is countenanced by the slowness of the process of change of colour in a mild autumn, and its imperfect accomplishment during a mild winter. Besides, in some animals, such as the black guillemot, the change is never complete in the more temperate regions, but becomes more perfect as we proceed northwards, until at Greenland the bird is of a pure white. If this change of colour proceeds from a renewal of feathers, here at least the colour of the feathers must be considered influenced by the temperature, and consequently a corresponding influence must be exercised on the secreting organs.

The distribution of colour in the animal kingdom in general seems to follow the same law; the deep and bright colours prevailing in the warm regions, while the tints of the colder regions are pale and dull. Are we to conclude, that cold diminishes the action of the vessels which furnish the colouring matter, and, when intense, entirely suspends their functions? or are we to consider light as in part concerned in producing the effect? In general, the fur of quadrupeds, and the feathers of birds, are darkest where exposed to the light, and are pale coloured towards the base; but in the instances before us this difference disappears, and a complete uniformity in all the parts of the covering prevails. Besides, the change does not take place on all parts of the body at the same time, but appears in spots, or on single hairs or feathers. Light therefore has little influence.

There is another agent besides cold apparently concerned in the change in the colour of the feathers of birds. In all birds the feathers become more vivid in spring, and certain spots appear which are not observable at other seasons. This brightness of plumage and these spots continue only during the season of love; and hence, instead of supposing them the production of new moultings, we consider them as resulting from the action of the generative impulse on the colouring secretions.

In attempting to account for these phenomena of nature, it has generally been supposed, that these periodical changes of colour take place, to enable the animals more readily to escape from their prey during the winter season. Thus Montagu, in reference to this subject, has the following reflections: "Here we perceive the ptarmigan invariably effect this curious, and, we may add, most providential change; for if the young of those birds at first assumed their snowy winter plumage, while yet the surface of the ground was not consonant with their colour, few would escape the piercing eye of the falcon or the eagle, in the lofty and exposed situations they are found to inhabit." To suppose that in winter the ptarmigan is rendered white, to cause it to resemble the snow and deceive birds of prey, and that the alpine hare undergoes similar changes for the same purpose, would be to yield our assent to public opinion. But all our conclusions concerning final causes ought to be the result of very extended observations; and if our observations on this subject are extended, some difficulties will present themselves. If this white colour yields protection to the ptarmigan and alpine hare, it must enable the ermine, an animal well qualified to provide for its wants at all times, by its determined boldness, extreme agility, and exquisite smell, to prey with greater certainty upon its defenceless neighbours. What protection, we would ask, is afforded to the black guillemot, during the winter, by its mottled plumage, or to the little auk by its white chin, since the whiter they become, so much the more unlike the dark colour of the water? Protection from foes, therefore, cannot be considered as the object of nature in these curious changes, especially as the change of colour, always from dark to white, does not differ, however different the habits and even stations of the animals may be.

Perhaps the laws of chemistry may furnish us with a more consistent and plausible explanation. If the radiating power of bodies with regard to heat be inversely as their reflecting power, a conclusion very generally admitted, then the white winter dress of these animals must be better calculated for retaining the heat generated in their bodies by the vital principle, than any other coloured dress which would possess greater radiating power, and, consequently, would more readily contribute to the reduction of their temperature. It is probable, therefore, that these changes in the quantity and colour of the clothing of animals, are designed by nature to regulate their temperature in the different seasons of the year.

## CHAP. II.

### Hybernating Animals which lay up a Stock of Provisions.

The kind of hybernation of which we treated in the last Chapter, is of more frequent occurrence than that which we are now to consider. In common with those animals, they obtain an addition to their clothing, while they differ from them in being provident of futurity. They collect with care the superabundant productions of autumn, and dispose of them in such a manner, as to furnish a supply of food when the fruits and flowers are destroyed by the frost. Such may with propriety be termed *storing animals*, as they all possess the industry so beautifully expressed by Virgil.

*Venturæque hiemis memores æstate laborem.*
*Experiuntur, et in medium quæsita reponunt.*

This class of hybernating animals contains but few species. These are all phytivorous, and, without exception, belong to the natural tribe of Glires or Gnawers. All the animals of this tribe do not possess this *storing* inclination, although it is certainly observable in many of them.

Of all those animals, whose industry in collecting, and wisdom in preserving a winter store, have attracted the notice of mankind, the beaver stands pre-eminently conspicuous. But, as the habits of that singular animal have been detailed under the article Beaver, we forbear in this place to reconsider the subject. And, as we rather wish to confine our remarks to British animals, wherever the subject will permit, we select as an example of this kind of hybernation, the common squirrel, (*Sciurus vulgaris*). This active little animal prepares its winter habitation among the large branches of an old tree. After making choice of the place where the timber is beginning to decay, and where a hollow may be easily formed, it scoops out with its teeth a suitable magazine. Into this storehouse, acorns, nuts, and others fruits are industriously conveyed, and carefully concealed. This granary is held sacred until the inclemency of the weather has limited the range of its excursions, and consequently diminished its opportunities of obtaining food. It then begins to enjoy the fruits of its industry, and to live contentedly in its elevated dwelling. All the species of mice seem to possess the inclination to lay up provisions; even the house mouse and the rat; but the field mouse is the most remarkable instance. Says the pious and intelligent Derham, "I have in autumn, not without pleasure, observed, not only the great sagacity and diligence of swine, in hunting out the stores of the field mice, but the wonderful precautions also of those little animals, in hiding their food before hand against winter. In the time of acorns falling, I have, by means of the hogs, discovered that the mice had, all over the neighbouring fields, treasured up single acorns in little holes they had scratched, and in which they had carefully covered up the acorn. These the hogs would, day after day, hunt out by their smell."

Among birds, reptiles, and fishes, no examples are known of this kind of hybernation. The bee, among insects, is an interesting example, but requiring no explanation. No instances occur among the animals which compose the inferior classes.

Since all these storing animals are destined to live on the productions of the vegetable kingdom, we witness the wise provisions of nature in assigning to them such propensities. By this faculty, existence is comfortably maintained, under circumstances which would prove fatal without it. The seeds of many plants are translated by them from the places of their growth, and more extensively disseminated. But how are we to account for the conduct of those animals, in thus providing for a futurity, who have never suffered from former inexperience, as must be the case with young animals—that in autumn, when the bounties of nature are scattered so profusely, they should subject themselves to much labour, in heaping up a treasure for supplying the deficiencies of a winter, of whose accompanying privations they are ignorant. Part of this industry may, in those animals which are gregarious, be the result of education; but in other instances, we must confess our inability to offer any explanation.

Such baffled searches mock man's prying pride,
The God of Nature is your secret guide.

## CHAP. III.

### Hybernating Animals which Migrate.

This subject has long occupied the attention of naturalists; and several important observations have been published by different authors. It is chiefly, however, as it regards birds, that the subject is deserving of particular consideration. We are acquainted with but few circumstances connected with the migration of quadrupeds. Limited in their powers of locomotion, their range of travelling is confined, so that other means are provided for their safety and sustenance during winter. The cheiroptera are well fitted for migrating; and accordingly we find that some species are known to do so. In Italy, the common bat (*Vespertilio murinus*) abounds; but it migrates southwards at the approach of winter, and is not found in any of the caves in a torpid state. The *V. noctula*, however, arrives annually to winter, although it retires to spend the summer in more northern regions. Dr Barton informs us, that some species of dipus migrate from the northern to the southern parts of America during winter. Many of the ruminating animals shift their habitations according to the changes of the year. Thus, the stag and the roebuck leave the alpine regions at the approach of winter, and seek protection in the more sheltered plains. More extensive migrations are performed by the palmated quadrupeds, particularly the *seals*. These shift their stations to reach safe breeding places, in whatever country they live in. But the common seal (*Phoca vitulina*) often performs regular migrations in quest of food. In the Statistical Account of the parish of North Knapdale, we are told that the lake called Lochow, about twenty miles in length, and three miles in breadth, "abounds with plenty of the finest salmon; and, what is uncommon, the *seal* comes up from the ocean, through a very rapid river, in quest of this fish, and retires to the sea at the approach of winter." Another species, the *P. Groenlandica*, seems to seek more temperate regions during the winter. Seals of this kind, says Horrebow in his History of Iceland, "arrive annually in the month of December, especially about the northern parts of the country, and generally stay till May, at which time those that escape the Icelanders depart." A few curious facts regarding the migrations of the Cetacea may be found under the article Greenland. Several kinds of small whales visit the coasts of Scotland, chiefly during the autumnal months; but we are ignorant of the places from whence they come, and unacquainted with the laws of their migration.

### *Migration of Birds.*

The migrations of the feathered race, as connected with their hybernation, have been the subject of popular observation since the days of the prophet Jeremiah. "Yea, the stork in the heaven knoweth her appointed times; and the turtle, and the crane, and the swallow, observe the time of their coming," (ch. viii. v. 7.) Many important facts have been ascertained, and a few general conclusions have been established. But the subject is still far from being exhausted; nay, without fear of contradiction, we may venture to assert, that it is but very imperfectly understood by naturalists in general. Popular errors have gained admittance as scientific documents, and the well authenticated facts have been suffered to remain in their original detached form, destitute of connection and arrangement.

It is not our intention to enter into any minuteness of detail regarding the migrations of the different species of birds. This has already been done under the article Birds, where the reader will find a statement of several facts connected with the migration of our native species. And he may also consult at his leisure, the ornithological productions of Pennant, White, and Montagu. Our observations in this place will be of a general nature, and will have for their object to ascertain the laws of migration, and the circumstances under which it takes place.

Migrating birds may be divided into two classes, from the different seasons of the year in which they arrive or depart. To the first class will belong those birds which arrive in this country in the spring, and depart in autumn, and are termed *Summer Birds of Passage*. The second will include those which arrive in autumn, and depart in spring, and are called *Winter Birds of Passage*.

The Summer Birds of Passage are not confined to any particular order or tribe; nor are they distinguished by similarity of habits. Some of them belong to the division of *Water Fowls*, as the terns and gulls; while others are *Land Birds*, as the swallow and rail. They differ also remarkably with regard to their food. Thus, the hobby is carnivorous; the gulls and terns, piscivorous; the swallow, insectivorous; and the turtle dove and the quail, granivorous.

In many particulars these summer birds of passage exhibit very remarkable differences. They, however, present one point of resemblance. All of them, during their residence in this country, perform the important offices of pairing, incubation, and the rearing of their young, and hence may with propriety be termed the natives of the country. We hail their arrival as the harbingers of spring, and feel the blank which they leave on their departure, although it is in some measure supplied by another colony of the feathered race, who come to spend with us the dreary months of winter.

The Winter Birds of Passage have more points of resemblance among themselves than those of the former division. They chiefly belong to the tribe of water-fowls. None of them are insectivorous, and very few are granivorous. They chiefly frequent the creeks and sheltered bays of the sea, and the inland lakes, or they obtain their food in marshy grounds, or at the margins of springs. When the rigours of the season are over, and when other birds which are stationary are preparing for incubation, these take their departure, to be again succeeded by our summer visitants.

We have stated generally, that our summer and winter birds of passage visit us at stated seasons of the year; that the summer visitants arrive in spring and depart in autumn; and the winter visitants arrive in autumn and depart in spring. But the different species do not all observe the same periods of arrival and departure. Thus, among the summer birds of passage, the wheat-ear always precedes the swallow, while the swallow arrives before the martin, and the martin before the landrail or cornerake. Among the winter birds of passage, similar differences in the time of arrival are observable. Thus the woodcock precedes the fieldfare, and the fieldfare the redwing. The time of departure has not been observed with so much attention, as the subjects have then lost their novelty, so that we do not so readily perceive their absence. It is probable, however, that in their departure, as well as their arrival, each species has its particular period.

The periods of arrival and departure, even in the same species, do not always take place at exactly the same day, or even month of the year. In different years these vary from one to four weeks, and evidently depend on very obvious circumstances. The meanest rustic, in regard to the summer birds of passage, is aware, that cold weather prevents the arrival of these messengers of spring; and that the early arrival of our winter birds of passage indicates a proportionally early winter. The same circumstances which retard our summer visitants also check the progress of vegetation. Hence, in all probability, we might be able to prognosticate the arrival of these birds, by attending to the time of the leafing or flowering of particular trees or plants. As the state of vegetation depends on the temperature of the season, and the life of insects on the state of vegetation, we may safely conclude, that the movements of the phytivorous and insectivorous birds must be dependant on these circumstances.

Linnæus bestowed some attention on these connected circumstances, in his Calendar of Flora for Sweden; and Stillingfleet in that of England. Linnæus observed, that the swallow returned to Sweden when the bird-cherry came into leaf, and when the wood-anemone flowered. He also found the arrival of the nightingale accompanied with the leafing of the elm. Stillingfleet says, that the swallow returns to Norfolk with the leafing of the hazel, and the nightingale with the leafing of the sycamore. It has also been observed, that the cuckoo sings when the marsh-marigold blows. It would tend greatly to increase our knowledge of this subject, were observations of this sort multiplied. We earnestly recommend the subject to the attention of the practical naturalist.

Having thus offered a few observations on the periods of arrival and departure of migrating birds, let us now enquire after *the places from whence they come, and to which they return.* In doing this, it will be proper to bestow some attention on those birds whose migrations are only partial, and which merely shift from one part of the island to another. The movements of these birds, though confined within narrow bounds, are probably regulated by the same laws which with other species produce more extensive migrations.

In the inland districts of Scotland, the lapwing makes its appearance about the end of February or the beginning of March, and, after performing the purposes of incubation, hastens to the sea-shore, there to spend the winter, picking up the small crustacea from among the rejectamenta of the sea. These birds seldom however remain all winter on the Scottish shores, though they are always to be found at that season on the southern English shores. In that part of the island they do not perform such extensive migrations, but may with propriety be considered as resident birds. The curlew arrives at the inland districts along with the lapwing, and they depart in company about the beginning of August. The curlew, however, remains on the Scottish shores during the winter. The oyster-catcher, though it breeds in Scotland, retires to the English shores during the winter, and joins those which have remained there during the breeding season. The black-headed gull breeds both in England and Scotland; but it retires from the last mentioned country, while it continues resident in the former.

From the examples quoted, it appears that some birds, which are stationary in one district, are migratory in another. But that which chiefly merits our consideration is the circumstance of those birds, whose annual migrations are confined to our own shores, forsaking the high grounds when the purposes of incubation have been accomplished, and seeking for protection at a lower level, and in a warmer situation. When these migrations become more extensive, they forsake the bleak moors and shores of Scotland for the warmer and more genial climate of England. Hence it happens, that some of our Scottish summer visitants come from England, while some of the English winter visitants come from Scotland: the summer birds of passage coming from the south, and the winter passengers from the north. Do those birds, whose migrations are more extensive, obey the same laws?

As the summer birds of passage are more interesting to us, since they perform the great work of incubation in our country, than the winter birds of passage, which are the harbingers of storms and cold, and only wait the return of spring to take their leave of us, we will endeavour to find out the winter residence of the former, before we attempt to discover the summer haunts of the latter. Natural history, it is true, is still in too imperfect a state, to enable us to point out with certainty the retreats of those birds which visit us during summer. But enough appears to be known to enable us to ascertain the laws by which these migrations are regulated in a number of birds, and as the points of resemblance in the movements of the whole are numerous, we can reason from analogy on safer grounds with regard to the remainder.

The swallow, about whose migrations so many idle stories have been propagated and believed, departs from Scotland about the end of September, and from England about the middle of October. In the latter month M.

Adanson observed them on the shores of Africa after their migrations from Europe. He informs us, however, that they do not build their nests in that country, but only come to spend the winter. The nightingale departs from England about the beginning of October, and from the other parts of Europe, about the same period. During the winter season it is found in abundance in Lower Egypt, among the thickest coverts in different parts of the Delta. The birds do not breed in that country, and to the inhabitants are merely winter birds of passage. They arrive in autumn and depart in spring, and at the time of migration are plentiful in the islands of the Archipelago. The quail is another of our summer guests, which has been traced to Africa. A few indeed brave the winters of England, and in Portugal they appear to be stationary. But in general they leave this country in autumn, and return in spring. They migrate about the same time from the eastern parts of the continent of Europe, and visit and revisit in their migrations the shores of the Mediterranean, Sicily, and the islands of the Archipelago. When speaking of this subject, the intelligent Willoughby adds, that "when he sailed from Rhodes to Alexandria in Egypt, many quails from the north towards the south were taken in our ship; whence I am verily persuaded that they shift places: for formerly also, when I sailed out of the isle of Zante to Morea, or Negropont, in the spring time, I had observed quails flying the contrary way, from south to north, that they might abide there all summer. At which time also there were a great many taken in our ship." *Ornith.* p. 170.

While these birds perform those extensive migrations which we have here mentioned, others are contented with shorter journies. Thus the razor-billed auk (*Alca torda*) and the puffin (*Alca arctica*) frequent the coast of Andalusia during the winter season, and return to us in the spring.

These facts, and many others of a similar nature, which might have been stated, enable us to draw the conclusion, that our summer birds of passage come to us from southern countries, and after all the purposes of incubation are accomplished, return again to milder regions. A few of our summer visitants may winter in Spain or Portugal; but it appears that in general they migrate to Africa, that unknown country, possessing every variety of surface, and consequently great diversity of climate. It is true that we are unacquainted with the winter retreats of many of our summer birds of passage, particularly of many small birds; but as these arrive and depart under similar circumstances with those whose migrations are ascertained, and as the operations which they perform during their residence with us are also similar, we have a right to conclude, that they are subject to the same laws, and execute the same movements. What gives weight to this opinion, is the absence of all proof of a summer bird of passage retiring to the north during the winter season.

In proof of the accuracy of the preceding conclusion, we may observe, that it is a fact generally acknowledged, that the summer birds of passage visit the southern parts of the country a few days, or even weeks, before they make their appearance in the northern districts. Thus the common swallow (*Hirundo rustica*) appears in Sussex about the beginning of the third week of April; while in the neighbourhood of Edinburgh it is seldom seen before the first of May. The cuckoo appears in the same district about the last week of April; in Edinburgh seldom before the second week of May. The reverse of this holds true with these summer visitants at their departure. Thus dotterels (*Charadrius morinellus*) forsake the Grampians about the beginning of August, and Scotland by the end of that month; while they return to England in September, and remain there even until November. A difference of nearly a month takes place between the departure of the goatsucker (*Caprimulgus Europæus*) from Scotland and from the south of England.

Having thus ascertained the winter haunts of our summer birds of passage, let us now endeavour to find out the summer retreat of our winter visitants. The conclusions which we have already established dispose us to look for these birds in countries situated to the northward. And as we are much better acquainted with the ornithology of those countries than of Africa, it will be in our power to prosecute our researches with greater certainty of success.

The snow bunting, (*Emberiza nivalis*), which is among the smallest of our winter guests, retires to the hoary mountains of Spitzbergen, Greenland, and Lapland, and there performs the purposes of incubation, making its nest in the fissures of the rocks. In these countries it is therefore a summer visitant, as it retires southwards in autumn, to spend the winter in more temperate regions. To the sea coasts of the same regions the little auk (*Alca alle*), and the black-billed auk (*Alca pica*), repair for similar purposes as the snow-flake. The *woodcock* winters with us, but retires in the spring to Sweden, Norway, and Lapland. Eckmark says of this bird, as a Swedish summer bird of passage, "Pullis in sylvis nostris exclusis, mare transmigrans, in Angliam avolat; ut ex Austria in Italiam. Vere autem novo, dum blatire incipit Tetrao tetrix, illinct descedunt, matrimonio junctæ ad nos revertentes." The fieldfare and the redwing resemble the woodcock in their migrations, depart at the same season, and retire for similar purposes to the same countries.

These instances may suffice to support the conclusion, that all our winter birds of passage come from northern countries, and that the winter visitants of the south of Europe become the summer visitants of its northern regions. This is evidently an arrangement depending on the same law by which the African winter birds of passage are summer birds of passage in Europe.

In support of this conclusion it may be mentioned, that, in their progress southward, the winter birds of passage appear first in the northern and eastern parts of the island, and gradually proceed to the southward and westward. Thus the snow-bunting arrives in the Orkney islands about the end of August, and often proves destructive to the corn fields. It then passes into the mainland of Scotland, and is seldom seen in the Lothians, even in the high grounds, before November. In like manner, the woodcock, which crosses the German Ocean, is first observed on the eastern side of the island, and then by degrees disperses towards the west.

Having now ascertained the period and the direction of these migrations, let us next attend to the act of migration itself, and the circumstances attending the flight.

Migrating birds, before they take their departure, in general collect together in flocks. This is very obviously the case with the swallow, and is even still better known with woodcocks. These last arrive in this country in great flocks about the same time; and should adverse winds occur at the period of their departure, they accumulate in such numbers on the eastern shores, as to furnish the fowler with excellent sport. Geese too, during their migratory flights, always keep in company; and the picture which the poet draws of the movements of the crane is equally just when applied to them, only we do not vouch for the truth of their geometrical precision, and their knowledge of the power of the wedge.

> ————In figure wedge their way,
> Intelligent of seasons; and set forth
> Their airy caravan, high over seas
> Flying, and over lands: so steers the prudent crane
> Her annual voyage, borne on winds: the air
> Floats as they pass, fann'd with unnumbered plumes.
> MILTON.

But there are many migrating birds which have never been observed to congregate previous to their departure. Thus the cuckoo, seldom seen in company with his mate even during the breeding season, is to all appearance equally solitary at the period of migration. These birds are supposed by naturalists to go off in succession.

It is certainly a very curious, and perhaps unexpected occurrence, that the males of many species of migrating birds appear to perform their migrations a few days before the females. This is remarkably the case with the nightingale. The bird catchers in the neighbourhood of London obtain only males on the first arrival of this bird. The females do not make their appearance for a week or ten days after. Similar observations have been made with respect to the wheatear (*Motacilla œnanthe.*)

Those birds which feed during the night, may be expected to perform their migrations during the same interval, it being the season of their activity; while those birds which feed during the day, may be expected to migrate with the help of light. The migrations of the woodcock and quail confirm this conjecture. The woodcocks arrive in this country during the night, and hence they are sometimes found in the morning, after their arrival, in a neighbouring ditch, in too weak a state to enable them to proceed. Poachers are aware that they migrate during the night, and sometimes kindle fires on the coast, to which the woodcocks, attracted by the light, bend their course, and in this manner great numbers are annually destroyed. Quails, on the other hand, perform their migrations during the day, so that the sportsman in the islands of the Mediterranean can use his dog and gun.

It has often excited surprise in the minds of some, how migrating birds could support themselves so long on wing, so as to accomplish their journies, and at the same time live without food during their voyage. These circumstances have induced many to deny the existence of migration, and has excited others to form the most extravagant theories on the subject, to account for the preservation of these birds during the winter months. But the difficulties which have been stated, are only in appearance, and vanish altogether if we attend to the rapidity of the flight of birds.

The rapidity with which a hawk and many other birds occasionally fly, is probably not less than at the rate of one hundred and fifty miles in an hour. Major Cartwright, on the coast of Labradore, found, by repeated observations, that the flight of an eider duck (*Anas mollissima*) was at the rate of ninety miles an hour. Besides, it is generally known, that a falcon which belonged to Henry the Fourth of France, escaped from Fontainbleau, and in twenty-four hours afterwards was found at Malta, a distance computed to be no less than thirteen hundred and fifty miles; a velocity nearly equal to fifty-seven miles an hour, supposing the falcon to have been on wing the whole time. But as such birds never fly by night, and allowing the day to be at the longest, his flight was perhaps equal to seventy-five miles an hour. It is probable, however, says Montagu, that he neither had so many hours of light in the twenty-four to perform his journey, nor that he was retaken the moment of his arrival. But if we even restrict the migratory flight of birds to the rate of fifty miles an hour, how easily can they perform their most extensive migrations! And we know, in the case of woodcocks, and perhaps all other migrating birds, that they in general take advantage of a fair wind with which to perform their flights. This breeze perhaps aids them at the rate of thirty or forty miles an hour; nay, with three times greater rapidity, even in a moderate breeze, if we are to give credit to the statement of aërial navigators, who seem to consider the rate of the motion of winds as in general stated too low.

It has been already observed, that many species do not perform their migrations at once, but reach the end of their journey by short and easy stages. There is little exertion required from such; while those who execute their movements at one flight, (if there be any that do so,) may in a very short time, perhaps a day, by the help of a favourable breeze, reach the utmost limits of their journey. Many birds, we know, can subsist a long time without food; but there appears to be no necessity for supposing any such abstinence, since, as Catesby remarked, every day affords an increase of warmth and a supply of food. Hence we need not perplex ourselves in accounting for the continuance of their flight, or their sustenance in the course of it. Such journies would be long indeed for any quadruped, while they are soon performed by the feathered tribes.

It is often stated as a matter of surprise, how these birds know the precise time of the year at which to execute their movements, or the direction in which to migrate:—

> Who calls the council, states the certain day,
> Who forms the phalanx, and who points the way?

But this is merely expressing a surprise, that a kind and watchful Providence should bestow on the feathered creation, powers and instincts suited to their wants, and calculated to supply them. How, we ask, does the curlew, when perched upon a neighbouring muir during the flowing of the tide, know to return at the first of the ebb, to pick up the accidental bounty of the waves? How are the sea fowl, in hazy weather, guided to the sea-girt isles they inhabit, with food to their young, which they have procured at the distance of many miles? "The inhabitants of St Kilda," says Martin, "take their measures from the flight of these fowls, when the heavens are not clear, as from a sure compass; experience shewing, that every tribe of fowls bend their course to their respective quarters, though out of sight of the isle. This appeared clearly in our gradual advances; and their motion being compared, did exactly quadrate with our compass."

In the course of these annual migrations, birds are sometimes overtaken by storms of contrary wind, and carried far from their usual course. In such cases, they stray to unknown countries, or sometimes are found at sea in a very exhausted state, clinging to the rigging of ships. Such accidents, however, seldom happen, as these birds, year after year, arrive in the same country, and even return to the same spot. The summer birds of passage return not, it is true, in such numbers as when they left us; but, amidst all the dangers of their voyage, the race is preserved.

Having established the principal facts regarding the periods of migration, and the circumstances by which it is accompanied, it now remains for us to ascertain those proximate causes to which these movements are to be referred. Powerful indeed must be the causes which prompt those animals to forsake the woods in which they were reared, or the rocks on which they were hatched, and undertake a perilous journey to distant countries. They must be intimately connected with the first laws of life, otherwise the movements to which they give birth would not be so constant and uniform. The procuring of a supply of food, a suitable temperature, or a safe breeding place, are probably all the proximate causes which have any concern in such migrations.

If we attend to the *food* of many of our summer visitants, we may easily perceive, that it can only be procured during those months in which they remain with us. Subsisting chiefly on insects, they are compelled to shift their quarters, and retire to warmer districts at the end of our summer, in order to procure support. Montagu, when speaking of the cuckoo, makes the following pertinent observations. "Few birds but the titmice will devour the larvæ of the cabbage butterflies; and none that we have noticed make a repast on the hairy species of caterpillars but the cuckoo, who is a general devourer of all kinds of *Lepidopterous larvæ*, more especially the rough sort. It is therefore probable, that the early remigration of this bird is the defect of this favourite food, the greater part having by that time enclosed themselves, preparatory to a change. Of the many cuckoos we have dissected in the months of May and June, the stomach has always been found to contain more or less of the hairs of caterpillars, and sometimes quite full of them."

If insects are thus the favourite food of many of our summer birds of passage, it must frequently happen that their food will be scarce, even after their arrival in this country, owing to the variableness of our climate, and the dependence of the movements of insects on the temperature of the weather. Hence it happens, that some birds disappear again, retiring to other districts where insects are to be obtained. Montagu mentions a curious fact of this kind with regard to the chimney swallow. "It makes its first appearance with us in April, sometimes as early as the first week, if the weather is mild; and it sometimes happens, that after their arrival a long easterly wind prevails, which so benumbs the insect tribe, that thousands die for want of food. We recollect, as late as the ninth of May, the swallows on a sudden disappeared from all the neighbouring villages around. The thermometer was at 42°, and we were at a loss to conceive what was become of these birds, which a day or two before were seen in abundance. But by chance we discovered hundreds collected together in a valley close to the sea side, at a large pool which was well sheltered. Here they seem to have found some species of fly, though scarce sufficient to support them; for many were so exhausted, that after a short time on wing, they were obliged to pitch on the sandy shore." In the case of the waders, which obtain their food in the neighbourhood of springs and marshes, they are compelled to leave the regions of the north, where, during winter, these are all frozen, and the extent of their migration southwards depends on the severity of the weather.

A supply of food is certainly one of the proximate causes of migration, since we can support many of our summer visitants during the winter, as the nightingale for example, by giving them a regular supply of food. But powerful as this principle may appear, it is certainly not the only one in operation; as we observe one or two species of a genus migrating, while the others are stationary; and this taking place among granivorous as well as insectivorous birds. Equally powerful as the desire to obtain food, seems to be the love of a suitable *temperature*.

If we attend to the motions of the snow bunting, which is a granivorous bird, we find, that on its first arrival in this country it is only to be met with on the high grounds. As the temperature sinks at the approach of winter, it descends to a lower level, while it occupies the higher grounds in more southern districts. Its migrations to the south, therefore, depend entirely on the state of the winter. It has been attempted to preserve these birds during the summer season in this country, but, although liberally supplied with food, they have not survived. The experiment has succeeded, however, in America, with General Davies, who informs us, (*Linn. Trans.* vol. iv. p. 157.) that the snow bird of that country always expires in a few days, (after being caught, although it feeds perfectly well,) if exposed to the heat of a room with a fire or stove; but being nourished with snow, and kept in a cold room or passage, will live to the middle of summer; a temperature much lower than our summer heat proving destructive to these birds. The swallow, on the other hand, seems to delight in the temperature of our summer, and at that heat to be able to perform the higher operations of nature. When attempted to be kept during our winter, besides a regular supply of food, care must be taken to prevent it from being benumbed with cold. It is probably owing to some constitutional difference with respect to cold, that the female chaffinches in Sweden are migratory during winter, while the males are stationary. Eckmark, when speaking of the migrations of this bird, informs us, "*Mares* inter primas sunt aviculas, quæ sonum suum hieme usitatum in cantum vertunt jucundissimum: vere primo, sub initium *mensis regelationis*, arboribus ad pagos insidentes garruli, *fæminis* adhuc *absentibus*, ver indicant adstans. Redeuntibus denique turmis maximis, quæ cœlum fere abscondunt, *fæminis*, omnes conjuges requirunt, quibus conjuncti sylvas petunt, ibi ut nidulos construant et multiplicentur. Initio *mensis defoliationis* mares suos, apud nos remanentes, *fæminæ* deserunt mutabiles, solæ regiones petentes peregrinas." The same cause, namely temperature, renders some birds migratory in one country, while they are stationary in another. No separation of this kind takes place between the sexes of the chaffinch in this country. The linnet, which is a summer bird of passage in Greenland, is always stationary with us.

But, independent of these two causes, we presume, that the desire of obtaining a *safe breeding place* is likewise intimately connected with the movements of many species. "Of the vast variety of water fowl," says Pennant, "that frequent Great Britain, it is amazing to reflect how few are known to breed here: the cause that principally urges them to leave this country, seems to be not merely the want of food, but the desire of a secure retreat. Our country is too populous for birds so shy and timid as the bulk of these are. When great part of our island was a mere waste, a tract of woods and fens, doubtless many species of birds (which at this time migrate) remained in security throughout the year. *Egrets*, a species of heron, now scarce known in this island, were in former times in prodigious plenty; and the *Crane*, that has totally forsaken this country, bred familiarly in our marshes, their place of incubation, as well as of all other *cloven-footed water-fowl* (the heron excepted) being on the ground, and exposed to every one. As rural economy increased in this country, these animals were more and more disturbed; at length, by a series of alarms, they were necessitated to seek, during the summer, some lonely safe habitation. On the contrary, those that build or lay in the most inaccessible rocks that impend over the British seas, breed there still in vast numbers, having little to fear from the approach of mankind; the only disturbance they meet with, in general, being from the desperate attempts of some few to get their eggs." It happens, in consequence of this desire of safety during incubation, that the same species may be stationary at one place, while it is migratory at another. Thus, in the Western Islands, the common plover is stationary, while on the Grampians it is migratory. Herons may be met with along all the British shores during the winter season, while they are found congregated to breed in but few places. The turnstone is migratory in England, but stationary in the northern islands of Scotland. The same remark is applicable to the hooded crow, a few of which pass from us during the winter months into England, but return during the breeding season.

None of these causes, taken singly, may be able to account for the migrations of the feathered race; but, when viewed in connection, they seem to include all those proximate causes which operate in the production of these curious, and to us in some respects useful voyages. These migrations extend our knowledge of birds, by making us acquainted with the productions of the shores of Greenland, the mountains of Norway, and the marshes of Lapland. They also contribute to enliven the scenes of winter, and occasionally add to the delicacies of our table; while, in their movements, we discern the marks of benevolence in preserving their existence, increasing their happiness, and extending their usefulness.

We cannot dismiss this subject of migration without recommending it to the attentive consideration of our readers. To those who pass their time in the sweets of retirement in the country, it will prove a never-failing source of amusement; and to a reflecting mind, will yield no small portion of delight. The field of observation is extensive, the subject curious. "Quis non cum admiratione videat ordinem et polititiam peregrinantium avium, in itinere, turmatim volantium, per longos terrarum et maris tractus absque acu marina.—Quis eas certum iter in aëris mutabili regione docuit? Quis preteritæ signa, et futuræ viæ indicia? Quis eas ducet, nutrit, et vitæ necessaria ministrat? Quis insulas et hospitia illa, in quibus victum reperiat, indicavit, modumque ejusmodi loca in peregrinationibus suis inveniendi? Hæc sane superant hominum captum et industriam, qui non nisi longis experientiis, multis itinerariis, chartis geographicis—et acus magneticæ beneficio—ejusmodi marium et terrarum tractus conficere tentant, et audent."

As we descend in the scale of being, the instances of actual migration diminish in number. The locomotive powers of these animals, are too limited to enable them to undertake extensive journies, and when necessary to be protected from the cold of winter, nature employs, with respect to them, a more simple process, by subjecting them to a temporary lethargy. This is the case with reptiles, which present no instances of migration.

The migrations of fishes have long been the subject of keen discussion among naturalists. An agreement of opinion, however, has not been produced, although many observations have been published on the subject. Many of these observations, we fear, are the result of prejudiced inquiry, and ought therefore to be received with caution.

The movements of fishes are not performed with the same regularity and precision as the migrations of the feathered tribes. Shoals of haddocks, for example, frequent for several years a particular part of the coast, and, without any apparent cause, take their departure, accompanied with all those animals which feed on them. The movements of those fish which approach our shores, for the purpose of depositing their spawn, are more regularly performed. But these migrations can scarcely be considered as instances of hybernation. They have but little relation to the seasons of the year, as the fry of these fish may be found in almost every season in our rivers, and as their movements are known to depend on their condition with respect to fecundation. In our article Ichthyology, a particular account will be given of the migratory movements of the different species of British fishes.

Among the Mollusca, Cirrhipedes, and Annelides, no examples of a migrating hybernation have occurred. In the class Crustacea there is one very curious instance of migration, which the reader will find given in detail under the species *Ocypode uca*.

## CHAP. IV.

### Hybernating Animals which become Torpid.

This is one of the most curious subjects in zoology, and has long occupied the attention of the natural historian and the physiologist. All animals we know require stated intervals of repose to recruit exhausted nature, and prepare for further exertion,—a condition which we term sleep. But there are a few animals, which, besides this daily repose, require annually some months of continued inactivity, to enable them to undergo the common fatigues of life during the remaining part of the year. These animals exhibit, therefore, two kinds of sleep—that which they enjoy daily during the season of their activity, and that which they experience during their brumal retirement. This last kind of sleep is generally termed *torpidity*, and is also known by the term *hybernation*.

As the phenomena which torpid animals exhibit are somewhat different according to the classes to which they belong, it will be more convenient for us to treat of the animals of each class separately, beginning with Quadrupeds.

The quadrupeds which are known to become torpid belong exclusively to the digitated order. Some species are found among the *primates*, as the different kinds of bats; among the *feræ* we find the hedgehog and the tanric; while among the *glires* the torpid species are numerous, and their habits have been studied with the greatest attention, as the marmot, the hamster, and the dormouse.

The *food* of these animals is very different, according to the orders or genera to which they belong. The bats support themselves by catching insects, and those chiefly of the lepidopterous kinds; the hedgehog lives on worms and snails; while others, as the marmot and hamster, feed on roots, seeds, and herbs.

It is usually supposed that torpid animals are confined to the cold regions of the earth. That they abound in such regions, must be admitted; but their range of latitude is not so limited as to prevent their occurrence even in warm countries. Thus the *Dipus sagitta*, which is found from the 53d degree of north latitude to the tropics, is equally torpid during the winter months in Egypt as in Siberia. In the former country it is more easily revived by a very slight increase of temperature, its lethargy not being so profound. The Tanric (*Tanric caudatus*,) which is an inhabitant of India and Madagascar, becomes torpid even in those countries, and continues so during nearly six months of the year.

The precise period of the year in which these animals retire to their winter quarters and become torpid, has not been ascertained with any degree of precision. The jumping mouse of Canada (*Gerbillus Canadensis*) is said to retire to its torpid state in September, and is again restored to activity in the month of May. The torpid animals of this country usually retire in October, and reappear in April. It appears probable, however, that the different species do not all retire at the same time, but, like the migrating birds, perform their movements at separate periods. It is also probable that the time of retirement of each species varies according to the mildness or severity of the season. In general, however, they retire from active life when their food has become difficult to obtain, when the insects have fled to their hiding places, and the cold has frozen in the ground the roots and the seeds on which they subsist At the period of their reviviscence, the insects are again sporting in the air, and the powers of vegetable life are exerted in the various processes of germination and vegetation. In short, during the *dead season* of vegetable life, these animals pass their time in this lethargic state. We see the coincidence, but we cannot well account for the connection.

Previous to their entrance into this state of lethargy, these animals select a proper place, in general assume a particular position, and even in some cases provide a small stock of food.

All these torpid animals retire to a *place of safety*, where, at a distance from their enemises, and protected as much as possible from the vicissitudes of temperature, they may sleep out, undisturbed, the destined period of their slumbers. The bat retires to the roof of gloomy caves, or to the old chimnies of uninhabited castles. The hedge-hog wraps itself up in those leaves of which it composes its nest, and remains at the bottom of the hedge, or under the covert of the furze, which screened it, during summer, from the scorching sun or the passing storm. The marmot and the hamster retire to their subterranean retreats, and when they feel the first approach of the torpid state, shut the passages to their habitations in such a manner, that it is more easy to dig up the earth any where else, than in such parts which they have thus fortified. The jumping mouce of Canada seems to prepare itself for its winter torpidity in a very curious manner, as we are informed by Major-General Davies, in the *Linnean Transactions*, vol. iv. p. 156, on the authority of a labourer. A specimen which was found in digging the foundation for a summer-house in a gentleman's garden about two miles from Quebec, in the latter end of May 1787, was "enclosed in a ball of clay, about the size of a cricket ball, nearly an inch in thickness, perfectly smooth within, and about twenty inches under ground. The man who first discovered it, not knowing what it was, struck the ball with his spade, by which means it was broken to pieces, or the ball also would have been presented to me."

Much stress has been laid upon the *position* which these animals assume, previous to their becoming torpid, on the supposition that it contributes materially to produce the lethargy. In describing this position, Dr Reeves (in his Essay on the Torpidity of Animals) observes, "that this tribe of quadrupeds have the habit of rolling themselves into the form of a ball during ordinary sleep; and they invariably assume the same attitude when in the torpid state, so as to expose the least possible surface to the action of cold: the limbs are all folded into the hollow made by the bending of the body; the clavicles and the sternum are pressed against the fore part of the neck, so as to interrupt the flow of blood which supplies the head, and to compress the trachea: the abdominal viscera and the hinder limbs are pushed against the diaphragm, so as to interrupt its motions, and to impede the flow of blood through the large vessels which penetrate it, and the longitudinal extension of the cavity of the thorax is entirely obstructed. Thus a confined circulation is carried on through the heart, probably adapted to the last weak actions of life, and to its gradual recommencement." Professor Mangili of Pavia, (*Annales du Museum*, tom. ix.) with greater simplicity of language, says, that the marmot rolls itself up like a ball, having the nose applied contrary to the anus, with the teeth and eyes closed. He also informs us, that the hedge-hog, when in a torpid state, in general reposes on the right side. The bat, however, during the period of its slumbers, prefers a very different posture. It suspends itself from the ceiling of the cave to which it retires, by means of its claws, and in this attitude outlives the winter. This is the natural position of the bat when at rest, or in its ordinary sleep. In short, little more can be said of the positions of all these torpid animals, than the correspondence with those which they assume during the periods of their ordinary repose.

It is also observable, that those animals which are of solitary habits during the summer season, as the hedgehog and dormouse, are also solitary during the period of their winter torpidity; while the congregating social animals, as the marmot, the hamster, and the bat, spend the period of their torpidity, as well as the ordinary terms of repose, collected together in families or groups.

Many of those animals, particularly such as belong to the great natural family of *gnawers*, make provision in their retreats, during the harvest months. The marmot, it is true, lays up no stock of food; but the hamsters fill their storehouse with all kinds of grain, on which they are supposed to feed, until the cold becomes sufficiently intense to induce torpidity. The *Cricetus glis*, or migratory hamster of Pallas, also lays up a stock of provision. And it is probable that this animal partakes of its stock of provisions, not only previous to torpidity, but also during the short intervals of reviviscence, which it enjoys during the season of lethargy. The same remark is equally applicable to the dormouse.

Having thus made choice of situations where they are protected from sudden alterations of temperature, and assumed a position similar to that of their ordinary repose, they fall into that state of insensibility to external objects, which we are now to examine more minutely. In this torpid state they suffer a diminution of temperature; their respiration and circulation become languid; their irritability decreases in energy; and they suffer a loss of weight. Let us now attend to each of these changes separately.

1. *Diminished temperature.* When we take in our hand any of these hybernating torpid animals, which we are now considering, they feel cold to the touch, at the same time that they are stiff, so that we are apt to conclude, without farther examination, that they are dead. This reduction of temperature is not the same in all torpid quadrupeds. It varies according to the species. Hunter, in his "Observations on certain parts of the Animal Economy," informs us, on the authority of Jenner, that the temperature of a hedgehog at the diaphragm was 97° of Fahrenheit, in summer, when the thermometer in the shade stood at 78°. Professor Mangili states the ordinary heat of the hedgehog a little lower, at 27° of Reaumur, or about 93° of Fahrenheit. In winter, according to Jenner, the temperature of the air being 44°, and the animal torpid, the heat in the pelvis was 45°, and at the diaphragm 48½°. When the temperature of the atmosphere was at 26°, the heat of the animal in the cavity of the abdomen, where an incision was made, was reduced so low as 30°. The same animal, when exposed to the cold atmosphere of 26° for two days, had its heat at the rectum elevated to 93°, the wound in the abdomen being so much diminished in size as not to admit the thermometer. At this time, however, it was lively and active, and the bed in which it lay felt warm. As this animal allowed its heat to descend to 30°, when in its natural state of torpidity, and when there was no necessity for action, the increased temperature cannot be attributed to the cold, but to the wound, which called forth the powers of the animal to repair an injury, which reparation could not be effected at a temperature below the standard heat of the animal. The sources of error in making experiments where the living principle is concerned are so numerous, that attention

ought to be bestowed on every circumstance likely to influence the result.

The zizel, (*Arctomys citillus*), according to Pallas, usually possesses a summer temperature of 103° Fahr. but during winter, and when torpid, the mercury rises only to 80° or 84°. The temperature of the dormouse (*Myoxus muscardinus*) during summer, and in its active and healthy state, is 101°. When rolled up and torpid during winter, the thermometer indicates 43°, 39°, and even 35°, on the external parts of the body. When introduced into the stomach, the temperature was found to be 67°, and sometimes 73°. Mangili found this animal torpid even when the temperature of the air was 66°. Hence he considers it as the most lethargic of animals.

The marmot (*Arctomys marmota*) possesses a summer temperature of 101° or 102°, which is gradually reduced in the torpid season to 43°, and even lower.

Bats have a temperature in summer nearly equal to that of marmots. They are soon affected by the changes of the atmosphere, and they cease to respire in a medium of 43°. In the month of July, the thermometer standing at 80°, the internal temperature of a bat was 101°, which is just the degree of heat in a group of them collected together in summer, and may therefore be considered as the natural standard. Mr Cornish applied a thermometer to a torpid bat, and found that it indicated 36°. When awakened so much that it could fly a little, he again applied the thermometer, and it then indicated 38°. Spallanzani found a bat, after being exposed an hour to a temperature of 43°, to indicate 47°, the bulb of the thermometer being placed in the chest; exposed to a temperature below the freezing point, the heat of the animal became the same as the surrounding medium, yet it always remains internally higher than the low temperature produced artificially, though the skin indicates the same.

The wood-mouse (*Mus sylvaticus*) became torpid, according to Spallanzani, when the thermometer in its cage stood at 43°. The temperature of the belly externally was 45°, but its internal temperature is not much diminished even by a degree of cold sufficient to render it very torpid.

In these experiments we observe, that the temperature of these hybernating quadrupeds is greatly reduced below the summer standard, or the ordinary temperature of the animal in health and activity. Still, however, they continue to maintain a superiority in point of temperature above the surrounding medium, in whatever circumstances they are placed. Even in this torpid state, the energies of life, though feeble, are still sufficient to the production of a certain quantity of heat.

2. *Diminished Respiration.* In this, as in all the other departments of this curious subject, accurate and varied experiments are still wanting. The following are the principal facts which we have collected on the subject.

The hedgehog, according to Professor Mangili, who has bestowed more attention on this part of the subject than any of his predecessors, respires only from five to seven times in a minute during ordinary repose. When it becomes torpid, the process of respiration is periodically suspended and renewed. Thus a hedgehog, obtained after it had revived naturally from its winter lethargy in April, was placed in a chamber whose temperature was about 54°. It refused vegetable food, and became torpid, and continued in that state to the tenth of May. At first, after every fifteen minutes of absolute repose, it gave from thirty to thirty-five consecutive signs of languid respiration. In the beginning of May, when the thermometer was about 62°, it gave from seven to ten consecutive respirations, after an interval of ten minutes of absolute repose. Upon lowering the temperature, the intervals of repose became greater, while the number of respirations increased to eighteen or twenty.

Marmots, according to the same author, when in health and active, perform about five hundred respirations in an hour, but when in a torpid state, the number is reduced to fourteen, and these at intervals of four minutes, or four minutes and a half, of absolute repose.

Bats, when kept in a chamber from 45° to 50°, were observed at the end of every two, three, or four minutes of absolute repose, to give four signs of respiration. Spallanzani, not aware of these periodical intervals of repose, could not discover any signs of respiration. Indeed, when their temperature is reduced to about 47°, this function does not appear to be exercised.

The dormouse, when in a torpid state on the 27th December, exhibited a languid respiration of one hundred and forty times in forty-two minutes. On the tenth of January, the thermometer being at 43°, it respired at intervals in the following manner, according to Mangili.

| Intervals of repose. | Number of consecutive respirations. |
|---|---|
| 5 minutes | 16 |
| 4 | 30 |
| 3 | 29 |
| 2 | 29 |
| 12 | 5 |
| 9 | 10 |
| 10 | 6 |
| 13 | 18 |
| 12 | 23 |
| 12 | 8 |

In some instances, the intervals of repose or suspended respiration lasted sixteen minutes.

Mangili also found the fat dormouse (*Myoxus glis*) when in a torpid state on the 27th December, and when the thermometer indicated 40°, to respire at intervals. After every four minutes of repose, it respired from twenty-two to twenty-four times every minute and a half. The thermometer being raised one degree of Reaumur, the intervals became only three minutes. The temperature being reduced to 37°, the intervals of repose became four minutes, and the consecutive respirations twenty to twenty-six. The cold increasing, it awoke and ate a little, and then became torpid again. On the 10th of February the intervals of repose were eighteen or twenty minutes, and then thirteen to fifteen respirations. On the 21st February, the thermometer being 48°, the intervals of repose were from twenty-eight to thirty, and the consecutive respirations from five to seven.

From the observations already made on this important subject, it appears, that respiration is not only diminished, but even in some cases totally suspended. During the severe winter of 1795, Spallanzani exposed dormice to a temperature below the freezing point, and enclosed them in vessels filled with carbonic acid and azotic gas, over mercury three hours and a half without being hurt, and the sides of the vessels were not marked by any vapour. Hence we may conclude, that they did not breathe, nor give out any carbonic acid.

Mangili placed a marmot under a bell glass, immersed in lime water, at nine o'clock in the evening. At nine next morning the water had only risen in the glass three lines. Part of the oxygen was abstracted, and a portion of carbonic acid was formed, as a thin pellicle appeared on the surface of the lime-water, which effervesced with nitric acid. Spallanzani placed torpid marmots in vessels filled with carbonic acid and hydrogen, and confined them there for four hours, without doing them the least injury, the temperature of the atmosphere being several degrees below the freezing point. But he found, that if these animals were awakened by any means, or if the temperature was not low enough to produce complete torpor, they very soon perished in the same noxious gases. A bird and rat, introduced into a reservoir containing carbonic acid gas, did not live a minute ; whereas a torpid marmot remained in it an hour, without betraying the least desire to move, and recovered perfectly on being placed in a warmer medium.

In the exhausted receiver of an air pump, a torpid bat lived seven minutes, in which another bat died at the end of three minutes. Torpid bats, when confined in a vessel containing atmospheric air, consumed six hundredths of the oxygen, and produced five hundred parts of carbonic acid. Viewing this in connection with his other experiments, this philosopher concluded, that the consumption of the oxygen, and the evolution of the carbonic acid, proceeded from the skin.

The respiration of torpid quadrupeds is thus greatly diminished, and even in some cases suspended ; and in general, instead of being performed with regularity as in ordinary sleep, the respirations take place at intervals more or less remote, according to the condition of the lethargy.

3. *Diminished Circulation.* From the experiments already detailed with regard to the reduction of the temperature and the respiration of torpid quadrupeds, we are prepared to expect a corresponding diminution of action in the heart and arteries.

In the hamster, (*Cricetus vulgaris,*) the circulation of the blood during its torpid state is so slow, according to Buffon, that the pulsations of the heart do not exceed fifteen in a minute. In its active and healthy state they amount to one hundred and fifty in the same space.

We are informed by Barrington in his Miscellanies, that Mr Cornish applied a thermometer to the body of a torpid bat, and found that it indicated 36°. At this temperature the heart gave sixty pulsations in a minute. When awakneed so much as to be able to fly a little, he again applied the thermometer, which now indicated 38°, and the heart beat one hundred times in a minute. As the torpor becomes profound, the action of the heart is so feeble, that only fourteen beats have been distinctly counted, and those at unequal intervals.

Dormice, when awake and jumping about, breathe so rapidly, that it is almost impossible to count their pulse ; but as soon as they begin to grow torpid, eighty-eight pulsations may be counted in a minute, thirty-one when they are half torpid, and only twenty, nineteen, and even sixteen, when their torpor is not so great as to render the action of the heart imperceptible.

Spallanzani and others are of opinion, that the circulation of the blood is entirely stopped in the remote branches of the arteries and veins, and only proceeds in the trunks of the larger vessels, and near the heart. But it is probable, that however languid the circulation may be, it is still carried on, as the blood continues fluid. He found, that if the blood of marmots be subjected, out of the body, to a temperature even higher than that to which it is exposed in the lungs of these animals, it is instantly frozen ; but it is never congealed in their dormant state.

4. *Diminished Irritability.* The irritability of torpid animals, or their susceptibility of being excited to action, is extremely feeble, and in many cases is nearly suspended. Destined to remain for a stated period in this lethargic state, a continuance of their power of irritability would be accompanied with the most pernicious consequences ; as thereby they would be often raised prematurely into action under a temperature which they could not support, and at a time when a seasonable supply of food could not be obtained. In their torpid state, therefore, they are not readily acted upon by those stimuli, which easily excite them to action during the period of their activity. Parts of their limbs may be cut off without the animal shewing any signs of feeling. Little action is excited, even when their vital parts are laid open. When the hamster is dissected in this torpid state, the intestines discover not the smallest sign of irritability upon the application of alcohol or sulphuric acid. During the operation, the animal sometimes opens its mouth, as if it wanted to respire, but the lethargy is too powerful to admit of its reviviscence.

Marmots are not roused from their torpid state by the electric spark, strong enough to give a smart sensation to the hand, and a shock from a Leyden phial only excited them for a short time. They are insensible to pricking their feet and nose, and remain motionless and apparently dead. Bats are also equally insensible to the application of stimuli.

The most curious experiments on this subject are those of Mangili. Having killed a marmot in a torpid state, he found the stomach empty and collapsed, the intestines likewise empty, but there was a little matter in the cœcum and rectum. The blood flowed quickly from the heart, and in two hours yielded a great quantity of serum. The veins in the brain were very full of blood. The heart continued to beat during three hours after. The head and neck having been separated from the trunk, and placed in spirits of wine, gave signs of motion even after half an hour had elapsed. Some portions of the voluntary muscles gave symptoms of irritability with galvanism four hours after death. In a marmot killed in full health, the heart had ceased to beat at the end of fifty minutes. The flesh lost all signs of irritability in two hours ; the intercostal and abdominal muscles retaining it longer than those of any other part of the body.

5. *Diminished Action of the Digestive Organs.* The digestive faculty in torpid animals is exceedingly feeble, and in general ceases altogether. The situation, and still more the lethargic state of the system, render this process unnecessary. The intestines are in general empty, and in a collapsed state, and the secretions so small, that a supply of nourishment from the stomach is not requisite. Mr Jenner found a hedgehog, when the heat of the stomach was at 30°, to have no desire for food, nor power of digesting it. But when the temperature was increased to 93° by inflammation in the abdomen, the animal seized a toad which was in the room, and, upon being offered some bread and milk, immediately began to eat. The heat excited the action of the various functions of the animal, and the parts unable to carry on these actions, without nourishment, urged the stomach to digest.

While many torpid quadrupeds retire to holes in the earth unprovided with food, and in all probability need no sustenance during their lethargic state, there are others, as we have already mentioned, which provide a small stock of provisions. These, we are inclined to believe, eat a little during those temporary fits of reviviscence to which they are subject. This is in part confirmed by the experiments of Mangili, both on the common dormouse and the *Myoxus glis.* Whenever these awoke from their torpid slumbers, they always ate a little. Indeed he is of opinion, that fasting long produces a reviviscence, and that, upon the cravings of appetite being satisfied, they again become torpid.

6. *Diminished Weight.* All the experiments hitherto made on this subject indicate a loss of weight sustained by

these animals from the time they enter their torpid state until the period of their reviviscence. Mangili obtained two marmots from the Alps on the first of December 1813. The largest weighed twenty-five Milanese ounces, the smallest only $22\frac{3}{24}$th ounces. On the third of January the largest had lost $\frac{18}{24}$ths of an ounce, and the smallest $\frac{17}{24}$ and a half. On the fifth of February the largest was now only $22\frac{21}{24}$th ounces, the smallest twenty-one ounces. He adds, that they lose weight in proportion to the number of times in which they revive during the term of their lethargy.

Dr Monro kept a hedgehog from the month of November (1764) to the month of March (1765), which lost in the interval a considerable portion of its weight. On the 25th of December it weighed thirteen ounces and three drams, on the 6th of February eleven ounces and seven drams, and on the 8th of March eleven ounces and three drams. He observed a small quantity of feculent matter and urine among the hay, although it neither ate nor drank during that period. In this experiment there was a daily loss of thirteen grains. According to Mr Cornish, both bats and dormice lose from five to seven grains in weight during a fortnight's hybernation.

Dr Reeves endeavours to account for the lean state of the marmot when found in the spring, as occasioned by another cause than the slow but uniform exertions of the vital principle. "I have (he says) been repeatedly assured by men who hunt for these animals in winter, that they are always found fat in their holes on the mountains of Switzerland, and it is only when they come out of their hiding places before provisions are ready for them, or if a sharp frost should occur after some warm weather, that they become emaciated and weak. This testimony may be received as explaining the emaciated appearance of some marmots, but does not in the smallest degree invalidate the general conclusion, that all torpid animals sustain a loss of weight during the continuance of their lethargy.

From the experiments which we have already quoted it must appear obvious, that respiration is in general carried on, although sometimes in a very feeble manner. Carbon, consequently, must be evolved. Accordingly we find carbonic acid produced in those vessels in which these torpid animals have been confined; and hence must conclude, that a loss of weight has taken place.

Such being the preparatory and accompanying phenomena of this torpid state, let us now endeavour to discover the cause of these singular appearances.

In a subject of this kind, so intimately connected with the pursuits of the naturalist and the physiologist, it was to be expected that numerous hypotheses would be proposed to explain such interesting phenomena. Unfortunately, indeed, many hypotheses have been proposed, while few, from a connected view of the subject, have ventured to theorise. Perhaps we are not prepared to draw a sufficient number of general conclusions from the scanty facts which we possess, in order to build any theory. But the following observations may be considered as embracing the principal opinions which have been formed on the subject, and announcing the more obvious causes in operation.

In an investigation of this sort, it was natural to attempt to trace this singularity of habit in torpid animals to some peculiar conformation in the structure of the organs. Accordingly we find many anatomists assigning a peculiarity of organization as a reason why these animals become torpid, or at least pointing out a structure in torpid animals different from that which is observable in animals that are not subject to this brumal lethargy.

Pallas observed the thymus gland unusually large in torpid quadrupeds, and also perceived two glandular bodies under the throat and upper part of the thorax, which appear particularly florid and vascular during their torpidity.

Mangili is of opinion that the veins are larger in size, in proportion to the arteries, in those animals which become torpid, than in others. He supposes that, in consequence of this arrangement, there is only as much blood transmitted to the brain during summer as is necessary to excite that organ to action. In winter, when the circulation is slow, the small quantity of blood transmitted to the brain is inadequate to produce the effect. This circumstance, acting along with a reduced temperature and an empty stomach, he considers as the cause of torpidity. By analogy he infers, that the same cause operates in producing torpidity with all the other hybernating animals of the other classes.

Mr Carlisle, in his Croonian Lecture on Muscular Motion, asserts, that "animals of the class mammalia, which hybernate and become torpid in the winter, have at all times a power of subsisting under a confined respiration, which would destroy other animals not having this peculiar habit. In all the hybernating mammalia there is a peculiar structure of the heart and its principal veins: the superior cava divides into two trunks, the left passing over the left auricle of the heart into the inferior part of the right auricle, near to the entrance of the vena cava inferior. The veins usually called azygos accumulate into two trunks, which open into the branch of the vena cava superior, on its own side of the thorax. The intercostal arteries and veins in these animals are unusually large." *Phil. Trans.* 1805.

We cannot refrain from observing, that these general views do not appear to be the result of a patient investigation of a number of different kinds of torpid animals, but a premature attempt to theorise from a few insulated particulars. Passing, therefore, from these attempts of the anatomist to illustrate the phenomena in question, let us attend to those other causes which are concerned in the production of torpidity.

From the consideration, that this state of torpidity commences with the cold of winter, and terminates with the heat of spring, naturalists in general have been disposed to consider a *reduced temperature* as one of the principal causes of this lethargy. Nor are circumstances wanting to give ample support to the conclusion.

When the temperature of the atmosphere is reduced, as we have already seen, below 50°, and towards the freezing point, these animals occupy their torpid position, and by degrees relapse into their winter slumbers. When in this situation, an increase of temperature, the action of the sun, or a fire, rouse them to their former activity. This experiment may be repeated several times, and with the same result, and demonstrates the great share which a diminished temperature has in the production of torpidity. If marmots are frequently disturbed in this manner during their lethargy, they die violently agitated, and a hemorrhage takes place from the mouth and nostrils.

The circumstance of torpid animals being chiefly found in the colder regions is another proof, that a diminished temperature promotes torpidity. And, in confirmation of this, Dr Barton informs us, that, in the United States of America, many species of animals, which become torpid in Pennsylvania, and other more northern parts of the country, do not become torpid in the Carolinas, and other southern parts of the continent.

But while a certain degree of cold is productive of this lethargy, a greater reduction of temperature produces reviviscence as speedily as an increase of heat. Mangili placed a torpid marmot, which had been kept in a temperature of 45°, in a jar surrounded with ice and muriate of lime, so that the thermometer sunk to 16°. In about half an hour a quickened respiration indicated returning animation. In sixteen hours it was completely revived. It was trembling with cold, and made many efforts to escape. He also placed a torpid bat under a bell glass, where the temperature was 29°, and where it had free air. Respiration soon became painful, and it attempted to escape. It then folded its wings, and its head shook with convulsive tremblings. In an hour no other motions were perceptible than those of respiration, which increased in strength and frequency until the fifth hour. From this period, the signs of respiration became less distinct; and, by the sixth hour, the animal was found dead. He also exposed a torpid dormouse (from a temperature of 41°) to a cold of 27°, produced by a freezing mixture. Respiration increased from ten to thirty-two times in a minute, and without any intervals of repose. There were no symptoms of uneasiness, and the respirations seemed like those in natural sleep. As the temperature rose, respiration became slower. He then placed it in the sun, when it awoke. Two hours afterwards, having exposed it to the wind, respiration became frequent and painful; it turned its back to the current, without, however, becoming torpid.

That cold is calculated to produce effects similar to torpidity on man himself, is generally known. When persons in health are immersed in salt water at a temperature of 40°, the thermometer under the tongue sinks from seven to nine degrees below the standard heat. In a little time, however, it recovers its ordinary elevation, and becomes stationary. Exposure to cold has also the effect of diminishing the force of the pulse very much—of producing great exhaustion, and an accumulation of blood in the extreme vessels.

But the effects of a reduced temperature on the human system are still better illustrated in the tendency to sleep, produced by a cold atmosphere in certain situations. Those who have ascended to the summits of high mountains, have, by the exposure to cold, felt an almost irresistible propensity to lie down and sleep. Dr Solander, while exploring Terra del Fuego, though perfectly aware of the inevitable destruction attending the giving way to this inclination; nay, though he had even cautioned his companions against indulging it, could not himself overcome the desire. When this feeling is gratified, sleep succeeds, the body becomes benumbed, and death speedily arrives. How long this sleep might continue without ending in death, were the body defended from the increasing cold and the action of the air, will probably never be determined by satisfactory experiments. Partial torpor has often been experienced in the hands and feet, which is easily removed by a gradual increase of temperature. We may add, that in the case of persons exposed to great cold in elevated situations on mountains or in balloons, there are other causes in operation which may have a tendency to produce sleep. The previous exertions have reduced the body to a very exhausted state—the pressure of the atmosphere on the body is greatly diminished, and the air inhaled by the lungs is rarefied.

When these torpid animals, kept in a confined state, are regularly supplied with food, and kept in a uniform temperature, it has been observed that they do not fall into their wonted lethargy, but continue lively and active during the winter season. This experiment has often been repeated with the marmot and other animals. But when in this state they are peculiarly sensible to cold. Dr Reeves, in some experiments which he performed, says, "When I was in Switzerland I procured two young marmots in September 1805, and kept them with the view of determining the question, whether their torpidity could be prevented by an abundant supply of food and moderate heat. I carried them with me to Vienna, and kept them the whole of the winter 1805-6. The months of October and November were very mild. My marmots ate every day turnips, cabbages, and brown bread, and were very active and lively: they were kept in a box filled with hay in a cellar, and afterwards in a room without a fire, and did not show any symptoms of growing torpid. December the 18th, the weather was cold, and the wind very sharp; Fahrenheit's thermometer stood at 18° and 20°. Two hedgehogs died which were kept in the same room with the marmots; and a hamster died also in a room where a fire was constantly kept, though these animals had plenty of hay and food. The marmots became more torpid than I ever saw them before; yet they continued to come out of their nest, and endeavoured to escape: the food given them in the evening, was always consumed by the next morning. In January the weather was unusually mild and warm; my marmots ate voraciously, and were jumping about in the morning; but at four o'clock in the afternoon I examined them several times, and found them not completely rolled up, half torpid, and quite cold to the touch. They continued in this state of semi-torpor for several weeks longer, never becoming so torpid as to live many days without eating, and never so active as to resist the benumbing effects of the cold weather." Spallanzani performed similar experiments with the same result on the dormouse. He found, that although cold to the touch during the day, and completely torpid, that it awoke at night and ate a little, and fell asleep again in the morning. He shews also that dormice, kept in a situation more resembling their wild state, became torpid in the month of November, and remained till the middle of March without eating the food which was placed near them.

With some animals, at least, a *confined atmosphere* appears to be indispensibly necessary to the production of torpidity. This is very strikingly illustrated in the case of the hamster. This animal does not become torpid though exposed to a cold sufficient to freeze water, unless excluded from the action of the air. Even when shut up in a cage filled with earth and straw, and exposed to cold, he still continues awake; but when the cage is sunk four or five feet under ground, and free access to the external air prevented, in eight or ten days he becomes as torpid as if he had been in his own burrow. If the cage be brought above ground, in two or three hours he recovers, and will resume his torpid state when again sunk under ground. This experiment may be repeated several times, at proper intervals, either in the day time or during the night, the light having no apparent influence. A confined atmosphere, such as the hamster requires, does not appear necessary to the torpidity of the hedgehog, the dormouse, or the bat. But exposure to the open air seems to be equally hostile to the lethargic state, in many animals. Mangili always found that marmots awoke when taken from their nest, and exposed to the free action of the air. A current of air he found always to have the effect of producing reviviscence, both with dormice and bats. From these circumstances, we perceive the utility of the precautions of those animals in retiring to places where the air is still, and where they may enjoy a confined atmosphere.

Torpidity appears also in some cases to depend on the state of the *constitution*. Thus, in the same chambers, one marmot shall continue awake and active, while the others are in a profound lethargy. A hedgehog, during the winter season, becomes torpid upon the application of cold; but, during the summer season, or after the period of reviviscence, it resists the sedative effects of that agent. Mangili took a hedgehog, on the 21st June, and placed it in a temperature of 8° of Reaumur. It first rolled itself up; afterwards lifted its head and tried to escape. Its respiration became frequent and painful. At the end of the first hour, respiration had become feeble; at the end of an hour and a half, it had ceased to respire; and twenty minutes after, it was frozen to the heart. When examined in this condition, the flesh was found white, the veins of the neck were much swollen, and a small quantity of extravasated blood was observed in the brain and the lungs. It appears probable, that, during torpidity, the constitution experiences a change something similar to ordinary sleep, by which its exhausted energies are recruited, and it becomes better able to resist the effects of those ordinary agents with which it has to contend.

There are some circumstances in the history of these torpid animals which seem to indicate, that they possess the power of becoming torpid at pleasure, even in the absence of those disposing circumstances which we have enumerated. Spallanzani has seen bats in a torpid state even during summer, and supposes, that as these animals appear to possess some voluntary power over respiration, this torpidity may be some instinctive propensity to preserve life. Mangili, in spring, when the *Cricetus glis* was awake, and when the temperature of the air was between 66° and 68°, placed it in a vase along with nuts and other food. The animal attempted to escape, and refused to eat. It then became torpid. In this state the number of its respirations diminished. Instead of rolling itself up as usual before becoming torpid, it lay all the while upon its back, and remained in that state until the 17th of July.

By some it has been supposed, that the *fat* accumulated in torpid animals during the winter is another of those causes which produce this lethargy. The circumstance is certainly very common, but no direct experiments have hitherto been performed to warrant the conclusion. Spallanzani has indeed asserted, that among the dormice which he caught for his experiments, some were very fat, while others were lean, and yet they were equally susceptible of torpidity from the action of cold. All this may be the case; but there is certainly reason to believe, that these animals stand in need of some previous store of nourishment to enable them to support that gradual waste which takes place during the period of their slumbers.

Before concluding our account of torpid quadrupeds, it may be proper to add a few observations on their *reviviscence*. When the hamster passes from his torpid state, he exhibits several curious appearances. He first loses the rigidity of his members, and then makes profound respirations, but at long intervals. His legs begin to move; he opens his mouth, and utters rattling and disagreeable sounds. After continuing this operation for some time, he opens his eyes, and endeavours to raise himself on his legs. All these movements are still unsteady, and reeling like those of a man in a state of intoxication; but he repeats his efforts till he acquires the use of his limbs. He remains fixed in that attitude for some time, as if to reconnoitre, and rest himself after his fatigues. His passage from a torpid to an active state is more or less quick, according to the temperature. It is probable that this change is produced imperceptibly when the animal remains in his hole, and that he feels none of those inconveniences which attend a forced and sudden reviviscence.

It is evident, from the situations which some torpid animals occupy, that they must experience, in the course of their lethargy, considerable changes of temperature. It would form a very curious subject of inquiry, to ascertain the superior and inferior limits of this torpid state with respect to temperature. The *Cricetus glis* has been observed dormant from 34° to 48°; the dormouse from 27° to 66°; the marmot from 40° to 51°; and the hedgehog from 26° to 56°.

It is certainly very difficult to account for the torpidity of those animals, which, like the marmot and hamster, congregate and burrow in the earth. Previous to their becoming torpid, a considerable degree of heat must be generated, from their numbers, in their hole; and besides, they are lodged so deep in the earth, as to be beyond the reach of the changes of the temperature of the atmosphere. Their burrow, during the winter season, must preserve a degree of heat approaching to the mean annual temperature of the climate. If this is the case, how is reviviscence produced in the spring? It cannot be owing to any change of temperature, for their situation prevents them from experiencing such vicissitudes. Is it not owing to a change which takes place in their constitution? and, is not awakening from torpidity similar to awakening from sleep?

A similar remark may be made with regard to bats in their winter quarters. The caves to which they resort approach at all times the mean annual temperature. A few individuals, not sufficiently cautious in choosing proper retreats, are sometimes prematurely called into action, at a season when there is no food, so that they fall a prey to owls, and the cold of the evening. But what indications of returning spring have those who are attached to the roofs of the deeper caves? Surely no increase of temperature. Perhaps an internal change is the cause which again excites to action.

There is another very curious circumstance attending the reviviscence of quadrupeds from their torpid state, which deserves to be mentioned. As soon as they have recovered from their slumbers, they prepare for the great business of propagation. This is a proof, that torpidity, instead of exhausting the energies of nature, increases their vigour. It also indicates a peculiarity of constitution, to the preservation and health of which a brumal lethargy is indispensibly requisite.

It appears to be the general practice of modern naturalists, to treat with ridicule those accounts which have been left us of Birds having been found in a torpid state during winter. These accounts, it is true, have in many instances been accompanied with the most absurd stories, and have compelled us to pity the credulity of our ancestors, and withhold our assent to the truth of many of their statements. But are there no authenticated instances of torpidity among birds?

In treating of the torpidity of quadrupeds, we were unable to detect the cause of torpidity, as existing in any circumstances connected with structure or with circulation, respiration, or animal temperature; nor in the places which they frequent, nor the food by which they are supported. Hence we cannot expect much help from a knowledge of the anatomy, physiology, or even habits of birds, in the resolution of the present question. It has indeed been said, that as birds can readily transport themselves from one country to another, and in this manner shun the extremes of temperature, and reach a supply of food, the power of becoming torpid would be useless if bestowed on them, although highly beneficial to quadrupeds, that are impatient of cold, and cannot migrate to places where there is a supply of food. This mode of reasoning, however, is faulty, since we employ our pretended knowledge of final causes, to ascertain the limits of the operations of nature, and cannot be tolerated in a science depending entirely on fact and observations. Besides, there are many animals, as we have seen in the class *Mammalia*, which become torpid, and a similar state obtains among the reptiles. As birds, in the scale of being, hold a middle rank between these two classes, being superior to the reptiles, and inferior to the mammalia, we have some reason to expect instances of torpidity to occur among the feathered tribes.

These remarks have for their object, to prepare the mind for discussing the merits of the question, by the removal of presumptions and prejudices, as we fear preconceived opinions have already exercised too much influence.

In treating of the migrations of the swallow, we endeavoured to point out their winter residence, and even traced them into Africa. We are not however prepared to assert, that in every season all these birds leave this country. If they remain, in what condition are they found?

Many naturalists, such as Klein, Linnæus, and others, have believed in the submersion of swallows during winter in lakes and rivers. They have supposed, that they descend to the bottom, and continue there until the following spring. Many of the proofs produced in support of this opinion may be found by consulting the article BIRDS. On this subject we willingly quote the judicious note in the introduction to Bewick's *Land Birds*. "There are various instances on record, which bear the strongest marks of veracity, of swallows having been taken out of water, and of their having been so far recovered by warmth as to exhibit evident signs of life, so as even to fly about for a short space of time. But, whilst we admit the fact, we are not inclined to allow the conclusion generally drawn from it, viz. that swallows, at the time of their disappearance, frequently immerse themselves in seas, lakes, and rivers, and, at the proper season, emerge and reassume the ordinary functions of life and animation; for it should be observed, that in those instances which have been the best authenticated, it appears, that the swallows so taken up were generally found entangled amongst reeds and rushes, by the sides, or in the shallowest parts of the lakes or rivers where they happened to be discovered, and that having been brought to life so far as to fly about, they all of them died in a few hours after. From the facts thus stated we would infer, that, at the time of the disappearance of swallows, the reedy grounds by the sides of rivers and standing waters are generally dry, and that these birds, especially the later hatchings, which frequent such places for the sake of food, retire to them at the proper season, and lodge themselves among the roots, or in the thickest parts of the rank grass which grows there; that during their state of torpidity they are liable to be covered with water from the rains which follow, and are sometimes washed into the deeper parts of the lake or river, where they have accidentally been taken up; and that probably the transient signs of life which they have discovered on such occasions, have given rise to a variety of vague and improbable accounts of their immersion."—We may add, that whoever denies that swallows have been found in such situations, let his reasonings be what they may, tramples under his feet the laws of evidence, and cherishes a scepticism as unphilosophical as the most unthinking credulity.

But, independent of these instances of submersion, as it is termed, which we regard as purely accidental, there have been many instances of actual torpidity observed. Swallows, if we may credit the testimony of many who have been eye-witnesses of the fact, are often found during the winter season in a torpid state in their old nests, and in the crevices of old buildings. The belief of this kind of torpidity is very common in many parts of Scotland, and can scarcely be supposed to have originated from any other cause than the occurrence of the fact.

But besides the occurrence of the torpidity of the swallow, Bewick relates an instance of the same condition being observed in the cuckoo. "A few years ago a young cuckoo was found in the thickest part of a close whin-bush. When taken up it presently discovered signs of life, but was quite destitute of feathers. Being kept warm, and carefully fed, it grew and recovered its coat of feathers. In the spring following it made its escape, and in flying across the river Tyne it gave its usual call."— *Brit. Birds*, I. Introd. xvii.

There is a still more decided example of torpidity in birds recorded by Mr Neill, in his *Tour through Orkney and Shetland*, as having been observed in the case of the land-rail, or corncrake, as it is called in Scotland. "I made," says he, "frequent inquiry, whether corncrakes had been seen to migrate from Orkney, but could not learn that such a circumstance had been observed. It is the opinion of the inhabitants, indeed, that they are not able to undertake a flight across the sea. Mr Yorston, the farmer at Aikerness, further related a curious fact, rather leading to the conclusion that they do not migrate. In the course of demolishing a *hill-dyke*, (*i. e.* a mud wall,) at Aikerness, about midwinter, a *corncrake* was found in the midst of the wall. It was apparently lifeless; but, being fresh to the feel and smell, Mr Yorston thought of placing it in a warm situation, to see if it would revive. In a short time it began to move, and in a few hours it was able to walk about. It lived for two days in the kitchen, but would not eat any kind of food. It then died, and became putrid.—I do not assert that this solitary instance ought to be regarded in any other light than as an exception to the general rule of migration, till further observation has determined the point."

These are the only instances, with which we are acquainted of actual torpidity having occurred among the feathered tribes. They seem calculated to remove all doubt as to the fact, while they point out to us the numerous resources of nature in extreme cases to preserve existence. Thus when birds from disease or weakness, or youth, are incapable of performing the ordinary migrations of their tribes, they become dormant during the winter months, until the heat of spring restores to them a supply of food and an agreeable temperature.

Hitherto we have been considering the torpidity which warm-blooded animals experience. Several cold blooded animals observe a similar mode of hybernation.

The period of the year at which REPTILES prepare for this state of lethargy varies in the different species. In general, when the temperature of the air sinks below the 50th degree of Fahrenheit, these animals begin their winter slumbers. They adopt similar precautions as the mammalia, in selecting proper places of retreat, to protect them from their enemies, and preserve them from sudden alternations of temperature. Those which inhabit the waters sink into the soft mud, while those which live on the land enter the holes and crevices of rocks, or other places where the heat is but little affected by changes in the temperature of the atmosphere. Thus provided, they obey the impulse, and become torpid.

As the temperature of these animals depends on the surrounding medium, they do not exhibit any peculiarities with respect to it. When the air is under 50°, these animals become torpid, and suffer their temperature to sink as low as the freezing point. When reduced below this, either by natural or artificial means, the vital principle is in danger of being extinguished. In this torpid state, they respire very slowly, as the circulation of the blood can be carried on independent of the action of the lungs. Even in a tortoise kept awake during the winter by a genial temperature, the frequency of respiration was observed to be diminished.

The circulation of the blood is diminished, in proportion to the degree of cold to which these torpid reptiles are exposed. Spallanzani counted from eleven to twelve pulsations in a minute in the heart of a snake at the temperature of 48°, whose pulse in general in warm weather gives about thirty beats in the same period. Dr Reeves made some very interesting experiments on the circulation of the toad and frog. "I observed," he says, "that the number of pulsations in toads and frogs was thirty in a minute, whilst they were left to themselves in the atmosphere of which the temperature was 53°; when placed in a medium cooled to 40°, the number of pulsations was reduced to twelve within the same period of time; and when exposed to a freezing mixture at 26°, the action of the heart ceased altogether."

The powers of digestion are equally feeble during torpidity as those of respiration or circulation. Mr John Hunter conveyed pieces of worms and meat down the throats of lizards when they were going to their winter quarters, and, keeping them afterwards in a cool place, on opening them at different periods, he always found the substances, he had introduced, entire, and without any alteration; sometimes they were in the stomach, at other times they had passed into the intestines, and some of the lizards that were allowed to live, voided them toward the spring entire, and with very little alteration in their structure.

The immediate cause of torpidity in reptiles has been ascertained with more precision, than in the animals belonging to the higher classes with warm blood. This condition with them, does not depend on the state of the heart, the lungs, or the brain; for these different organs have been removed by Spallanzani, and still the animals became torpid, and recovered according to circumstances. Even after the blood had been withdrawn from frogs and salamanders, they exhibited the same symptoms of torpidity as if the body had been entire, and all the organs capable of action.

Cold, with these animals, is evidently the chief cause of their torpidity, acting on a frame extremely sensible to its impressions. During the continuance of a high temperature, these animals remain active and lively; but when the temperature is reduced towards 40°, they become torpid, and in this condition, if placed in a situation when the temperature continues low, will remain torpid for an unknown period of time. Spallanzani kept frogs, salamanders, and snakes, in a torpid state in an ice-house, where they remained three years and a half, and readily revived when again exposed to the influence of a warm atmosphere. These experiments give countenance to those reports in daily circulation of toads being found enclosed in stones. These animals may have entered a deep crevice of the rock, and during their torpidity been covered with sand, which has afterwards concreted around them. Thus removed from the influence of the heat of spring or summer, and in a place where the temperature continued below the point at which they revive, it is impossible to fix limits to the period during which they may remain in this dormant state.

Since reptiles are easily acted upon by a cold atmosphere, we find but few of those animals distributed in the cold countries of the globe; while in those countries whose temperature is always high, these animals are found of vast size, and of many different kinds, and in great numbers.

The torpidity of the *Mollusca* has not been studied with care. Those which are naked and reside on the land, retire to holes in the earth, under the roots of trees, or among moss, and there screen themselves from sudden changes of temperature. The different kinds of land Testacea, such as those belonging to the genera Helix, Bulimus, and Pupa, not only retire to crevices of rocks and other hiding places, but they form an operculum or lid for the mouth of the shell, by which they adhere to the rock, and at the same time close up even all access to the air. If they be brought into a warm temperature, and a little moisture be added, they speedily revive. In the case of the *Helix nemoralis*, the operculum falls off when the animal revives, and a new one is formed when it returns again to its slumbers. The first formed opercula contain a considerable portion of carbonat of lime, which is found in smaller quantity in the later formed ones. If the animal has revived frequently during the winter, the last formed opercula consist entirely of animal matter, and are very thin. The winter lid of the *Helix pomatia* resembles a piece of card.

All the land testacea appear to have the power of becoming torpid at pleasure, and independent of any alterations of temperature. Thus, even in midsummer, if we place in a box specimens of the *Helix hortensis*, *nemoralis* or *arbustorum*, without food, in a day or two they form for themselves a thin operculum, attach themselves to the side of the box, and remain in this dormant state. They may be kept in this state for several years. No ordinary change of temperature produces any effect upon them, but they speedily revive if plunged in water. Even in their natural haunts, they are often found in this state during the summer season, when there is a continued drought. With the first shower, however, they recover, and move about, and at this time the conchologist ought to be on the alert.

The Spiders pass the winter season in a dormant state, enclosed in their own webs, and placed in some concealed corner. Like the torpid mammalia, they speedily revive when exposed to intense cold, and strive to obtain a more sheltered spot.

Many Insects which are destined to survive the winter months, become regularly torpid by a cold exceeding 40°. The common honey bee, in a small hive, when reduced to this temperature, loses all power of motion, but may be easily revived by an increase of temperature. When the hive is large, there is always as much heat generated, as to protect them against this lethargic disposition. The house fly may always be found in the winter season torpid, in some retired corner; but exposure for a few minutes to the influence of a fire recalls it to activity. Even some of the lepidopterous insects, which have been hatched too late in the season to enable them to perform the business of procreation, possess the faculty of becoming torpid during the winter, and thus have their life prolonged beyond the ordinary period. These insects can all be preserved from becoming torpid by being placed in an agreeable temperature, as the following experiments of Mr Gough's (Nicholson's *Journal*, vol. xix.) abundantly testify. In speaking of the Hearth Cricket, (*Gryllus domesticus*,) he says, "Those who have attended to the manners of this familiar insect will know that it passes the hottest part of the summer in sunny situations, concealed in the crevices of walls and heaps of rubbish. It quits its summer abode about the end of August, and fixes its residence by the fireside of the kitchen or cottage; where it multiplies its species, and is as merry at Christmas as other insects are in the dog-days" Thus do the comforts of a warm hearth afford the cricket a safe refuge, not from death, but from temporary torpidity; which it can support for a long time, when deprived by accident of artificial warmth. "I came to the kowledge of this fact," he says, "by planting a colony of these insects in a kitchen, where a constant fire is kept through the summer, but which is discontinued from November to June, with the exception of a day, once in six or eight weeks. The crickets were brought from a distance, and let go in this room in the beginning of September 1806: here they increased considerably in the course of two months, but were not heard or seen after the fire was removed. Their disappearance led me to conclude that the cold had killed them: but in this I was mistaken; for, a brisk fire being kept up for a whole day in the winter, the warmth of it invited my colony from their hiding place, but not before the evening, after which they continued to skip about and chirp the greater part of the following day, when they again disappeared; being compelled by the returning cold to take refuge in their former retreats. They left the chimney corner on the 28th of May 1807, after a fit of very hot weather, and revisited their winter residence on the 31st of August. Here they spent the summer merely, and lie torpid at present (Jan. 1808) in the crevices of the chimney, with the exception of those days on which they are recalled to a temporary existence by the comforts of a fire."

Nothing is known with regard to the hybernation of the Intestina. Those which inhabit the bodies of torpid quadrupeds, in all probability, like them, experience a winter lethargy. If they remain active, they must possess the faculty of resisting great alterations of temperature. Among the *infusory animals*, numerous instances of suspended animation have been observed, continued not for a few months, but during the period of twenty-seven years. But such instances of lethargy do not belong to our present subject. Besides, they have been fully discussed under the article Animalcula, in this work.

There is another kind of hybernation, in some respects resembling torpidity, which deserves to be taken notice of in this place, and which merits the appellation of Quiescence. The animals which observe this condition, remain during the winter months in an inactive state, requiring but little food, without however experiencing the change to torpidity.

Of these quiescent animals, the common bear (*Ursus arctos*) is the most remarkable example. Loaded with fat, he retires in the month of November to his den, which he has rendered comfortable by a lining of soft moss, and seldom reappears until the month of March following. During this period he sleeps much, and when awake almost constantly licks with his tongue the soles of his feet, particularly those of the fore paws, which are without hair, and full of small glands. From this source it is supposed that he draws his nourishment during the period of his retirement.

This quiescence appears to differ in its kind from torpidity. This animal is always in season before he retires to his winter quarters, and the female brings forth her young, before the active period of the spring returns, and before she comes forth from her hiding place.

The common badger is supposed to pass the winter in the same manner as the bear, with which, in structure and habit, he is so nearly related. It is also probable, that many species of the genus Arvicola become quiescent, particularly the *amphibia*, or common water rat, which always leaves its ordinary haunts during the winter.

It is in this state of hybernation that many of our river fishes subsist at the season of the year when a supply of food cannot be obtained. A similar condition prevails among the fresh water mollusca, and also among many species of Annelides. But we must observe, that accurate observations on this branch of the subject are still wanting.

In concluding the subject of torpidity, it may be proper to mention a few of those questions to which it has given rise, without, however, going into detail. It has been asked, Is torpidity a condition natural to those animals, or is it a habit produced by external circumstances? Mr Gough, indeed, considers "the torpidity of these animals in a wild state, to be nothing but a custom, imposed by necessity, on a constitution which nature has intended to retain life during the cold season of winter, with but little food, and an imperfect degree of respiration, as well as a languid, or perhaps a partial action of the sanguiferous system." Since these animals, when in a natural or perfectly wild state, invariably become torpid, we must regard such a condition, not as the effect of "custom imposed by necessity," but as the effect of a law of their constitution, enabling them to accommodate themselves to circumstances natural to their condition.

Some have supposed that these torpid animals were at first natives of warmer regions, and have acquired the habit of torpidity, in consequence of having removed to colder countries. Before attempting to account for the occurrence of torpidity in such circumstances, a proof of the assertion regarding the origin of these torpid animals ought to be given. Besides, we know but little of the effects exerted by climate on this tendency to become torpid; neither do we know whether our torpid animals would remain all the year active and lively if removed to a warmer country, nor whether the animals of warmer countries would become torpid if brought to us. The fact, that torpid animals are chiefly found in cold countries, is a proof of the great influence exerted by climate on the habits of animals; but it is also probable, that this influence will be chiefly felt, where the constitution has been previously arranged, to accommodate itself to the vicissitudes of cold regions.

In all these different kinds of hybernation, we meet with difficulties in investigating the laws of animal life. We cannot account for the phenomena which present themselves, or ascertain the relation of these to external objects. But it is both easy and delightful to trace the benevolent intentions of nature in providing for the wants of her creatures, in accommodating their feelings and propensities to the circumstances in which they are placed, in removing them from situations of danger, and in continuing to them life, and health, and enjoyment. (J. F.)

HYDATIDES. See Medicine.

HYDERABAD, is a province of the Deccan, in India. It is situated between the 16th and 19th degrees of north latitude, and bounded on the north by the Godavery, on the south by the river Krishna, on the east by the province of Gundwana, and on the west by Beeder and Aurungabad. It formed a considerable portion of the ancient kingdom of Telingana, which, in its independent state as a distinct Hindoo sovereignty, comprehended the principal part of the tract between the rivers Godavery and Krishna, and of which the capital city was Warangol. It was reduced at an early period of the Mahommedan invasion, and afterwards formed part of the great Bhamenee Empire of the Deccan. On the dissolution of this state, Telingana became again the seat of an independent government, under the name of Golconda, the first sovereign of which, Kooli Kuttub Shah, established the Kuttub Shahy dynasty in 1512. One of his successors, Abdullah Kuttub Shah, who ascended the throne in 1586, became tributary to the Mogul Emperor, Shah Jehan; and in this state the kingdom remained till 1687, when the reigning sovereign, Abou Houssein, was deprived of his capital, Golconda, by the Emperor Aurungzebe, and imprisoned for life in the fortress of Dowlatabad.

It was not till after a protracted siege, and only, at length, through the treachery of one of the king's sirdars, that the Mogul Emperor obtained possession of the place; and it is related, that when some of the assailants had fought their way into the apartment, where Abou Houssien was seated at supper, he requested them, with much composure, to sit down and partake with him, and that they quietly accepted the invitation. On the destruction of the Mogul empire, after the death of Aurungzebe, Nizam ul Moolk obtained possession of the Mahommedan conquests in the Deccan, about the year 1717. Under his successors, the limits of the state experienced much fluctuation; but its power was gradually declining, and would have been totally annihilated by the Mahrattas, had not the British government interposed for its support. In 1800, a treaty of perpetual alliance was concluded with Nizam Ali by Major Kirkpatrick on the part of the British; and by this arrangement a British force of 8000 regular infantry, and 1000 regular cavalry, with their proper complement of artillery and warlike stores, is stationed in the Nizam's territories, for their protection against hostile neighbours or turbulent subjects. For the regular payment of these troops, the Nizam ceded to the East India Company all the territories which he had acquired by the treaty of Seringapatam in 1792, and by that of Mysore in 1799. In the event of a war taking place, the Nizam engaged to join the British with 6000 infantry, and 9000 cavalry of his own army, with the necessary train of artillery and stores. By this treaty it was also arranged, that all the external political relations of the parties should be exclusively managed by the British, who undertook to protect his highness's dominions from every annoyance, and particularly to procure a total exemption from all claims of Choute on the part of the Mahrattas. In 1802, a commercial treaty was negociated, by which the free use of the port of Masulipatam was granted to the Nizam, with a promise of protection to his flag on the high seas; and an equality of duties on the mutual imports and exports was stipulated, the amount of which should not exceed 5 per cent. In 1804, a considerable part of the territories of Dowlet Row Sindia was transferred to the Nizam; by which the Hyderabad sovereignty acquired a great increase of territory, and obtained for the first time a well-defined boundary. At present, the Nizam's dominions, besides the whole of Hyderabad, comprehend Nandere and Beeder, the greater part of Berar, and a portion of Arungabad and Begapoor, being divided from the Nagpoor territories by the Wurda river, and from the British by the Krishna and Toombuddra. Hyderabad, which gives the general name to the sovereignty, is about 180 miles in length, and 150 at its average breadth. The surface of the province is hilly, but not mountainous; and it is an elevated table land, much colder in its temperature than the degree of latitude would indicate. In the city of Hyderabad, and the country to the north of it, the thermometer, during three months of the year, is frequently so low as 45°, 40°, and 35° of Fahrenheit. The soil is fertile, and tolerably well watered, but indifferently cultivated, and thinly inhabited. The cultivators are wretchedly poor, and much oppressed by their Mahommedan superiors, who are subject to little restraint from their nominal sovereign. From the same cause, they are almost destitute of the benefits of commerce; and the average import of European goods into the whole of the Nizam's dominions, prior to 1809, never exceeded 25,000*l.* per annum. The principal towns in the province are Hyderabad, Golconda, Warangol, Meduck, and Niecundah; and the whole population of the district is estimated not to exceed two millions and a half.

The reigning prince, Mirza Secunda Jah, ascended the throne in 1803, and has never been more than a few miles from the city of Hyderabad since the commencement of his reign. His government is absolutely despotic in theory; but, in point of fact, his power is much limited by circumstances. He takes little direct interest in the minutiæ of the executive, which is managed almost entirely by one or other of his ministers, according as their factions prevail, or as they may be able to carry along with them the support of the Company's resident. The influence of the East India Company's government is paramount in the councils of that of their ally, and all great political points are carried with considerable facility; yet, on some late trifling occasions, a lively jealousy has been manifested. While the officer, who had been appointed to conduct the grand trigonometrical survey, was approaching Hyderabad, he had fixed small flags on some points for directing his observations. This gave rise to repeated complaints; as if, in taking a few triangles, he had been taking possession of the country. The political intercourse is carried on by means of a resident, who has a superb mansion on the north-east side of the capital across the river. His suite consists of first and second assistants, a surgeon, and the officers of an escort of two companies of Bengal native infantry. The present Nizam was entertained at the residency on the occasion of paying him his army's share of the Seringapatam prize money, which had been laid out in splendid specimens of English and Chinese manufactures. His Highness was a little alarmed on this occasion, by the accidental firing of a few thousand rockets which happened to lie pointing towards the spectators, but by which fortunately no person near himself was wounded. The entertainment was concluded by laying before him a superbly mounted sabre, which had been sent by Louis XVI. to Tippoo Sultan.

It is difficult to say what is, and what is not, to be reckoned revenue under so irregular a government. Although a very large proportion of the whole produce of the soil be claimed as its share; yet so much of this is stopped for the expences of collection and payment of sebundee, or local troops, and so much is diverted into bye channels, that the sum which finally reaches the treasury is in many cases very small. The produce of the estates granted for military service should be reckoned as part of the revenue, were it not that the service is seldom performed. When lands are not granted to Jaghiredars for specific purposes, the common mode of collection is by Tahood, a farm, in which case any person may make an offer for a lease of a district; and that person is generally preferred who proposes the largest advance of ready money to the minister. Little inquiry is made into the methods which he may use to reimburse himself; and he may do nearly as he pleases, provided he keeps a good understanding at court. Sometimes, however, complaints are listened to, if there exist a hope of squeezing a further sum from the fears of the contractor; or if there be a wish to get rid of him, to make way for some other who may have offered a sum of ready money, or a larger portion of his expected profits. The other mode is by Amaunee, and is seldom resorted to, unless when a district is in such a rebellious state that no person can be found to farm it. Some military chief is then turned into it to collect what he can, and to account to government for the amount. This, however, is a last resource, as all Indians, whether Mussulmans or Hindoos, are adepts at making up accounts so as to suit their own interests.

The army of the Nizam, in consequence of the protection afforded by the British troops against the invasions of the Mahrattas, is now on a very inefficient footing. A list of its great officers and their troops, would be merely an enumeration of persons holding estates and emoluments under a nominal agreement to perform services, which they are scarcely expected to fulfil. This is quite true, as far as regards the great military jaheridars and risaldars, or cavalry officers, who hold valuable districts in their immediate possession; but there are many corps of mutinous and ill-paid infantry, who have hard service in the collection of the revenue, which the oppressive nature of the government, and the consequent bad faith and turbulence of the zemindars, render extremely difficult. These troops are distributed to the different collectorships, as occasion may require. With the exception of a few corps patronised by the Company's resident, none of them are either regularly paid, or decently equipped; and many battalions have not one-tenth of their arms in a serviceable state.

By a supplementary article in the treaty between the Nizam and the Company's government, it was agreed, that all the forts in the Hyderabad dominions should, in time of a joint war, be open to the British. Of these fortresses, the most important are that of Dowlatabad,* and of Golconda. The former, particularly, the most singular perhaps in the world, is situated on a high conical hill, which has it sides pared away perpendicularly in such a manner, that it would now be represented by a whipping-top set upon its head. There is a fortified tower on the plain, through which a passage lies to a tunnel in the bowels of the mountain, affording an ascent to the conical surface above, and opening to the day near the edge of the precipitous side. This upper opening is covered by an iron grating, on which a fire is kept burning when any danger is apprehended. Even after overcoming this obstacle, an enemy would still be required to advance in a path exposed to the whole fire of the fort on the summit. In this fort are lodgments cut in the solid rock for the garrison and their provisions. The fort of Golconda, about five miles west from Hyderabad, though very strong in some places, is, by a strange arrangement, most assailable on the side, which at the same time commands all the others. In a piece of broken ground, on the north-west side of the fort, are situated, in an irregular manner, the tombs of the Kootub Shahy kings, which are of such solid masonry, that they would afford bomb-proof lodgment for several battalions, though some of them are within battering-distance of the walls. In the lifetime of the late Nizam ul Moolk, the garrison used to make a great show of watchfulness and jealousy of any armed party approaching their walls; and, on one occasion, actually fired on some ladies and gentlemen, who were amusing themselves in looking at the tombs. Some years ago, a detachment of the Company's troops with a convoy of provisions having halted near them, the Killidar, or commandant, sent out a message to the officer in charge, desiring him to remove his encampment to a greater distance, and threatening that the guns on the works would be used to enforce compliance. The officer replied verbally, that he would not decamp until the next morning; and, pointing to a line of spirit carts, added, that if a single shot were fired at him from the fort, he was ready to return the compliment. The regularity of his line of carriages, and their compact form, made them be mistaken for so many mortars and battering guns, and immediately produced a more conciliatory tone, with quiet possession of the ground.

A great part of the province is occupied by Jaghiredars, some of whom are military officers in the service of the Nizam, as already mentioned; and the rest are Hindoo Rajahs or Zemindars, whose ancestors have long possessed their estates, and over whom the Nizam exercises a very uncertain and undefined authority. As Hyderabad is one of the few remaining Mogul governments, a greater proportion of Mahommedans are to be found among the higher and middle classes of the inhabitants; but the great mass of the lower classes are still Hindoos in the proportion of above ten to one. In the colder season of the year, the lower classes use a coarse woollen blanket made in the country, while the higher ranks wear shawls and quilted silks. A few of the noblemen and military chiefs clothe themselves in broad cloth, as a piece of fashionable luxury; and the regular infantry, as well as the troops of the principal Jaghiredars, are dressed in British red cloth.

HYDERABAD, the capital of the above province, and of the Nizam's dominions, is situated in 17° 15′ N. Lat. and 78° 42′ E. Long. on the Moossee Nuddee, below its junction with the Moossah, which flows pass the walls of Golconda. It was founded about the year 1585 by Mahommed Kooli Kootub Shah, and in consequence of its vicinity to the river, soon acquired the ascendancy over the neighbouring city of Baugnuggin, of which nothing now remains, except a few traces of the strongest buildings. It was taken and pillaged by the army of Aurengzebe in 1687, its principal inhabitants having retired to the neighbouring fortress of Golconda. The late Nizam Ali, father of the reigning prince, made it the seat of the royal residence in place of Aurungabad, which had hitherto been the capital, but which, by the fluctuation of his terriries, had become less centrical, and too adjacent to the Mahratta frontier. The new capital has been exempt from plunder and every hostile molestation, ever since it became the residence of the court, (a circumstance rarely paralleled in India for so long a period) and has rapidly increased in wealth and population. It is surrounded by a stone wall, which would afford no defence against artillery, but which serves as a protection from the incursions of cavalry. It is about four miles in length within the walls, and three in breadth. There are large magazines in the city belonging to the Nizam, in which are deposited the presents received at various times from the different native and European powers. The rooms are filled, almost from the floor to the ceiling, with bales of woollens, cases of glass, glass-ware, china-ware, clocks, watches, and other articles of European manufactures, which always continue locked up in the magazines. The houses and gardens of the Company's civil and military officers, and of a few other European gentlemen resident in the place, form the principal ornament of the environs. Hyderabad, having long been the principal Mahommedan station in the Deccan, contains a considerable number of mosques, and exhibits more of the old forms and ceremonies of the Mogul government than any other metropolis in Hindostan. The noblemen of the place have been bred either as soldiers or courtiers; and, as hoarded treasures would expose them to the avaricious machinations of their superiors, they generally spend their fortunes freely, in keeping up large retinues, or in the fashionable profligacy of their court. When any property is laid up, it is commonly in the form of ornaments for their females and children, which are always more remarkable for their weight than workmanship. A few of the wealthier Mahommedans, especially the Nizam's ministers, are fond of furnishing their houses richly with articles of European and Chinese manufacture, such as porcelain, crystal, lustres, chintz sofa covers, and some articles of plate. A favourite piece of luxury among them is to have an Aeena Khana, a room of which the roof and sides are entirely covered with mirror plates.

His Highness's ministers frequently entertain the resident and his suite at their palaces. The amusements at these parties are troops of dancing girls (kunchinees,)

* Doulut-abad, " wealth's abode."

wrestlers (puhlwauns,) mimics (bhans,) and musicians of various kinds, who afford some diversion to a newly-arrived European, but soon become tiresome, and often disgusting. A dinner, partly in the English style, and a magnificent display of fireworks, commonly close the day's entertainments. Some of the Mahommedan chiefs sit at table, and partake of the same fare with the Europeans, from which pork, in every shape, it may be supposed, is carefully excluded. The inhabitants of the city, both Mahommedans and Hindoos, though very polished in their manners, are both ignorant and profligate. Crimes are here committed every day with impunity, and even without notice, which would strike with wonder and horror the inhabitants of any country in Europe. A father, who had murdered his wife for not quietly acquiescing in his preference of his daughter, observed, that "no one had a better right to the fruit than the planter of the tree." The government derives a current revenue from licences to carry on the most horrid practices. Amongst such a people, and with such a government, truth and morality, as it may be supposed, are very rare qualities. The present number of inhabitants, including those of the suburbs, is estimated at 120,000, The distance of the city from Calcutta is 900 miles; from Madras, 391; from Bombay, 480; from Seringapatam, 406; from Delhi, 923. # HYDRODYNAMICS.

HYDRODYNAMICS, from the Greek Ὑδωρ, *water*, and Δυναμις, *power* or *force*, is that branch of natural philosophy which embraces the phenomena exhibited by water and other fluids, whether they are at rest or in motion. It treats of the pressure, the equilibrium, the cohesion, the motion, and the resistance of fluids; and of the construction of the machines by which water is raised, and in which it is the first mover, or the primary agent. This science is generally divided into *Hydrostatics* and *Hydraulics*, the former of which considers the pressure, equilibrium, and cohesion of fluids; and the latter, their motion, the resistance which they oppose to moving bodies, and the various machines in which they are the principal agent.

## HISTORY.

ALTHOUGH Hydrodynamics is but a modern science, and was studied by the ancients only in its most general principles, yet many of the leading doctrines and phenomena upon which it is founded are familiar to the rudest nations, and must have been well known in the very earliest ages of society. Even at that remote period when man first trusted himself to the waves, the pressure of fluids, and the phenomena of floating bodies, were undoubtedly known to him; and in the more advanced stage of navigation, when the Phenicians were able to colonise the most distant regions of the globe, the directing power of the helm, the force and management of the oars, the action of the wind upon the sail, and the resistance opposed to the motion of the vessel, were well known facts, which implied practical acquaintance with some of the most important doctrines of Hydrodynamics.

The motion of fluids, as affected by the size of the aperture from which they issued, and by the height of the superincumbent column, formed the fundamental principle of the *Clepsydræ* (from κλεπτω, *to steal*, and ὑδωρ, *water*) or water clocks, which were employed in the earliest ages, before the invention of sun dials, to measure time. The simplest, and probably the earliest form in which the Clepsydræ appeared, is that of two inverted cones, as represented in Plate CCCXIII. Fig. 1. This species of Clepsydra consisted of a hollow cone A, perforated at its vertex, and of a solid cone B, which was made to fill A with the greatest exactness. The aperture of A was so adjusted to the size of the cone, that, when filled with water, it emptied itself in the course of the shortest day in winter. The length of the cone was divided into 12 equal parts, which indicated the hours by the descent of the fluid, or the same result was obtained by divisions upon the vessel into which the water flowed. When the days lengthened, and the hours became longer, the solid cone B was introduced into the hollow cone A, and, according to the depth of its penetration, the water flowed from the aperture with less facility. A graduated index BC enabled the observer to accommodate the position of the solid cone to the varying length of the day.

Another Clepsydra, of a more ingenious construction, is represented in Plate CCCXIII. Fig. 2. The water is first received into the reservoir A, which is always kept full, and descends by the pipe B into a hole in the great drum MN. This hole corresponds to one of the openings in the groove round the circumference of the small drum LO, which is drawn out in the figure for the purpose of showing it, but when the machine is in use, it is fitted into the drum MN. The apertures of the groove in LO are of different sizes, so as to admit different quantities of water, according to the length of the day, and the proper aperture for the given day is found by placing the index L opposite the sun's place in the zodiac shewn at N, the index O being used for the night hours. The water which descends through the openings in the drum LO is conveyed by the pipe F, and falls through the aperture at G into the reservoir H. As the water rises in the reservoir, the inverted vessel I, suspended by a chain which passes over the axis R, and balanced by a counterweight P, ascends, and consequently the hour hand X, fixed upon the extremity of the axis, is made to revolve, and indicate the hours upon the dial plate.

Notwithstanding the ingenuity of these inventions, and the hydrodynamical knowledge which they indicated, the doctrine of fluids may still be considered as deriving its origin from the discoveries of Archimedes. The history of these discoveries has been rendered ridiculous by vul-

* In drawing up the two preceding articles, we have been indebted for much important information to John Robison, Esq. F. R. S. E. who spent many years in the Nizam's service. ED.

gar fables, which have long been discredited; but it appears unquestionable, that they originated in the detection of a fraud committed by the jeweller of Hiero, king of Syracuse. Archimedes was applied to by the king to ascertain, without injuring its workmanship, whether or not a new crown, which had been made for him, consisted of pure gold: The method of solving the problem is said to have occurred to him when in the bath, and he applied it successfully in detecting the fraud. The hydrostatical doctrines to which Archimedes was thus conducted, were illustrated in a work consisting of two books, and entitled *περι οχȣμενων, de insidentibus in Fluido*. He maintained, that every particle of a fluid mass in equilibrio is pressed equally in every direction. He examined the conditions, in consequence of which a floating body assumes and preserves its position of equilibrium, and he applied it to bodies that have a triangular, a conical, and a paraboloidal form. He shewed that every body plunged in a fluid loses as much of its own weight as the weight of the quantity of water which it displaces; and upon this beautiful principle is founded the process which he employed for ascertaining the impurity of Hiero's crown. When the result was communicated to the king, he exclaimed, *Nihil non dicenti Archimede, credam!* The screw of Archimedes, which is still used in modern times for raising water, is said to have been invented by him when in Egypt, for the purpose of enabling the inhabitants to free themselves of the stagnant water which was left in the low grounds after the inundations of the Nile; and Atheneus informs us, that navigators held the memory of Archimedes in the highest honour, for having furnished them with the means of carrying off the water in the holds of their vessels.

Hydraulic machinery appears to have been first invented in the Alexandrian school, which flourished under the patronage of the Ptolemies. Hippocrates, who was the first person that constructed tables of the sun's motion, enabled astronomers to carry the construction of Clepsydræ to a high degree of perfection; and it was probably in his time that the Anaphorical Clepsydræ were invented. Scipio Nasica, the cousin of Scipio Africanus, is said to have invented Clepsydræ about 200 years before Christ; but it is probable that he only introduced them into Rome, for the Egyptians had used them for many purposes at a much earlier period. This invention was carried to a still higher degree of perfection by Ctesibius, who flourished during the reign of Ptolemy Physcus, near the beginning of the second century before the Christian era. When he was one day amusing himself in the shop of his father, who was a barber in Alexandria, he observed, that, during the descent of a mirror, which was counterbalanced by a weight contained in a cylindrical frame, a musical sound was emitted from the narrow space between the roller and its frame. Hence he was led to conceive the idea of a hydraulic organ, which should operate by means of air and water. Having succeeded in this attempt, he applied the same principles to the construction of Clepsydræ, and invented the very ingenious machine represented in Plate CCCXIII. Figs. 3 and 4, which is probably the first machine to which toothed wheels were applied. Fig. 3. represents the outside of the machine, which consists of a cylinder standing upon a pedestal, and of two figures of children, one of which allows the water to fall drop by drop from his eyes, while the other rises and indicates the hour with a wand upon the vertical line AB. The cylinder AB turns round its axis once in a year, and the inequality of the hours in different days is marked by the unequal distances of the horizontal curve lines on the surface of the cylinder. In Fig. 4, which shews the internal construction of the machine, the water rises through the tube A into the figure of the infant on the right hand, and is discharged from its eyes into the square reservoir M, from which it passes, by a hole near M, into the pipe BCD. In this pipe a piece of wood floats upon the surface, and by its ascent, as the pipe fills, it raises the small pillar CD, on which the left hand figure is made to rest, so that the wand points to different hours as the float rises in the pipe. At the end of 24 hours the vessel BCD is filled, and also the arm FB of the inverted syphon FBE, which communicates with it. The water is therefore drawn off by the syphon, and falling in its descent into the buckets of the wheel K, it puts it in motion. This wheel has six buckets, and therefore performs a revolution in six days. Its axis carries a pinion N of six teeth, which works into the wheel I with 60 teeth; and this wheel, carrying a pinion of ten teeth, drives the wheel GO with 61 teeth, which, by its axis OL, turns the pillar L once round in 366 days.

The subject of Hydrodynamics was successfully cultivated by Hero, the friend and disciple of Ctesibius. Besides his treatise on mechanics, in three books, in which he treated at length of the different mechanical powers, and reduced them all to the lever, he wrote a work entitled *Spiritalia* or *Pneumatica*,* which contains an account of the Forcing Pump, and of the Fountain of Compression, commonly called *Hero's Fountain*, in which water was raised above its level by the elasticity of the air, which had been condensed by the water. The idea of the forcing pump was probably suggested by the Noria, or Egyptian wheel, which consisted of a number of earthen pots carried round upon the circumference of a wheel.

Although it has been believed, on the authority of an epigram in the Greek anthology, that water mills were invented in the reign of Augustus, yet there is reason to think that they belonged to a much earlier period; for Vitruvius, who flourished under Augustus, and who has given a description of these mills, does not speak of them as a recent invention. The Clepsydra of Ctesibius indeed, which we have already described, contains all the machinery of an overshot water mill. The wheel K is put in motion by the water, which is delivered into its buckets; and the force of the wheel is employed, through the intervention of wheels and pinions, to give a rotatory motion to the vertical pillar.

The first experiments on the motion of fluids seem to have been made by Sextus Julius Frontinus, who was inspector of the public fountains at Rome under the emperors Nerva and Trajan. His work consists of two short books, and is entitled, *Sexti Julii Frontini viri Consularis de Aqueductibus Urbis Romæ Commentarius*. It contains a full account of the different waters which flowed into Rome, of the nature and form of the aqueducts by which they were conveyed, of the times when they were erected, of the quarters of the city which they supplied, the number of public and private fountains from which they were distributed, and the laws which were ordained by the emperors for the management of the public fountains. After fixing the measures which were then used at Rome for ascertaining the quantity of water which flowed from different adjutages, he shews, that the water which flows in a given time from a given orifice does not depend merely upon the magnitude or superficies of the orifice itself, but

* See Heronis *Spiritalia* cura Fred. Commandini 1575, 4to. and 1647 cura N. Alleoti.

also upon the height of the fluid in the containing vessel; and that a pipe employed to carry off a portion of the water of an aqueduct should, according to circumstances, have a position more or less oblique to the direction of the current. Although Frontinus was unacquainted with the true law of the velocity of running waters, as depending upon the height of the reservoir, yet we may consider the foundation of the science of Hydrodynamics as having been laid by his experiments. As the civil engineer will naturally study with a deep interest the first account which has been given of one of the most important branches of his profession, we would recommend, as an accompaniment to the work of Frontinus, the three learned dissertations of Raphael Fabrettus, *De Aquis et Aqueductibus veteris Romæ*, which were published in 1679, and are illustrated by copious maps and engravings.*

Although the science of Hydrodynamics is so intimately connected with the wants and comforts of man, even in a state of considerable barbarity; yet, during the dark ages, it seems to have been treated with the same indifference as the more abstract sciences; and when physics revived under the auspices of Galileo, in the 17th century, the doctrine of fluids was in the same state in which it had been left by Julius Frontinus.

The attention of Galileo was in no respects particularly directed to the doctrine of fluids; but his discovery of the uniform acceleration of gravity paved the way for the rapid progress of this branch of science. In the *Systema Cosmicum* of this great astronomer, we find some occasional observations on the oscillation of fluids, which are marked with his usual sagacity; and in the first dialogue of his Mechanics, Sagredo enters into a very very interesting inquiry respecting the ascent of water in pumps. Galileo had studied the operation of a sucking pump, which had been erected to raise water out of a cistern. He describes the pump as having its piston raised high above the surface of the fluid, and he remarks, that in this case the water ascends by the attraction of the piston, whereas in pumps, where the piston is in the lower part of the tube, the water rises by the impulse of the piston. He was surprised, however, to find, that, when the water descended to a certain point, the pump ceased to act, and continued to lose its power, by any further subsidence of the fluid. Being quite satisfied that the pump was broken, he immediately sent for the pump-maker, who, after examining the machine, assured him, "that the water would not suffer itself to rise to a greater height than 18 cubits, whatever were the dimensions of the pump." After reflecting upon this singular fact, Galileo satisfies himself with the following explanation. When a rod of any solid substance whatever is suspended by one end, it may be made of such a length as to break by its own weight; and, in like manner, if a rod or column of water is raised in a pump to the height of 18 cubits, its weight overpowers the attraction of the piston, and the mutual cohesion of the fluid particles.†

This extraordinary explanation of the ascent of water in pumps attracted, no doubt, the attention of his pupil Evangelista Toricelli, by whom the fact was afterwards completely explained; and having learned from his master that the air possessed weight like all other bodies,‡ he entered upon the study of this branch of Hydrodynamics with very singular advantages. In the year 1643, the year after the death of his master Toricelli, being desirous of making an experiment on a small scale in the vacuum left between the piston of a pump and the column of water which it raised, it occurred to him, that, if he substituted in place of the water a denser fluid, such as mercury, the same cause which supported the water would support a column of mercury of the same height. He communicated this idea to his friend Viviani, who performed the experiment with success, and Toricelli afterwards repeated it with considerable modifications. He accordingly provided a glass tube about three feet long, and hermetically sealed at one end, and having filled it with mercury, he closed it at the open end with his finger, and inverted it in a basin of mercury. Upon withdrawing his finger, the column of mercury descended, and settled at the height of about twenty-nine inches in the tube. Toricelli was not immediately aware of the cause of this singular result; but a little reflection convinced him that it was owing to the pressure of the external air, and that the weight of the atmospherical column was balanced by the 29 inches of mercury in the tube, and by the 33 feet of water in the bore of the sucking pump. When this explanation was fully impressed upon his mind, Toricelli is said to have regretted, with a feeling of generosity of which there is no other example, that it had not fallen to the lot of his master to complete a discovery, of which he had the merit of laying the foundation.

The labours of Toricelli were not confined to Hydrostatics. Having observed, that when a *jet d' eau* was formed by the ascent of water through a small adjutage, it rose nearly to the same height as the reservoir from which it came, he sagaciously conjectured, that it ought to move with the velocity which it would have acquired by falling through the same height. Hence he deduced the fundamental proposition, that, abstracting all resistances, the velocities of fluids in motion are in the subduplicate ratio of the pressures. This result was published in 1643, at the end of his treatise *De Motu Gravium naturaliter accelerato*, and though true only in small orifices, it was confirmed by

* The works of Julius Frontinus and Raphael Fabrettus will be found in Grævii *Thesaurus Antiquitatum Romanorum*, tom. iv. p. 1630—1780. A new edition of Frontinus was published by the Marquis Poleni, with copious notes.

† As a very different account of this interesting anecdote is given in all the Histories of Hydrostatics and Pneumatics, we have subjoined the account of it given by Galileo himself, in his *Discursus et Demonstrationes Mathematicæ*. Dial. vol. i. p. 15.

"Sagr. Et ego hujus discursus ope causam invenio cujusdam effectus, qui diutissime mentem meam admiratione plenam, intellectu vero, vacuam reliquit. Observavi Cisternam, in qua ad extrahendam aquam constructa erat Antlia cujus ope minori cum labore eandem aut majorem aquæ quantitatem, quam urnis communibus, forsan (sed frustra) attolli posse credebam: Habetque hæc Antlia suum Epistomium et lingulam in alto positam, ita ut per attractionem non vero per impulsum adscendat aqua, sicut istæ Antliæ faciunt, quæ a parte inferiori suum opus exercent. Hæc autem magna copia aquam attrahit, donec ea in cisterna ad determinatam quandam constiterit altitudinem; ultra quam si subsederit inutilis est Antlia. Ego, cum prima vice accidens istud observarem, instrumentum fractum esse credens, Fabrum accersivi, ut illud repararet; qui nulli rei istum defectum adscribendum esse mihi respondebat, præterquam ipsi aquæ, quæ nimis depressa ad tantam altitudinem attolli se non patiebatur; subjungens nec Antlia, nec quavis allia machina, quæa quam per attractionem elevat, eam nequidem. pili latitudine altius attolli quam octodecim cubitos; et sive largior sive angustior sit Antlia, hanc maxime definitam ejus esse altitudinem. Et ego, licet jam pernoscam, chordam, massam ligneam et virgam ferream eousque prolongari posse, ut in altum erecta proprio diffringatur pondere, ejus imprudentiæ hucusque reum me feci, ut idem in chorda aut virga aquæ multo facilius evenire posse non meminerim: et quid illud quod per Antliam attrahitur, est aliud, quam Cylindrus aqueus qui superne affixus cum magis magisque prolongetur, ad eum tandem attingit terminum ultra quem elevata, a pondere suo excessivo ad instar chordæ disrumpitur."

‡ This important doctrine is demonstrated by Galileo from two experiments, which he describes in his *Discursus et Demonst. Mathemat.* Dial. vol. i. p. 71, 72.

the experiments of Raphael Magiotti, and paved the way for the discovery of the more complex law, which regulates the motion of fluids, when the area of the orifice has a considerable magnitude compared with the horizontal section of the vessel.

The subject of running water had been previously studied by Benedict Castelli, the disciple of Galileo, and the first master of Toricelli. Pope Urban VIII. had requested him to devote his attention to this interesting subject, when he was employed in teaching mathematics at Rome; and in order to discharge the duty which was thus imposed upon him, he made numerous experiments, of which he published a full account in a small treatise, *Della Mesura dell' acque correnti*, which appeared in 1628. In this work he explains several phenomena relative to the motion of fluids in rivers and canals of any shape, and he shews, that when the water has come to a state of permanent motion, the velocities at different sections of the river or canal are inversely as their areas. He applies these general propositions to the course of some rivers, and he explains several phenomena in a manner tolerably satisfactory. The conclusions which he draws are generally correct; but he has committed a mistake in making the absolute velocity proportional to the declivity of the canal, or to the height of the water.*

As soon as the curious results obtained by Toricelli were known in France, the celebrated Pascal, who was then residing at Rouen in Normandy, repeated them with great care, and under various modifications, in the year 1646; and in 1647 he published his *Experiences Nouvelles touchant le vuide*, from which he concluded, that the upper part of the tubes of glass which he used did not contain air similar to that of the atmosphere, nor any portion of water or mercury, and that it is entirely void of every material substance with which we are acquainted. He inferred also, that all bodies have a repugnance to separate into parts, and that this repugnance, which does not vary with the magnitude of the vacuity, is equivalent to the weight of a column of water 33 feet high. This little work was vehemently attacked by Father Noel; and Pascal was led, by the views and experiments of which we have given a detailed account in our article on the BAROMETER, to demonstrate the important principle in Hydrodynamics, that the rise of water in pumps was owing to the pressure of the atmosphere.

The researches of Pascal on the gravity of the air naturally led him to the examination of the laws which regulate the equilibrium and pressure of fluids. Stevinus had already observed, that the force exerted upon the bottom of a vessel by the superincumbent fluid was equal to the weight of a column of fluid, whose base was equal to that of the vessel, and whose height was the height of the fluid, and the quaquaversus pressure of fluids had been generally known; but it was reserved for Pascal to deduce from these principles the general laws of the equilibrium of fluid bodies. He supposes, that two apertures are made in a vessel full of fluid, and enclosed on all sides, and that two pistons applied to these apertures, are pushed with forces proportional to the areas of the apertures; and he demonstrates, in two different ways, that, under these circumstances, the fluid will remain in equilibrium. In the first demonstration he shews, that the pressure of the piston is communicated to every particle of the fluid, so that if the one piston advances through a certain space, the other must retreat; and, as the volume of water continues invariable, the spaces described by the two pistons will be reciprocally proportional to the area of their bases, or to the forces which impel them. Hence it follows, from the principles of mechanics, that the two pistons are in equilibrium. This general theorem conducts its ingenious author to the different cases of the equilibrium and pressure of fluids, which flow from it as so many corollaries. These fine results were not published during the life of Pascal, but were found after his death in a MS. entitled *Sur l'Equilibre de Liqueurs*, which appeared in 1663, a year after the death of the author.

Although Descartes is not entitled to be considered as the discoverer of the pressure of the atmosphere, yet it is obvious from one of his letters, which is dated in 1631, that he considered the suspension of the mercury in a glass tube as arising from the pressure of the superincumbent column of air; and by the same cause he accounts for the force with which a glass filled with air rarefied by heat adheres to the palm of the hand when it is quickly inverted upon it. In another of Descartes' letters, of a date only a little posterior to the publication of Galileo's Mechanics, he criticises this work with unjust severity, and, rejecting the idea of a vacuum as entertained by Galileo, he ascribes the adhesion of two polished surfaces to the pressure of the atmosphere, and attributes to the same cause the elevation of water in the sucking pump; and in another letter he maintains, that, in reservoirs kept full of water by the superior aperture being shut, the fluid is not suspended by the dread of a vacuum, but by the weight of the air.†

M. Mariotte, who was the first person that introduced experimental philosophy into France, contributed greatly to the progress of practical Hydrodynamics. Possessing the rare talent of contriving and performing experiments, he embraced the opportunity which circumstances presented to him, of executing a great number of experiments on fluids at the splendid water-works of Versailles and Chantilly. An account of the results which he obtained was published in 1684, after his death, in his *Traité du mouvement des Eaux*. In this work Mariotte employs the theorem of Toricelli; and though he treated some important points very superficially, and committed considerable errors in the discussion of others, yet it contains many valuable materials. He was unacquainted with the diminution of efflux, which arises from the *vena contracta*, when the adjutage is a perforation in a thin plate; but he had the honour of being the first who ascribed the discrepancies between the theory and experiment to the effect of friction. Having observed that water suffered considerable retardation even when moving in the smoothest glass tubes, he supposed the retardation to arise from the friction of the particles upon the sides of the tube, in the same way as the velocity of solid bodies is diminished by the friction of the surfaces over which they move. The particles or filaments immediately adjacent to those which rub upon the sides of the tube, outstrip them in velocity, and have their own velocity diminished in a less degree; so that the diminution of velocity arising from friction grows less towards the axis of the tube. Hence the medium velocity of the fluid from which the quantity of efflux is determined, is much smaller than it would have been had there been no friction to retard its motion.

The motion of rivers, or of water in open pipes and canals, is perhaps one of the most interesting subjects in which science can lend her aid, to relieve the wants and necessities of man. In Italy, where the fertility of the

* Several letters from Galileo to Castelli on the motion of fluids, but relating principally to Castelli's opinions, have been published in the *Nuova Raccolta*, tom. iv.

† See *Recueil des Lettres* de M. Descartes, tom. iii. sect. 3. p. 602; tom. ii. lett. 91. *L'eau ne demeure pas dans les vaisseaux par la crainte du vuide, mais a cause de la pesanteur de l'air*, tom. ii. lett. 94.

soil is not more owing to her genial climate than to the numerous canals and rivers with which it is traversed, the attention of her philosophers was imperiously called to the study of moving water. To protect themselves from the inundations with which they were often threatened, it became necessary to divert their rivers into new channels; and the ravages which were thus accidentally made on the territories of their neighbours gave rise to those fierce contentions which never fail to spring from contending interests. The defence of their persons and properties, and the necessity of adjusting the opposing interests of neighbouring states, rendered the cultivation of Hydrodynamics a matter of indispensable necessity among the different states of Italy, and hence a great number of valuable works were produced by the Italian engineers.

The most eminent of these engineers was Dominic Guglielmini, who was inspector of the rivers and canals in the Milanese, and who obtained such eminence in his profession, that a new chair on *Hydrometry* was erected for him in the university of Bologna. In his principal work, entitled *La Misura dell' acque Correnti*, he adopts the theorem of Toricelli, and founds upon it a system of Hydraulics sufficiently beautiful in theory, but utterly repugnant to experiment. He regards every point in a mass of fluid as an orifice in the side of a vessel, and as tending to move with the same velocity with which it would issue from the orifice. Hence it follows, that, since the velocities are as the square roots of the depths of the orifices, the velocity must be greatest at the bottom of a stream, and least at its surface; and that the velocity of a river must continually increase as it moves. These results were so hostile to established facts, that Guglielmini himself attempted to reconcile them. He had applied his theory to cases which occurred in the Milanese, and to the motion of the Danube, and he had seen, that the regular progress of the current was often opposed by transverse motions, and by a sort of boiling or tumbling motion which arises from ascending masses of fluid. Hence he supposed that these causes were sufficient to account for the errors of the parabolic theory. Guglielmini had now become acquainted with the labours of Mariotte, and in his work entitled *Della natura dell' Fiumi*, the first part of which appeared in 1697,* and acquired great celebrity to its author, he takes into account the retardation produced by friction and other causes. This work consists of 14 chapters, the three first of which contain definitions and general notions respecting the equilibrium of fluids, and the origin of springs and fountains. In the 4th chapter he treats of the motion of water falling vertically, or descending along an inclined plane; and he examines the various causes, such as friction, the resistance of the air, &c. which extinguish a part of its velocity, and render the theory inconsistent with experiment. The 5th chapter treats of the beds of rivers, their depth, their width, and their declivity. The 6th chapter is an application of the principles laid down in the 5th to the directions which are taken by the beds of rivers. In the 7th chapter he examines the various motions which are observed under different circumstances in the waters of rivers, and he thus follows the current from its source to its embouchure. In chapter 8. he treats of the embouchure of rivers, either when they fall into one another, or into the sea. In chapter 9. he considers the union of several rivers, and the effects which result from it. Chapter 10. treats of the increase or diminution of rivers. Chapter 11. relates to the formation of temporary currents in times of rain. Chapter 12. treats of regular canals, and the methods of deriving them from rivers or reservoirs of water. Chapter 13. treats of the drainage of wet land; and chapter 14. of the precautions which are necessary in changing the bed of a river.

In order to demonstrate the inconsistency of the Cartesian system of vortices with the laws of Hydraulics, Sir Isaac Newton directed his particular attention to the investigation of the manner in which the fluid vortices could be produced and preserved, and he has given the results of his inquiries in the 9th section of the second book of the *Principia*, entitled *De Motu Circulari Fluidorum*. In these elegant propositions, which are the 51st, 52d, and 53d, he lays down the hypothesis, that the resistance which arises from the want of perfect lubricity in fluids is *cæteris paribus* proportional to the velocity with which the parts of the fluid are separated from each other; and he demonstrates, that if a solid cylinder of infinite length revolves, with an uniform motion, round a fixed axis in an uniform and infinite fluid, the periodical times of the parts of the fluid, thus put into an uniform motion, will be proportional to their distances from the axis of the cylinder; whereas, if a solid sphere is made to revolve in a similar manner, the periodical times of the fluid particles will be proportional to the squares of their distances from the centre of the sphere. Hence it follows, from the equality of action and reaction, that the velocity of any stratum of the circulating fluid is a mean between the velocities of the strata by which it is bounded. In considering, therefore, the velocity of water in a pipe, as affected by viscidity and friction, it is obvious that the filaments immediately adjoining to the pipe will be greatly retarded. The contiguous filaments will be kept back by their adhesion to the others, and the velocity will thus increase towards the centre of the pipe, according to a law which is easily deducible from the principle, that the velocity of any filament is a mean between the velocities of the filaments which surround it. M. Pitot was the first person who took advantage of this important principle, and, in the Memoirs of the Academy for 1728, he shewed, that the total diminution of velocity in pipes of different kinds is inversely as the diameters of the pipes.

In the second book of the *Principia*, (See Prop. 36.) Newton has investigated the motion of fluids when issuing from an orifice made in the bottom of a vessel, without limiting himself to the hypothesis of an infinitely small orifice. Supposing the water to be always kept at the same height in the vessel, he considers the cylindrical mass of fluid as divided into two parts, one of which is in the centre of the vessel, and moveable; while the other, which is immoveable, is formed by the part of the fluid in contact with the sides of the vessel. The central portion, which Newton calls the *Cataract*, is supposed to have the form of a hyperboloid, formed by the revolution of a hyperbola of the 4th degree round the axis of the cylinder. The horizontal strata of the cataract are always in a state of gradual descent; while all the rest of the fluid is absolutely at rest, as if it had been converted into ice. From this manner of considering the subject, it followed, that the water ought to issue with a velocity equal to that which it would acquire by falling through the height of the fluid; but when Newton came to investigate the subject experimentally, he concluded, that the velocity of efflux was only that which was due to half the height of the fluid. This result, however, was in direct opposition to the known fact, that jets of water rise to nearly the same height as their reservoirs, and the error arose from his not having

* The second part of this work did not appear till after his death in 1712. The whole was published with notes by Manfredi, in the *Nuova raccolta di autori che trattano del moto dell' acque*, tom. ii.

attended to the contraction of the fluid vein, (or *vena contracta*) which he afterwards found to take place in such a manner, that, at the distance of nearly a diameter of the orifice from the orifice itself, the section of the vein of issuing fluid is reduced or contracted in the ratio of 1 to the square root of 2, or of 1 to 1.4142. He accordingly corrected this error in the edition of the *Principia* which appeared in 1714; and considering the area of the section of the *vena contracta* as the true area of the orifice from which the water should be conceived to flow, he made the velocity equal to that of the height of the fluid, and obtained results more agreeable to experience. Notwithstanding this additional accuracy to which Newton had brought his theory, it was still liable to the very serious objections which have been urged against it by succeeding authors. Giannini has written a dissertation against it in his *Opuscula*, and John Bernoulli, in the 4th volume of his works, has demonstrated, that, if such a *cataract* existed, the part of the fluid without the cataract would be stagnant, and consequently would exert a pressure, in virtue of its gravity, against the cataract itself in which the fluid ought to experience no pressure. But, independent of this species of argument, it may be shewn, as Bossut has done, by direct experiment, that when a vessel of water empties itself by an orifice in the bottom, every fluid particle descends vertically, whether it is situated near the axis or the side of the vessel; and that this vertical motion is not changed into a lateral one till the particles are very near the orifice itself.

The subject of the resistance of fluids, one of the most important and difficult in Hydrodynamics, was likewise investigated by Sir Isaac Newton. He first considers the fluid as a rare medium, composed of equal parts, situated at equal distances from each other, and possessing the property of perfect intermobility, so that one particle may strike the solid, without being prevented by any of the adjacent ones. Hence he finds, that if a globe and a cylinder, of equal diameters, move in such a medium with equal velocities, the resistance of the globe will only be one half of that of the cylinder. He next proceeds to determine the absolute resistance which the globe will experience, whether the parts of the fluid are perfectly elastic, or absolutely inelastic. In the case of perfect elasticity he shews, that the resistance of the globe is to the force by which its total motion may be produced or destroyed in the time that it takes to describe two-thirds of its diameter by a uniform velocity, as the density of the medium is to the density of the globe. In the case of absolute inelasticity, he shews that the resistance is twice as small. After examining the resistance in different mediums, as water, mercury, oil, &c. he advances another theory, suited to those mediums in which the globe does not immediately strike all the resisting parts of the fluid, but only communicates to the neighbouring particles a pressure which is transmitted to all the rest. From this theory it follows, that the resistance of a globe is equal to that of the circumscribed cylinder. This hypothetical theory, though it exhibits much of Newton's characteristic ingenuity, it still founded on false principles, and is radically inconsistent with the results of experiment.

With the exception of a few observations by Galileo in his *Systema Cosmicum*, we are indebted to Sir Isaac Newton for all that was known in his time respecting the oscillation of waves. In order to investigate this difficult subject, he considers the fluid as at rest in the two vertical branches of a syphon connected by a horizontal branch. If the one column is raised to a greater height than the other, and is then permitted to descend, it will obviously fall below its original level, and raise the other column to a greater height than that at which it formerly stood. This column will in like manner descend, and the opposite column will rise, till, after a certain number of oscillations, the fluid will return to a state of rest. In order to determine the time in which these oscillations are performed, Newton considered the water as in the same state with a pendulum vibrating in a cycloid, and he shews by a very simple demonstration, that a pendulum, whose length is equal to half the length of the column of water in the syphon, will perform its oscillations in the same time with the fluid. Hence it follows, that all the oscillations of the fluid will be isochronous, whatever be the intensity of the motions of the fluid; and that the velocity of waves will vary as the square roots of their breadth.

The motion of fluids was treated, both experimentally and theoretically, by Michelotti, a celebrated Italian physician, in his work, entitled *De Separatione Fluidorum in Corpore Animalia*, published in 1719 or 1720. He rejects Newton's idea of a cataract, and considers the water in a vessel as all frozen, excepting a small part of it immediately above the orifice. This thin plate of water is pressed by the superincumbent solid, which is supposed to melt gradually as the water is discharged. In this work Michelotti criticises, with rather too much severity, a paper "On the Motion of Running Water," published by Dr Jurin in the *Philosophical Transactions* for 1718. Jurin replied to this criticism in the *Phil. Trans.* for 1722, and successfully defended Sir Isaac Newton against the charge of inconsistency, which was rashly brought against his doctrine of effluent water by the Italian philosopher.

A series of valuable experiments on the motion of water in conduit pipes, were made on a very large scale by M. Couplet, on the water-pipes at Versailles. These experiments, though not sufficiently varied, shew the great effect which is produced by friction on the motion of water. A full account of them is published in the Memoirs of the Academy for 1732, in the paper entitled *Des Recherches sur le mouvement des Eaux dans les tuyaux de conduite.* The theory which he has founded upon his experiments, and also that which M. Belidor has substituted in its place, are not deserving of notice.

Italy produced about this time several authors on Hydrodynamics, that have acquired considerable celebrity. The most distinguished of these was Guido Grandi, who wrote a geometrical treatise on the motion of water, deduced from the theorems of Galileo and Toricelli. He invented also a method of measuring the velocity of a river at different depths by a tin parallelopiped, which had an aperture that could be opened and shut by a moveable plate. The box was sunk to the required depth, and the orifice opened. After a certain time had elapsed, the orifice was again shut, and the velocity was determined from the quantity of water in the box. Grandi was also the author of several dissertations on the river Æra, and on other small Italian rivers. All these works are published in the *Nuova Raccolta*, already referred to. Eustachio Manfredy, another Italian author, contributed to the progress of Hydrodynamics. He added valuable notes to Guglielmini's work on rivers. He published a dissertation in conjunction with Zendrini, on the means of preventing the inundations of the Ronco and the Montone in the town of Ravenna; and he was the first person who proved, by decisive experiments made on several of the ancient buildings of Ravenna in 1731, that the bottom of the Adriatic Sea was continually rising. The names of Zendrini and Frisi deserve to be mentioned among the Italian writers on Hydrodynamics. Bernard Zendrini, a Venetian mathematician, wrote a very ample work, both theoretical and practical, entitled *De Motu Aquarum*, which contains many excellent practical observations. Frisi composed a work on the method of regulating rivers and torrents, in which he has endeavoured to prove that gravel and sand are original productions, and not the detritus of pre-existing materials. A selection of practical observations from the work of Zendrini will be found in the 5th volume of the *Nuova Raccolta*, and the whole of Frisi's work in the 7th volume of the same collection.

One of the most celebrated writers on Hydraulics that Italy produced, was the Marquis Poleni, professor of mathematics at Padua. In the year 1695 he published a treatise in 4to. entitled *De Motu Aquæ mixto*, which, though it contains nothing that possesses much novelty, yet the reader will find in it many observations both of local and general utility. He supposes, that the bed of a river is a rectangular canal, and regarding any perpendicular section of it as an orifice, he gives the name of *dead water* to that which is comprehended between the surface, and a point in relation to which all the fluid molecules would have equal *momenta*, and would therefore be in equilibrium, according to the laws which are observed in the equilibrium of solid bodies: The rest of the water which is comprehended between this centre of equilibrium and the bottom of the canal or orifice, he calls the *living water*. He then considers the motion of the water that flows through the orifice as partly produced by the action which the *living water* derives naturally from its fall, and partly by the pressure which the *dead water* exerts upon the *living water*. Hence arises the title of Poleni's work, *De motu mixto Aquæ*. After detailing a number of experiments, and comparing the results with the theory, he applies the same principles to the motion of rivers, and to the lakes of Venice. His principal work, however, appeared at Padua in 1718, under the title of *De Castellis per quæ derivantur fluviorum aquæ*. This work contains many important observations and experiments. From an extensive series of experiments on the quantity of water discharged by an orifice in the bottom of a vessel, he concluded, that, instead of being proportional to 2 A H, A being the area of the orifice, and H the height of the reservoir in the vessel, it was proportional to $2\text{AH}\times\frac{0.571}{1.000}$, which is only a little more than one half of what is discharged, upon the supposition that the water issues with a velocity due to the altitude H. Poleni was the first person who observed, that a greater quantity of water issued from a small cylindrical tube, fitted into the orifice in the bottom or sides of a vessel, than from a simple orifice of the same diameter. This remarkable fact may be explained by supposing that the fluid vein, instead of suffering a contraction, flows out in a column of the same diameter as the orifice, from the viscidity of the water, and its capillary adhesion to the sides of the tube. We are indebted also to Poleni for a new edition of the works of Julius Frontinus, which he enriched with ample notes. Poleni is likewise the author of a dissertation on dikes, and of another on the measure of running waters, both of which, along with his first work, are republished in the 3d volume of the *Nuova Raccolta*.

Hitherto the science of Hydrodynamics was founded upon vague and uncertain principles; but it was now destined to receive a more scientific form from the labours of Daniel Bernoulli. So early as the year 1726, he communicated to the academy of St Petersburgh a memoir, entitled *Theoria Nova de Motu Aquarum per Canales quoscunque fluentes*. In this memoir he informs us, that his father having shewn, that the principle of the *vires vivæ* was of great use in the resolution of problems incapable of being solved by more direct methods, it had occurred to him to employ this principle in discovering a true theory of the motion of running waters, and that he had found it to answer his utmost expectations. After the publication of this memoir, which contains merely the germ of his theory, he made a great number of experiments at St Petersburgh, in order to illustrate his theoretical views, and was thus enabled to produce his great work, entitled *Hydrodynamica seu de viribus et motibus fluidorum Commentarii*, which was published at Strasburg in 1738. In considering the efflux of water from an orifice in the bottom of a vessel, he conceives the fluid to be divided into an infinite number of horizontal strata, which are supposed to move in such a manner, that the upper surface of the fluid always preserves its horizontality; that the fluid forms a continuous mass; that the velocities vary by insensible gradations, like those of heavy bodies; and that every point of the same stratum descends vertically with the same velocity, which is inversely proportional to the area of the base of the stratum. By the aid of these assumptions, which are conformable to experience, Bernoulli obtains an equation from the principle that there is always an equality between the actual descent of the fluid in the vessel, and its vertical ascension, which is the principle of the conservation of living forces. In those cases, where sudden irregularities in the shape of the vessel, or other causes, produce rapid changes in the velocity of the fluid strata, he then considers that there is a loss of living force, and therefore the equations founded on the entire conservation of this force require to be modified. In the whole of this investigation, Bernoulli displays the greatest sagacity and originality of thought, though he has taken it for granted, without sufficient evidence, that the law of the conservation of living forces is really applicable to the motion of fluids (a point which it was reserved for D'Alembert to demonstrate); yet his work will be long regarded as one of the finest specimens of mathematical genius.

The important subject of the resistance of fluids was likewise indebted to the genius of Daniel Bernoulli. In the *Commentaria Petropolitana* for 1727, he modestly proposed a new method of determining the resistance of fluids, founded upon principles different from those of Sir Isaac Newton; but having found that it gave results quite hostile to experiment, he afterwards called his determination in question in his treatise on Hydrodynamics, and in the year 1741, in the eighth volume of the commentaries of St Petersburgh, he proposed a very ingenious and elegant method of determining the impulse of a column of fluid falling perpendicularly upon a plain surface infinitely extended. He considers the curve described by every filament of fluid as a canal in which a body moves, which experiences at each point the action of a centrifugal force, and which he supposes also to be subjected to the action of a tangential force, varying according to a given law. He then calculates all these forces, and finds that the impulsion against the horizontal plane is equal to the weight of a column of fluid whose base is equal to the section of the fluid vein, and whose altitude is twice the height of the fall due to the velocity of the fluid. Although there are cases, in which this proposition may be safely and advantageously used in practice, yet it does not easily apply either to oblique impulses, or to impulses against curved surfaces, and it is of no service whatever in determining the resistance of fluids, when the resisting body is completely submerged. In order to put this theory to the test of experience, Daniel Bournoulli, and his pupil, Professor Krafft, instituted a series of experiments on the impulse of a stream of water against a plain surface placed horizontally. These experiments, which are highly valuable, are published in the 8th and 11th volumes of the Commentaries of St Petersburgh. The stream of water was received on a plain surface fixed on the arm of a balance, which had a scale suspended at the opposite extremity. The weights in the scale were made to balance the resistance produced by the impulse on the surface, and the velocity of the issuing fluid was determined from the distance to which it was projected on a horizontal plane. These results were wonderfully conformable to the deductions of theory. The experimental was always a little less than the theoretical resistance, as appears from the following results.

| | | | | | | |
|---|---|---|---|---|---|---|
| Resistance by theory | 1701 | 1720 | 1651 | 1602 | 1520 | 1072 |
| Resistance by experiment | 1403 | 1463 | 1486 | 1401 | 1403 | 1021 |

John Bernoulli, the father of Daniel, was occupied with the subject of Hydrodynamics at the same time with his son; and there is reason to believe, that so early as the year 1726, he was in possession of the chief part of his theory of running water. The work which he composed upon this subject remained in MS. till his death, when it appeared in 1742 in the fourth volume of his works, under the title of *Hydraulica nunc primum detecta et directe demonstrata ex principiis pure mecanicis.* It was also published in the Memoirs of the Academy of St Petersburgh for 1737 and 1738. The method of John Bernoulli is founded upon an assumption not very unlike to the Newtonian cataract; and the principal results of his theory did not differ very widely from those of his son. In the opinion of the celebrated La Grange, it is defective in perspicuity; but Euler, who had seen the MS. congratulates Bernoulli, in a letter prefixed to the work, for having discovered the true principles of Hydrodynamics. In his discourse on the laws of the communication of motion, John Bernoulli has determined, on the same supposition, the resistance of fluids; but the formula, by which he represents the resistance, though sufficiently simple, is still insufficient.

About the same time, our Countryman, Colin Maclaurin, objected to the theory of Daniel Bernoulli, in so far as he employed the doctrine of the conservation of living forces, and endeavoured to solve the problem of the motion of fluids that are discharged from reservoirs by a more direct method. This method, which is only an extension of the theory of Newton, was published in his Treatise on Fluxions, which appeared in 1742. It is given under two sections, one of which treats of the motion of water issuing from a cylindric vessel, and the second of the motion of water issuing from any vessel; but the method has not been considered as sufficiently rigorous.

The science of hydraulics was now destined to receive the most important accessions from the genius of the celebrated D'Alembert. When he was employed in generalising the theory of pendulums given by James Bernoulli, he discovered his famous dynamical principle for determining the motion of a system of solid bodies which act upon each other. He considers the velocity with which each body tends to move as composed of two other velocities, one of which is destroyed, while the other does not obstruct the motion of the adjacent bodies. In applying this principle to hydraulics, he first enquires what ought to be the motion of the particles of a fluid, in order that they may not obstruct one another's movements. He shews, both from theory and experiment, that when a fluid issues from a vessel, its upper surface always preserves its horizontality, from which he concludes that the velocity of all the points of any horizontal stratum, when estimated in a verticial direction, is the same, and that this velocity, which is that of the stratum, ought to be in the inverse ratio of the area of the base of the stratum itself, in order that it may not obstruct the motions of the other strata. By combining this principle with the general one, D'Alembert has reduced all the problems relative to the motion of fluids to the ordinary laws of hydrostatics. The problems which relate to the pressure of fluids against the sides of vessels in which they run, and to the motion of a fluid which escapes from a vessel moveable and carried by a weight, though they had formerly been solved only by indirect method, flow as corollaries from D'Alembert's general principles. This theory has also the great advantage of enabling us to demonstrate, that the doctrine of the conservation of living forces applies to the motion of fluids as well as to that of solids; and the principles of the theory are applicable to elastic as well as inelastic fluids, and to the determination of the motion of fluids in flexible pipes, a case which applies to the mechanism of the human frame. These fine views were first published at the end of D'Alembert's Dynamics in 1743, and they were afterwards more fully developed in his *Traité de l'equilibre et du Mouvement des Fluides*, which appeared at Paris in 1744.

After having established the laws of the equilibrium and motion of fluids, D'Alembert next directed his attention to the resistance which they oppose to the motion of solid bodies. This eminent mathematician attributes the slow progress of discovery in this branch of hydrodynamics to those unphilosophical investigations, in which a greater fondness was shewn for the calculus than for the physical principles on which it is founded; and he does not scruple to say, that the choice of these principles was often made, more from their forming a good ground work for the application of the calculus, than from their having a real foundation in nature. In order to avoid this error, D'Alembert first investigated the principles upon which he was to proceed, before he thought of the analysis which he was to apply to them; and by this truly philosophical mode of enquiry, he has established a theory founded upon no arbitrary suppositions. He merely supposes that a fluid is a body composed of very small particles, detached, and capable of moving freely among one another. D'Alembert regards the resistance which one body suffers from another as nothing more than the quantity of motion which it loses; and when the motion of a body is changed, he considers this motion as composed of that which the body will have in the following instant, and of another which is destroyed. This principle he found applicable to the resistance of fluids, and the investigation of this resistance he reduces to the laws of equilibrium between the fluid and the solid body. He supposes at first, that a body is by some external means kept at rest in the middle of a fluid which is about to strike it. When the filaments of the fluid strike the solid, they bend themselves round it in different directions, and that part of the fluid which covers the anterior part of the body is, to a certain extent, stagnant. The pressure experienced by the solid, or the resistance which it opposes to the motion of the fluid particles, is occasioned by the loss of velocity which each of these particles sustains. The problem is then reduced to this, to find the velocity of the fluid which slides immediately over the surface of the body, which D'Alembert has done by two different methods, and he then obtains a formula exhibiting the pressure exerted upon the solid. By a little modification of the general method, D'Alembert determines the action of a vein of fluid which strikes a plain surface, and he finds it to be a little less than the weight of a cylinder of fluid, the area of whose base is equal to that of the section of the vein, and whose altitude is double of that which is due to the velocity of the fluid; a result which agrees most wonderfully with the experiments of Bossut, who found that it was always a little less than that which was due to twice the height which produces the velocity.* The results of this enquiry were published in 1752, in D'Alembert's *Essai d'une nouvelle theorie sur la resistance des Fluides*, and the theory was afterwards extended in his *Opuscules Mathematiques*.

The celebrated Euler, to whom every branch of science owes such deep obligations, did not fail to exhibit the wonderful resources of his genius on a subject of such difficult investigation as the theory of running water. In the Memoirs of the Academy of St. Petersburgh, for 1768, 1769, 1770, and 1771, he has published a new and complete theory of the motion of fluids, which is founded on the laws of mechanics and hydrostatics, and occupies no less than 513 quarto pages. The first of these memoirs is entitled *De Statu Equilibrii Fluidorum*, and is divided into four sections: 1. *De Natura et varietate Fluidorum.* 2. *De Equilibrio Fluidorum, remota gravitate aliisque similibus viribus.* 3. *De Equilibrio Fluidorum a viribus quibuscunque sollicitatorum*; and, 4. *De Equilibrio Fluidorum a sola gravitate sollicitatorum*, in which he applies his reasonings both to compressible and incompressible fluids. The second memoir is entitled *De Principiis Motus Fluidorum*; the third, *De Motu fluidorum lineari potissimum aquæ*, and the fourth, *De Motu aeris in Tubis*. In the third memoir, he deduces, from his general theory, explained in the preceding memoir, the solution of a great number of beautiful problems upon a particular species of the motion of fluids, which he calls *linear*. The same general theory is applied in his memoir *De Motu Aeris* to the linear motion of air. In these memoirs, he reduces the whole theory of the motion of fluids to two differential equations of the second order, and he applies the general principles to the discharge of water from orifices in vessels, to its motion in conduit pipes, whether their diameters be constant or variable. In extending his investigation to elastic fluids, and particularly to air, he obtains very simple formulæ respecting the propagation of sound, and its formation in flutes and in the pipes of an organ. It is much to be lamented, that in all these researches, Euler has proceeded on the hypothesis of a mathematical fluidity, which has no existence in nature. Had he only treated the subject in reference to those resistances, such as cohesion and friction, which modify the action of gravity, the solutions which he has given might have been advantageously applied to the motion of water in pipes and canals.

In the year 1765, a very complete work on the theory and practice of hydrodynamics was published at Milan, by P. Lecchi, a celebrated Milanese engineer. It was entitled, *Idrostatica esaminata ne' suoi principi, e stabilita nelle sue regole della mesura delle acque correnti*, and contains a complete examination of all the different theories which have been proposed to explain the phenomena of effluent water, and the doctrine of the resistance of fluids. The author treats of the velocity and the quantity of water, whether absolute or relative, which issues from orifices in vessels or reservoirs, according to their different altitudes, and he afterwards enquires if this law is applicable to large masses of water, which flow in canals and in rivers, and he demonstrates the rules which have been found most useful in practice for the division and the mensuration of running water. This work contains several pieces by the celebrated Italian geometer Father Boscovich, by whom the work was revised and corrected. The extensive and successful practice of Lecchi as an engineer, has stamped a high value upon his work.

A very extensive series of experiments on the motion of water in pipes and canals, was made at Turin by professor Michelotti, and at the expence of the King of Sardinia. These experiments were performed upon a splendid scale, and with every attention to accuracy. The water issued from orifices and tubes of various shapes and sizes, from a tower of the finest masonry, twenty feet high and three feet square, supplied by a canal two feet wide, and under pressures, which varied from five to twenty-two feet. A huge reservoir, whose area was 289 feet square, built of masonry, and lined with stucco, received the effluent waters, which were conveyed in canals of brickwork, lined with stucco, and having various forms and declivities. Michelotti's experiments on the motion of water in pipes, are the most numerous and exact that have yet been performed. The trials which he made in open canals are still more numerous, but they are complicated, with many unnecessary circumstances, and seem to have been made more with the view of examining some disputed points in hydraulics, than of furnishing us with rules for cases which are likely to occur in practice. A full account of these experiments was published at Turin in 1774, in Michelotti's *Sperienze Idrauliche*. Michelotti published also a memoir on the impulse of a vein of fluid, in which he describes some experiments which do not agree with the common theory. It appeared in the Memoirs of the Academy of Turin for 1778.

One of the most zealous and enlightened cultivators of hydrodynamics, was the late Abbé Bossut, who has published a full account of his theoretical and experimental investigations, in his *Traité Theorique et Experimental d'Hydrodynamique*, in 2 vols. 8vo. The first edition was published in 1771; the second edition appeared in 1786, considerably enlarged; and a third edition, with very considerable alterations, was published in 1796. The experiments of Bossut, though made on a much less scale than those of Michelotti, have, in as far as they coincide, afforded similar results; and while they have the merit of equal accuracy, they are much more applicable than those of the Italian philosopher to cases which are likely to occur in practice. In order to determine the motion of the particles of a fluid which was in the act of being discharged from an orifice, Bossut employed a glass cylinder about eight inches high, and six inches diameter, to the bottom of which he fitted different adjutages for the efflux of the water. Whether this vessel was kept constantly full, or emptied itself without any supply, he observed that all the particles descended at first vertically, but at a certain distance from the orifice the lateral particles began to turn from their vertical direction towards the orifice; so that they entered the orifice near its circumference with an oblique motion, which continuing during a certain time, caused the effluent vein of fluid to have the form of a truncated conoid, whose greatest base was the orifice itself, the smaller base being a vertical section of the fluid, at a certain distance from the orifice. Beyond this section, which Newton called the *vena contracta*, the fluid vein preserved its cylindrical form. Bossut found the height of the conoid to be nearly equal to the radius of the orifice, and its bases to be in the ratio of three to two. He expected to have been able to employ this conoid as one of the elements for determining the quantity of water discharged; but subsequent experiments convinced him that this was impracticable. The contraction of the fluid vein, which Bossut has so well explained, cannot be removed, as Daniel Bernoulli maintained, by applying a small tube to the orifice; for though the quantity of water discharged is thus increased, yet it is never so great as if all the filaments of the fluid had issued in lines perpendicular to the plane of the orifice. Bossut's next object was to perform a complete set of experiments on the quantities of water discharged by

* See Bossut's *Hydrodynamique*. Chap. xiv. Exp. 5, 6, 7, 8.

orifices in thin plates, and by additional tubes fitted to these orifices. When the orifice was very small in comparison with the size of the vessel, he found that the theoretical law —that the quantity of water discharged was as the product of the line by the orifice, and the square root of the height of the reservoir—was sufficiently correct, and might be employed in ordinary practice. But when the water flowed through an orifice in a thin plate, the contraction of the vein of fluid diminished the theoretical discharge in the ratio of sixteen to ten; and when the fluid was discharged through an additional tube, two or three inches long, so as to follow the sides of the tube, the theoretical discharge was diminished only in the ratio of sixteen to thirteen. In examining the effects of friction and contraction, Bossut found, that small orifices discharged less water in proportion than great ones, on account of friction; and that as the height of the reservoir augments, the contraction of the fluid vein also augments, and consequently the quantity of water discharged diminishes. By combining these two circumstances, he has furnished us with the means of measuring with precision the quantities of water delivered, either by simple orifices or tubes, whether the vessel is kept constantly full, or allowed to empty itself without any supply.

Bossut next proceeds to consider the motion of jets of water. He determines the most suitable form that can be given to the adjutages, and the best proportion between the diameter of the adjutage and that of the pipe in which the water is conveyed. Hence we are able to obtain the best possible effects for the decoration of gardens or public buildings.

As the conducting of water is one of the most important and useful branches of hydraulics, Bossut made a great variety of experiments on the motion of water in canals and pipes. The effect of friction, and of sinuosities or bendings in the pipes, is so remarkable, that the quantity of water actually delivered may be twenty or thirty times less than what might have been expected from theory. M. Bossut has shewn, that when the height of the reservoir is increased, the diminution in the discharge of the water is less sensible. He points out the law, according to which the discharge diminishes as the pipe becomes longer, or as the number of its bendings is increased. In considering the motion of water in open canals, he first examines the law, according to which the friction diminishes the velocity of the stream in rectangular canals; and he shews, that in an open canal, with the same height of reservoir, the same quantity of water is always discharged, whatever be its declivity and its length; whereas in pipes there is a very remarkable variation, by a variation in its declivity and its length. He found, that the velocities in a canal are not as the square roots of the declivities; and that at an equal declivity and an equal depth of the canal, the velocities are not as the quantities of water discharged. The subject of rivers next occupies the attention of our author. He considers the variations which take place in the velocity and level of the waters when two rivers unite, and the manner in which rivers form and establish their beds. He next treats of the formation of bars at the mouths of rivers, or at the junction of two rivers; he points out the means which may be successfully employed, either in removing wholly or in part these dangerous banks; and he concludes this part of his work, by determining the change which takes place in the depth of a river, when any change takes place in the width of its bed, as happens from the construction of a bridge; and by ascertaining the depression of its level when a part of the river is turned aside for any useful purpose.

The experiments of Bossut, on the resistance and percussion of fluids, were made with singular care. His first trials, which were published in 1771, related chiefly to the impulse of a vein of fluid against a plain surface; but he afterwards extended them to many more useful questions. In the year 1775, the celebrated Turgot, comptroller-general of the finances of France, appointed Bossut, D'Alembert, and Condorcet, as a commission, for the purpose of executing a new set of experiments on the resistance which fluids oppose to the motion of bodies of various forms. These experiments were made almost solely by Bossut, within the grounds of the Ecole Militaire at Paris, in a basin of water 100 feet long, 53 feet wide, and 6½ feet deep; and the results which they obtained were published in 1777, in a separate work, entitled *Experiences sur le resistance des Fluides*. According to theory, the impulse upon a plane surface is equal to the area of the surface multiplied by the square of the velocity of the fluid, and the square of the sine of the angle of incidence. Bossut found that this measure of the resistance was sensibly correct, when the fluid impinged perpendicularly upon the surface; that the deviation from the theory increased with the angle of incidence; but that the theory might still be employed when this angle was not less than 50°. As the funds intrusted to the commission had been managed with the utmost economy, Bossut employed the surplus in determining the resistance experienced by all kinds of prows, whether plane, angular, or curvilineal. These experiments were performed in 1778, and were published in the Memoirs of the Academy for that year. He next made a number of experiments on the effects of undershot and overshot water wheels. The former he found to give a maximum effect, when the velocity of the stream was to that of the wheel as five to two, while the effect of the latter increased with the slowness of their motion. The valuable labours of Bossut were recompensed by M. Turgot, who established for him in the Louvre a professorship of Hydrodynamics, to which he was appointedin 1775.

We have already seen, that Newton was the first philosopher who investigated the laws of the motion of waves. His theory was, however, only an approximation to the truth, and, as he himself was aware, was suited only to the hypothesis, that the particles of the fluid ascended and descended vertically in the course of their vibrations. When the ascent and descent is made in curve lines, the velocity of the waves cannot be accurately determined by Newton's method. It is only by means of the general laws of the motion of fluids that this subject can be properly treated. M. De La Place was the first who applied this mode of investigation to reclineal undulations, in the Memoirs of the Academy of Sciences for 1776. This investigation is contained in a separate section, *Sur les ondes*, published in his paper, entitled *Suite des Recherches sur plusieurs points du Systeme du Monde*. He supposes the water to be shut up in a canal infinitely narrow, and of an indefinite length, but of a constant depth and breadth. He imagines that the wave is produced by immersing a curve in the fluid to a very small depth. The curve being kept in its place till the water has recovered its equilibrium, it is then drawn out, and waves are formed by the water while it recovers its equilibrium. When the curve is plunged more or less deep into the fluid, the time of the propagation of the waves to a given distance will be always the same, as the oscillations of a pendulum are constant, whatever be the length of the arcs which they describe, provided they are very small. If the depth of the canal is very great, in proportion to the radius of curvature of the curve at its lowest point, the times of the propagation of waves generated by different curves, or by the same curves in different situations, are reciprocally as the square roots of the radii of curvature; and the velocities of the waves are directly as the same roots. Hence La Place concludes, that the velocity of waves is not like that of sound, independent of the primitive agitation of the air.

The subject of the oscillation of waves was now examined experimentally by M. Flaugergues, who endeavoured to overturn the opinions of Sir Isaac Newton. In a memoir on the motion and figure of waves, of which an abstract is given in the *Journal des Sçavans* for October 1789, Flaugergues gives an account of a series of experiments which he made upon this subject. He combats the opinion of Newton, that waves arise from a motion of the particles of the fluid, in virtue of which they ascend and descend alternately in a serpentine line, while they move from their common centre; and he attempts to prove, that they are a kind of intumescence raised round the common centre, by the depression which the impulse has occasioned; and that this intumescence is afterwards propagated circularly from the centre of impulse. A portion of the intumescence, or elevated water, flows, as he conceives, from all sides into the cavity formed at the centre of impulse; and this water being, as it were, heaped up, produces another intumescence, which occasions a new wave, that is propagated circularly as before. M. Flaugergues proceeds to determine the figure of a wave, and gives the equation of it, and also the equation of the curve which the centre of gravity of a vessel describes from the motion of waves. From this theory he deduces the conclusion, that all waves, whether great or small, have the same velocity; whereas Newton made their velocity proportional to the square roots of their breadth. In order to examine this result, our author made the following experiment on a branch of the Rhone, shut up at one end to make the water stagnant. Having measured a distance or base of thirty feet, he threw into the water small stones at the end of this base, and he found that the waves which they produced, whether they were great or small, occupied exactly twenty-one seconds in moving over the space of thirty feet.

In the Memoirs of the Academy of Berlin for 1781 and 1786, and also in his *Mecanique Analytique*, M. De La Grange, one of the most distinguished mathematicians of the last century, has endeavoured to determine the oscillation of waves in a canal. He found that it is the same as that which a heavy body would acquire by falling through a height equal to half the depth of the water in the canal. Hence, if the depth of the canal is 1 foot, the velocity of the wave will be 5.495 feet, and, at greater or less depths, the velocity will be as the square roots of the depth, provided it is not very great. If it is admitted, that when waves are formed, the water is affected only to a small depth, the theory of La Grange will give tolerably correct results, whatever be the depth of the water in the canal, and the figure of its bottom; but although this supposition is countenanced by experience, and derives probability from the viscidity of water, yet La Grange's theory does not harmonize with experiment. Dr Wollaston observed, that in a place where the depth of the water was said to be 50 fathoms, a bore, or large wave, moved at the rate of one mile in a minute; whereas La Grange's theory gives only 40 fathoms as the depth which corresponds with the velocity. Dr Thomas Young has also observed, that the waves, or oscillations of water in a cistern, always move with a velocity smaller than that of a body falling through half the depth, but nearly in the same proportion.

The first engineer who examined experimentally the motion of water in canals, in reference to the resistances arising from the cohesion of water, and to that kind of friction of which fluids are capable, was M. Chezy, the predecessor of M. Prony, in the direction of the School of Roads and Bridges. Towards the year 1775, when he was working with Perronet on the subject of the canal of Yvette, he was anxious to determine from observation and calculation, the relation which subsisted between the declivity and length of a canal, the width and figure of its transverse section, and the velocity of the water which it conveyed. In the course of this investigation, he obtained a very simple expression of the velocity, involving these different variable quantities, and capable, by means of a single experiment, of being applied to all currents whatever. He assimilates the resistance of the sides and bottom of the canal to known resistances, which follow the law of the square of the velocity, and he obtains the following very simple formula,

$V=\sqrt{\frac{gd}{\beta s}}$, where $g$ is $= 16.087$ feet, the velocity acquired by a heavy body after falling one second; $d$, the hydraulic mean depth, which is equal to the area of the section divided by the perimeter of the part of the canal in contact with the water; $s$, the slope or declivity of the pipe; and $\beta$, an abstract number to be determined by experiment.

The attention of the Chevalier Buat, Lieutenant Colonel of the Royal Corps of Engineers, was called to the subject of hydraulics by the publication of Bossut's *Hydrodynamique* in 1771. In studying the motion of canals and rivers, it occurred to him, that if water possessed perfect fluidity, and flowed in a channel infinitely smooth, its motion would be constantly accelerated like that of heavy bodies descending upon an inclined plane. But as the velocity of a river is not accelerated *ad infinitum*, but soon arrives at a state of uniformity, and is not afterwards increased without some cause, it follows that there is some obstacle which destroys its accelerating force, and prevents it from impressing upon the water new degrees of velocity. This obstacle must therefore be the viscidity of the water, which gives rise to two kinds of resistance, one, namely, which proceeds from the intestine motion of an imperfect fluid, and the other from the natural adhesion of its parts to the channel in which it flows. Our author, therefore, found it to be a general principle, "that when water runs uniformly in any channel, the accelerating force which obliges it to run is equal to the sum of all the resistances which it experiences, either from its own viscidity, or from the friction of its channel." Encouraged by the discovery of this principle, and by its application to the solution of many important problems, it occurred to M. Buat, that the motion of water in a conduit pipe had a great analogy to the uniform motion of a river, and upon this idea he composed a formula founded on the experiments of Bossut on conduit pipes and artificial canals. The result of this investigation was published in 1779, in the first edition of his *Principes d'Hydraulique*. M. Buat, however, was speedily convinced that a theory so new, and which led to results so different from the common theory, required the sanction of new experiments, more direct and varied than those which had hitherto been made. Through the influence of M. de Fourcroy, director of the Royal Corps of Engineers, the French Minister ordered an annual sum to be put at the command of the Chevalier Buat, for the purpose of performing a set of experiments upon this important subject; and during the years 1780, 1781, 1782, and 1783, he was constantly occupied with these experiments, with the assistance of Messrs Dobenheim and Benezech de St Honoré, two officers of the Royal Engineers. The latter took a particular interest in these researches, and from his great mathematical knowledge, he was of particular service to M. Buat, not only by the general aid which he gave him, but from the number of beautiful problems and important researches which he communicated to the work.

As the experiments of Bossut had been made only on pipes of moderate declivity, M. Buat supplied this defect by using declivities varying from 90° to the 40,000th part of a right angle, and channels which varied from a line and a half in diameter to areas of seven or eight square toises. Experiments were also made with syphons and pipes bent at various angles, and on the resistance both of compressible and incompressible fluids. In this way our author has collected an immense number of facts, which he classed according to their resemblance in one particular point; and by studying the cause of the differences which accompanied their differences in other circumstances, he was led to general rules, by which these differences formed a regular series. The experiments were again classed under another point of resemblance, and the same method followed; and by pursuing this plan, he obtained the following general formula, which represents, in a most surprising manner, the great variety of facts which he has collected: namely,

$$V = \frac{\sqrt{n\,g}\,(\sqrt{d} - 0.1)}{\sqrt{s} - \text{Log.}\sqrt{s + 1.6}} - 0.3\,(\sqrt{d} - 0.1)$$ in which

V is the mean velocity in inches per second.

$d$ the hydraulic mean depth, or the quotient which arises from dividing the area of the section of the canal in square inches by the perimeter of the part in contact with the water in linear inches.

$s$ the slope or declivity of the pipe, or of the surface of the water.

$g = 16.087$, the velocity in inches per second which a heavy body acquires by falling in one second.

$n$ An abstract number, which was found by experiment to be $= 243.7$.

In 1783, when M. Buat's experiments were finished, they were submitted to the Academy of Sciences through the minister of war, and were afterwards published in 1786, under the title of *Principes d'Hydraulique verifiés par un grand nombre d'experiences faites par ordre du gouvernment*. A third volume of this work was published in 1816, under the title of *Principes d'Hydraulique et Pyrodynamique*. It relates chiefly to the phenomena of heat and elastic fluids.

In the year 1784, M. L'Espinasse, corresponding member of the Academy of Thoulouse, published two memoirs in the Transactions of that society, which contain very interesting observations on the motion of water through large orifices, and on the junction and separation of rivers. The experiments which are contained in these two memoirs were made in the Fresquel and Aude, two rivers in the department of the Upper Garonne, and on part of the *Canal du Midi*, which is below the lock of Fresquel, towards the point where it meets with the bed of that river.

Don George Juan D'Ulloa, an eminent mathematician, and inspector of the naval academies of Spain, proposed a new physico-mathematical theory of collision, in his *Examen Maritimo*, a work which was published at Madrid in 1771, in 2 vols. 4to. This theory includes all the circumstances of motion, both during the continuance of the shock and after the shock, and embraces the laws of the collision of hard bodies, of soft bodies, and of bodies perfectly or imperfectly elastic, whether they are moved in virtue of constant velocities and accelerating forces, or by both of these causes combined. This theory is however not applicable, as might at first sight have been expected, to the impulse of fluids; but the same author has favoured us with a new theory of the resistance of fluids, which has been adopted by Prony and several other French writers. This theory has, in Prony's opinion, been confirmed by very good experiments, and also by its conformity with the progress and other motions of vessels. It has also, as Prony has remarked, the advantage of presenting the discussion of the question with the different physical circumstances which it involves, an advantage which is not possessed by the ordinary theory. In order to confirm his theory, Don George Juan made the following experiments: He exposed a plane surface of the form of a parallelogram a foot wide, to the action of a current of water which moved with the velocity of two feet per second. When it was immersed just one foot under the water, it supported a weight of $15\frac{1}{2}$ pounds (English measure). When the same plane was sunk two feet in a current of water moving with the velocity of one foot four inches in a second, it supported a weight of $26\frac{1}{2}$ pounds. The following Table shews the theoretical and practical results.

| | Velocity of Water. | Depth of Submersion. | Observed Resistance. | Calculated Resistance. |
|---|---|---|---|---|
| Exp. 1. | 2—0 feet. | 1 foot. | $15\frac{1}{2}$ pounds. | $20\frac{1}{2}$ pounds. |
| Exp. 2. | 1—4 | 2 | $20\frac{1}{4}$ | $39\frac{1}{4}$ |

The ratio of the observed resistance is as $15\frac{1}{2} : 26\frac{1}{2}$, while that of the calculated results is as 15 to 28. Don George Juan has printed two appendices at the end of his first volume, in one of which he applies his theory to the resistance of elastic fluids; and in the other he examines the experiments of our countryman Smeaton on the maximum effect of water mills. He shews, from this theory, that the velocity of the floatboards ought to be a little less than one half of the velocity of the water, in order to produce a maximum effect; a result which is almost exactly the same which Smeaton found from experiment. It is a singular circumstance, that the experiments of Don George Juan give resistances much greater than those of Bossut, D'Alembert, and Condorcet, which were made under great pressures; so that his theory will differ very widely from the best experiments which have been made on the resistance of fluids. Dr Robison has remarked, (see his *System of Mechanical Philosophy*, vol. ii. art. *Resistance of Fluids*, which contains an examination of this new theory), that Don George Juan's equation exhibits no resistance in the case of a fluid without weight. A new edition of the *Examen Maritimo*, with copious notes and additions, was published at Paris in 1783, by M. L'Eveque, entitled *Examen Maritime, Theorique et Pratique, ou Traité de Mecanique, appliqué a la Construction et a la Manœuvre des vaisseaux et autres batimens*.

In the year 1798, M. J. B. Venturi, Professor of Natural Philosophy at Modena, published his experiments and observations on fluids, in a work, entitled *Sur la communication laterale du Mouvement dans les Fluides*, which was some time afterwards translated into English by Mr Nicholson. This work contains many new and valuable results, of which the following are the most important. He found, that in any fluid, the parts which are in motion carry along with them the lateral parts which are at rest. This proposition he established by introducing a current of water, with a certain velocity, into a vessel filled with stagnant water. The current, after passing through a portion of the fluid, was received in a curvilineal channel, the bottom of which gradually rose till it passed over the rim of the vessel; and in a short time there remained in the vessel only that portion of the fluid which was originally below the aperture at which the current was introduced. By the aid of this principle, which he calls the lateral communication of motion in fluids, and which he thinks is not sufficiently accounted for by the cohesion of the fluid particles, he explains many facts in hydraulics. In examining the effect of additional tubes, Venturi found, that if the part of an additional tube, near the orifice, has the form of the *vena contracta*, the quantity of water discharged will be the same as if there was no contraction; that atmospherical pressure increases the expenditure through a simple cylindrical tube, compared with that which is seen through an orifice in a thin plate; that in descending cylindrical tubes, whose upper ends have the form of the *vena contracta*, the expenditure corresponds with the height of the fluid above the lower end of the tube; that, with additional conical tubes, the expenditure is increased by the pressure of the atmosphere, in the ratio of the exterior section of the tube to the section of the contracted vein; that cylindrical pipes discharge less water than conical pipes which have the same exterior diameter, and diverge from the place of the contracted vein; that, by suitable adjutages applied to a horizontal cylindrical tube, the expenditure may be increased in the ratio of 24 to 10, the head of water remaining invariable; that the expenditure by a straight tube, a quadrantal arc, and a rectangular tube, each of which is placed horizontally, is nearly as the numbers 70, 50, and 45; and that the expenditure is diminished by the internal roughness of a pipe,—an effect which he conceives is not produced by the friction of the water against the asperities themselves.

Although, as M. Prony has remarked, "the results obtained by the Chevalier Du Buat, and his sagacious mode of classifying the different kinds of resistances which appear in the motion of fluids, might have conducted him to express the sum of these resistances by a rational function of the velocity composed of two or three terms only, yet the glory of this discovery was reserved for M. Coulomb." This eminent philosopher, who had applied the doctrine of torsion with such distinguished success in investigating the phenomena of electricity and magnetism, entertained the idea of examining in a similar manner the resistance of fluids; and in the year 1800 he laid before the National Institute of France his memoir upon this subject, entitled *Des Experiences destinées a determiner la coherence des Fluides, et les lois de leurs resistances, dans mouvemens tres lents*, which was published in the third volume of the *Memoires de l'Institut*. In determining the resistance of the air to the oscillations of a globe, Sir Isaac Newton employed a formula of three terms, one of which varied as the square of the velocity; the second, as the $\frac{3}{2}$ power of the velocity; and the third, as the simple velocity: and in another part of the *Principia* he reduces his formula to two terms, one of which is constant, while the other is as the square of the velocity. Daniel Bernoulli* has employed a formula similar to this of Newton's; and M. S'Gravesende† makes the presssure of a fluid in motion against a body at rest, partly proportional to the simple velocity, and partly to the square of the velocity; while, when the body moves in a fluid, he makes the resistance in proportion to a constant quantity, and to the second power of the velocity. M. Coulomb, however, has proved, by many fine experiments, that there is no constant quantity of sufficient magnitude to be detected, and that the pressure sustained by the moving body is represented by two terms, one of which varies with the simple velocity, and the other with its square. The apparatus by which these results were obtained, consisted of discs of various sizes, which were fixed to the lower extremity of a brass wire, and were made to oscillate under a fluid by the force of torsion of the wire. By observing the successive diminution of the oscillations, the law of the resistance was easily found. The oscillations which Coulomb found to be best suited for this kind of experiments, continued for twenty or thirty seconds; and the amplitude of the oscillations that gave the most regular results, was between 480, the entire division of the disc, and 8 or 10 divisions, reckoned from the zero of the scale. The following are the principal results which Coulomb has obtained:

1. That in extremely slow motions, the part of the resistance proportional to the square of the velocity is insensible, and therefore the resistance is proportional merely to the simple velocity.
2. That the resistance is not sensibly increased by increasing the height of the fluid above the resisted body.
3. That the resistance arises solely from the mutual cohesion of the fluid particles, and not from their adhesion to the body upon which they act. This result was obtained by covering the oscillating disc with grease, and at other times with coarse sand. In these cases the oscillations suffered no particular change.
4. That the resistance in clarified oil, at the temperature of 69° of Fahrenheit, is to that in water as 17.5 to 1; which expresses the ratio of the mutual cohesion of the particles of oil to the mutual cohesion of the particles of water.

M. Coulomb concludes his experiments, by ascertaining the resistance experienced by cylinders that move very slowly and perpendicular to their axes; but for an account of the results which he obtained, we must refer the reader to the memoir itself, or to the subsequent part of the present article.

The first person who thought of applying the law of the resistance of fluids, discovered by Coulomb, to the determination of the velocity of water flowing in natural or artificial channels, was M. Girard, chief engineer of roads and bridges, and director of the works on the canal of Ourcq. In his *Essai sur le mouvement des Eaux Courantes*, and his *Rapport sur le Canal de l'Ourcq*, he adopts as a measure of the resistance the product of a constant quantity, by the sum of the first and second powers of the velocity; and after determining the value of the constant quantity, from twelve experiments of Chezy and Du Buat, he obtains a formula much more simple than that of Du Buat, but representing the experiments with equal precision. Considering that the water which moves over the wetted sides of the channel, or over the film of water which adheres to these sides (*paroi mouillée*) is at first retarded by the viscidity, which tends to keep it upon this film, he concludes, that from this cause the water will experience a retardation proportional to the simple velocity. From the roughness of the channel he deduces a second retardation, (analogous to friction in solid bodies, but differing from it in so far as it does not vary with the pressure,) which is proportional to the second power of the velocity, as it is in the compound ratio of the force and number of impulsions which the asperities receive during a given time. He then expresses the resistance produced by cohesion by $R \times p\,V$; R being a quantity to be determined by experiments; $p$, the perimeter of the fluid section in contact with the channel; and V, the velocity; and considering the adhesion of the asperities to the wetted sides of the channel as the same with that of the fluid par-

* *Comment. Petropol.* tom. iii. and v.

† *Physices Elementa Mathematica*, tom. i. § 1911.

ticles to each other, he makes the resistance due to these asperities equal to $R \times p V^2$, whence he obtains the formula $\frac{g}{\beta}\frac{d}{s} = R(V + V^2)$. M. Prony is of opinion, that the adhesion of the asperities to the *paroi mouillée*, or wetted sides of the channel, ought to be supposed greater than that of the fluid particles; for if the two adhesions were equal, the asperities would have no more tendency to unite to the wetted sides than to the mass of fluid in motion.

Such was the state of hydrodynamics, when M. Prony published, in 1804, his *Recherches Physico-Mathematiques sur la Theorie des Eaux Courantes*. In order to establish the theory of running waters on a proper foundation, this eminent mathematician collected the best experiments that had been published on the motion of water in conduit pipes, and in natural and artificial channels. Out of this collection he selected 82 of the best, viz. 51 on conduit pipes, and 31 on open canals; and he endeavoured to combine these data with the principles of physics and mechanics, so as to deduce from them general formulæ, from which the velocity might in every case be obtained by calculation. By these means he has been able to express the velocity of water, whether it flows in pipes or open canals, by a simple formula, free of logarithms, and requiring merely the extraction of a square root. The formula, which is applicable both to pipes and canals, is

$$V = -0,0469734 + \sqrt{0,0022065 + 3041,47 \times G},$$

which gives the velocity in metres; or, when reduced to English feet,

$$V = -0.1541131 + \sqrt{0,023751 + 32806,6 \times G}.$$

When this formula is applied to pipes, we must take

$G = \frac{1}{4}DK$, which is deduced from the equation

$$K = \frac{H + Z = H}{L}.$$

When it is applied to canals, we must take $G = RI$,

Which is deduced from the equation $I = \frac{Z}{L}$, R, being equal to the mean radius of Buat, or the hydraulic mean depth, as already explained.

M. Prony has drawn up extensive tables, in which he has compared the observed velocities with those which are calculated from the preceding formulæ, and from those of Du Buat and Girard; and it is surprising to observe their agreement with the observed results, and their decided superiority to those of Du Buat and Girard. The progress of hydrodynamics has likewise been greatly indebted to the *Nouvelle Architecture Hydraulique* of M. Prony, which appeared in the year 1790. This able work is divided into two parts; the first of which is a treatise on mechanics, in which the author has explained the general principles of equilibrium and motion, which are necessary for engineers. The second part is divided into four sections: The first section treats of statics, the second of dynamics, the third of hydrodynamics, and the fourth of machines and first movers, considered under the different physical circumstances which have an influence upon their equilibrium and motion. In the chapter on hydrodynamics, he resolves the general problem of the efflux of water through an orifice in one of the sides of a vessel, upon the supposition that the fluid strata preserve their parallelism, and that their particles descend with the same velocity; and from this he deduces, as a corollary, all the ordinary theory of the motion of fluids. He next gives an account of the experiments of Bossut on the efflux of water, and deduces formulæ, by which the results may be expressed with all the accuracy that practice requires. In treating of the impulse and resistance of fluids, he adopts and explains the theory of Don George Juan, and afterwards gives an account of the ordinary theory of resistance, with the experiments by which it has been corrected and rendered applicable to practice. M. Prony then proceeds to give an account of the general and rigorous theory of the motion of fluids, and he applies the equations to the motion of fluids in narrow pipes. In the 5th section, which contains much valuable practical information, the author has treated at great length the subjects of friction and of the strength of men, and has given a detailed account of the history and construction of the steam engine, from the rude form in which it came from the hands of the Marquis of Worcester to the almost perfect state to which it has been brought by our celebrated countryman Mr. Watt.

In the year 1795, Mr. Vince of Cambridge published in the Philosophical Transactions, his *Observations on the Theory of the motion and resistance of Fluids, with a Description of the Construction of Experiments in order to obtain some fundamental principle*; and in the year 1798, he published, in the Transactions of that year, another paper, entitled, *Experiments on the Resistance of Bodies moving in Fluids*. The experiments contained in the first of these papers were made chiefly with the view of ascertaining how far the theory of the motion of fluids could be applied to the discharge of water from vessels. Mr. Vince has concluded, from the results of this inquiry, that the great difference between the experimental and theoretical results, in most of the cases which respect the times in which vessels empty themselves through pipes, leads us to suspect the truth of the theory of the action of fluids under all other circumstances. In the second memoir, he gives an account of a variety of experiments on the resistance of fluids, when the resisted body is immersed at some depth in the fluid made with a particular apparatus which he contrived for this purpose. The results which he obtained differ widely from those obtained by Bossut with bodies floating on the fluid, which Mr. Vince explains, by supposing, that at the surface, the fluid from the end of the body may escape more easily than when the body is immersed below the surface.

The late Dr. Matthew Young, Bishop of Clonfert, made a number of experiments on the efflux of fluids from orifices of different kinds, of which he has published an account in the 7th volume of the *Transactions of the Royal Irish Academy*. In order to explain the increase in the discharge by inserting an additional tube in an orifice in the bottom of a vessel, he filled a cylindrical vessel with mercury to the height of six inches, and inserted in its bottom a tube 7.8 inches long. Having closed the orifice of the pipe, he placed the apparatus under the receiver of an air pump, when the barometer was at 30 inches, and the gauge at $28\frac{1}{2}$, the time of the efflux was in this case 26 seconds; but when the experiment was repeated in the open air, without any variation, the time of the efflux was only 19 seconds. Unless the gauge stood higher than $22\frac{1}{2}$ inches, no difference was observed in the times of the efflux in the open air and in the receiver. When the efflux was made *in vacuo*, the pipe was not filled during the efflux, as it was when the discharge was made in the open air. Hence Dr. Young concludes, that the plate of fluid at the orifice, where the additional tube is inserted, has its perpendicular pressure increased by the weight of the column of fluid in the additional pipe, without any increase of its lateral pressure; and, consequently, the quantity of water discharged by a pipe of this kind must exceed that which is discharged by a simple orifice. The results of experiments, therefore, made with additional tubes, will be more consonant to theory than when they are made with a simple orifice, unless when the tube has such a length, that a sensible effect is produced by the friction of the fluid against the sides of the tube, or when the additional tube is so short as not to be capable of giving a vertical direction to the particles of water. Dr. M. Young found, that this view of the subject agreed remarkably well with the experiments of Mr Vince.

In the year 1801, M. Eytelwein, of Berlin, who was known to the public as the translator of Du Buat's works into German, and who was honoured with several employments and titles relative to the public architecture of the Prussian dominions, published a work, entitled *Handbuch der Mechanik und der Hydraulik*, which contains not merely an exposition of the labours of preceding writers, but an account of many new and valuable experiments made by the author himself. The second part of this work, which treats of hydraulics, is divided into 24 chapters. Chap. 1. Treats of the efflux of water from reservoirs, and of the contraction of the fluid vein. Chap. 2. Of the discharge of water from horizontal and lateral orifices in a vessel constantly full. Chap. 3. Of the discharge of rectangular orifices in the side of a reservoir extending to the surface. Chap. 4. Of the discharge from reservoirs with lateral orifices of considerable magnitude, the head of water being constant. Chap. 5. Treats of the efflux from reservoirs which receive no supply of water. Chap. 6. Of the discharge from compound or divided reservoirs. Chap. 7. Of the motion of water in rivers. In this chapter, M. Eytelwein has shewn that the mean velocity of water in a second in a canal, or river, flowing in an equable channel, is $\frac{10}{11}$ths of a mean proportional between the fall in two English miles, and the hydraulic mean depth; and that the superficial velocity of a river is nearly a mean proportional between the hydraulic mean depth and the fall in two English miles. Chap. 8. Treats of the discharge and the swell in the case of falls, weres, and contractions in rivers and canals. In Chap. 9. On the motion of water in pipes, our author expresses the velocity in English feet by the following simple formula: $v=50\sqrt{\frac{dh}{l+50d}}$, where $l$ is the length of the pipe, $d$ the hydraulic mean depth, and $h$ the height of the reservoir. If the pipe is bent into angles or sinuosities, the value of $v$ must be corrected by taking the product of its square multiplied by the sum of the sines of the several angles of inflection, and then by 0.0038. This will give the degree of pressure employed in overcoming the resistance occasioned by the angles, and by subtracting this height from that which is due to the velocity, we may thence find the corrected velocity. Chap. 10. Treats of jets of water. Chap. 11. Of the impulse or hydraulic pressure of water. Chap. 12. Of overshot water-wheels. Chap. 13. Of undershot water-wheels. Chap. 14. Of the properties of air, in so far as they are connected with hydraulic machines. Chap. 15. Of syphons. Chap. 16. Of sucking pumps. Chap. 17. Of forcing pumps. Chap. 18. Of mixed pumps, or the combination of sucking or forcing pumps. Chap. 19. Of acting columns of water. Chap. 20. Of the spiral pump. Chap. 21. Of the screw of Archimedes. Chap. 22. Of bucket wheels or throwing wheels. Chap. 23. Of cellular pumps and Paternoster works. Chap. 24. Of instruments for measuring the velocity of currents of water.*

During the year 1814, a very extensive series of experiments was made by M. Girard, on the motion of fluids in capillary tubes. We have already seen, that M. Coulomb had given a common co-efficient to the two terms of his formula representing the resistance of fluids, one of which was proportional to the simple velocity, and the other to the square of the velocity. M. Girard has, however, found, that this identity between the co-efficients, which may suit particular fluids under particular circumstances, is not generally admissible; and this idea is confirmed by the researches of M. Prony; from which it follows, that the co-efficients ought to be different. M. Prony has deduced the value of these co-efficients from a great number of experiments; but as his formula gives only the mean velocity, which is much greater than the velocity of the fluid contiguous to the pipe or canal which ought alone to enter into an expression of the retarding force, it follows that the co-efficients deduced from all the experiments hitherto made, have a value greatly inferior to what they ought to have, for the motion of the fluid contiguous to the side of the pipe. The object of M. Girard's experiments was to determine this velocity. He observes, that the velocity of the central filament in conduit pipes differs less from the velocity of the sides of pipes as the diameter of the tube is diminished; and that the theory of the linear motion of fluids, which was first given by Euler in 1770, is strictly applicable to the case where the water flows in very small tubes. Hence the experimental results obtained with tubes of a small diameter ought to accord best with the formula deduced from theory. In order to make a correct series of experiments of this kind, M. Girard constructed two sets of tubes made of copper, and of uniform calibre, and drawn upon maundrels of steel. The first series was composed of tubes 2.96 millimetres in diameter, and 2 decimetres long. These tubes were made to screw on to one another, and form as many tubes of different lengths, from 20 to 222 centimetres. The second series was composed of tubes 1.83 millimetres in diameter, and capable of being screwed together. These tubes were then fixed horizontally on the sides of a reservoir, which was a cylinder of white iron 25 centimetres in diameter, and 5 decimetres high. The reservoir was kept full by the usual contrivances; and the water discharged by the tube subjected to trial, was received into a copper vessel placed horizontally, and whose capacity had been accurately ascertained. The filling of the vessel was indicated by the instant when the water which it contained had wetted equally a plate of glass which covered almost the whole of its surface, and the time employed to fill this vessel was measured with great accuracy. The temperature of the water was also carefully noted. The results thus obtained amounted to 1200, and were arranged by M. Girard into thirty-four tables, according to the differnt circumstances of the experiment. When the capillary tube has such a length, that the term proportional to the square of the velocity disappears in the general formula, the velocity with which the fluid is discharged, is affected in a very singular manner by a variation of temperature. If the velocity is expressed by 10, when the temperature is 0° of the centigrade thermometer, the velocity will be so great as 42; or increased more than 4 times when the temperature amounts to 85°. When the length of the capillary tube is below the above mentioned limit, a variation of temperature exercises but a slight influence upon the velocity of the issuing fluid. If the length of the adjutage, for example, is 55 millimetres, and if the velocity is represented by 10 at 5° of the centigrade thermometer, it will be represented only by 12 at a temperature of 87°. In conduit pipes of the ordinary diameter, a change of temperature produces almost no perceptible change in

* This abridged Account of M. Eytelwein's work, is taken from an excellent abstract of it, drawn up by Dr Thomas Young, and published in the Journals of the Royal Institution.

the velocity of efflux. M. Girard also found, that the quantity of water discharged by capillary tubes varied, not only with the fluids which were used, but with the nature of the solid substance of which the tubes were composed. A full account of these valuable experiments will be found in the *Memoires des Sçavans Etragers* for 1815, which is not yet published.

In the year 1815, the National Institute of France proposed as the subject of one of its annual prizes for 1816, *the theory of waves at the surface of a heavy fluid of an indefinite depth.* The prize was gained by M. Augustin Louis Cauchy, a young mathematician of great promise. The differential equations which he has given apply rigorously only to the case where the depth of the fluid is infinite; and he has treated only of that species of waves which are propagated with velocities uniformly accelerated. The same subject had occupied the attention of M. Poisson, who, before he had seen the Memoir of M. Cauchy, had laid before the Institute formulæ similar to his for the case of infinite depth. M. Poisson has himself studied the subject under a more extended aspect, and has laid before the Institute other memoirs, which, we have no doubt, will throw much light upon this difficult branch of hydraulics. He supposes that the water has not received any percussion at the commencement of its motion, and that the waves have been produced in the following manner. A piston of any form is supposed to be plunged in the water to a small depth, and is left there till the equilibrium of the fluid is restored. The piston is then suddenly withdrawn, and waves are formed round the place which it occupied. In determining the propagations of these waves, whether at the surface, or in the interior of the fluid mass, M. Poisson considers only the case where the agitations of the water are so small, that the second and the higher powers of the velocities, and of the displacements of the molecules, may be neglected; for, without such a restriction, the problem would be so complicated, that no solution of it could be expected. He supposes the depth of the water constant throughout its whole extent, so that the bottom is a fixed horizontal plane, situated at a given distance below its natural level. He then treats successively in his memoir, the case of a fluid contained in a vertical canal of an invariable width, and of an indefinite length; and that of a fluid, whose surface is indefinitely extended in every direction. This valuable memoir will, we trust, be published in the Memoirs of the Institute for 1815.

Having thus given a general view of the history and progress of hydrodynamics, we shall conclude this part of the article by a list of the best works and most important memoirs which have been written on the subject.

Archimedes *De Insidentibus in Fluido*. Id. *De iis quæ in humido vehuntur.* Heronis *Spiritalia* Edit. Commandini, 1575; Sexti Julii Frontini, *De Aqueductibus Urbis Romæ Commentarius* (Poleni's edit.); Stevini *Hydrastatica;* Schotti *Mechanica Hydraulico-Pneumatica*, 1657; Baliani *De Motu Gravium*, Geneva, 1646; Toricelli *De Motu Gravium naturaliter accelerato*, 1643; Castelli *Della Mesura dell' acque correnti*, 1628; Pascal *Sur L'Equilibre des Liquers;* Descartes *Recueil des Lettres de M. Descartes.* tom. iii.; Mariotte *Traité du mouvement des eaux*, Par. 1686, and *Mem. Acad. Par.* I. 69. II.; Guglielmini *La Mesura dell' acque correnti;* Guglielmini *Della natura dell' Fiumi.* Bologn, 1697; Polenus *De Motu aquæ mixto*, Patav. 1697, 1718, 1723; Parent *Mem. Acad. Par.* 1700; Varignon *Mem. Acad. Par.* II. p. 162; *Id.* 1703, p. 238; Picard *De aquis effluentibus, Mem. Acad. Par.* VII. 323; Newtoni *Principia*, lib. ii.; Raccolta *Di Autori che trattano dell moto dell acque*, 3 vols. 4to. Flor. 1723. This collection contains the works of Archimedes, Albici, Galileo, Castelli, Michelini, Borelli, Montanari, Viviani, Cassini, Guglielmini, Grandi, Manfredi, Picard, and Narducci. Polenus *De Castellis per quæ derivantur fluviorum aquæ*, Patav. 1718; Michelotti *De separatione fluidorum in corpore animali*, 1719; Jurin, *Phil. Trans.* 1718, 1722; Couplet, *Mem. Acad. Par.* 1732, p. 113; Daniel Bernoulli *Hydrodynamica seu de viribus et motibus fluidorum commentarii.* Strasb. 1738; *Id. Comment. Petrop.* 1727, 1741; Pitot, *Mem. Acad.* 1727, p. 49; 1730, p. 306; 1732, 1738; John Bernoulli, *Opera*, tom. iv.; and *Comment. Petrop.* 1737, 1738; Cotes *Hydrostatical and Pneumatical Lectures*, 1747; S. Gravesende *Physices Elementa Mathematica*, Leid. 1719, 1742; Maclaurin's *Fluxions*, vol. ii. book ii. chap. xii. § 537—550, Edin. 1742; D'Alembert *Traite de l'Equilibre et du mouvement des Fluides*, Par. 1744; D'Alembert *Essai d'une Nouvelle Theorie sur la resistance des Fluides*, and also his *Opuscules Mathematiques*, tom. vi. Switzer's *Hydrostatics;* Euler, *Mem. Acad. Berlin*, 1752, p. 111; 1755, p. 217; Id. *Nov. Comment. Petrop.* 1768, 1769, 1770, 1771; Id. *Theorie complete de la construction et Manœuvre des vaisseaux;* Bouguer, *Mem. Acad. Par.* 1755, p. 481; Lecchi *Idrostatica esaminata ne suoi principi e stabilita nelle sue regole della mesura delle acque correnti*, 1765; Borda, *Mem. Acad. Par.* 1763, p. 358; 1766, p. 579; 1767, p. 595; Käestner *Anfangsgrunde der Hydrodynamik*, Gotting. 1769, and *Nov. Comment. Gotting.* 1769, I. 45.; *Nuova Raccolta di autori che trattano del moto dell' acque*, 7 vols. Parma, 1766. The 1st vol. of this excellent collection contains, 1. Castelli's treatise *Della Mesura*, &c. 2. Several letters of Castelli and other authors. 3. A paper by Montanari on the Adriatic Sea and its currents. 4. A discourse by Viviani on the method of preventing the filling up and the corrosion of rivers applied to the river Arno. 5. Several papers by J. D. Cassini, on the regulation of the courses of rivers; and, 6. Guglielmini's treatise, entitled *La Mesura*, &c. The 2d volume contains Guglielmini on rivers, illustrated with the notes of E. Manfredi. The 3d volume contains, 1. Guido Grandi's geometrical treatise on the motion of water; 2. Several dissertations, by the same author, on the River Era and the streams in Italy; 3. The Marquis Poleni's treatise *de motu aquæ mixto;* 4. A treatise, by the same author, on dikes, &c.; 5. A letter, by Poleni, on the measure of running waters; 6. A paper, by J. Buteon, on the same subject. Tom. IV. contains, 1. Several hydraulic dissertations by Castelli; 2. Several letters from Galileo to Castelli; 3. A paper, by E. Manfredi, on the construction of a dike upon the River Era; 4 A reply, by Manfredi, to a criticism by Ceva and Moscatelli; 5. A reply, by the inhabitants of Bologna, to those of Ferrara on the course of the Reno; 6. An examination of a book, entitled The Injurious Effects of the Reno. 7. A refutation of another work, published at Modena, on the same subject. Tom. V. contains, 1. A report, by Cardinals Adda and Barbarini, on the state of the waters in the countries of Romagna, Ferrara, and Bologna; 2. A report, by Riviera, on the state of the Reno, the Panaro, and the Po; 3. A selection of practical information from the work of Zendrini on running waters; and, 4. A memoir on preventing the inundations of the Ronco and the Montone, by Zendrini and Manfredi. Tom VI. contains, 1. A translation of Picard's book on levelling; 2. A translation of Gennete's experiments on the course of rivers; 3 Experiments of Bonati in opposition to those of Gennete; 4 Gennete's reply; 5. Remarks, by Manfredi, on the constant elevation of the bottom of the sea; 6. A discourse, by Zanotti, on the beds of rivers near their embouchure; 7. A memoir, by Bolognini, on the ancient and present state of the Pontine Marshes, and on the means of draining them;

8. A comparison of canals, by Narducci; 9. A paper, by Perelli, on a torrent called the Maroggia. Vol. VII. contains, 1. A discourse on the ancient and present state of the Valdichiana; 2. A memoir, by Lecchi, on the Tradate, the Gardaluso, and the Bozzenti; 3. A paper on the inundations of the Adige, by Lorgna; and, 5. A paper, by Frisi, on the management of rivers and torrents. Bossut et Viallet, *Recherches sur la Construction des digues*, 1764. ## PART I. HYDROSTATICS.

HYDROSTATICS, from the Greek ὕδωρ, *water*, and ἵστημι, *I stand*, is that branch of the science of hydrodynamics which treats of the properties of fluids at rest. It comprehends the pressure and equilibrium of non-elastic fluids, the doctrine of specific gravities, the phenomena of cohesion and capillary attraction, and the equilibrium of floating bodies.

### *Definitions and Preliminary Observations.*

A *fluid* is a collection of very minute material particles, (probably of a spherical form,) which cohere so slightly to each other, that they yield to the smallest force, and are easily moved among one another in every direction.

The phenomena exhibited by fluids, whether they are at rest or in motion, afford us no reason to believe, that the particles of which they are composed possess any polarity, or any tendency to arrange themselves in one particular manner more than another. When a mass of water is in a state of perfect equilibrium, a certain point of one particle is in physical contact with a certain point of another particle; but if the equilibrium is destroyed by violent agitation, there is no ground even for conjecturing, that the same points of the particles will return into contact when the equilibrium is restored. The recent discoveries, however, which have been made in optics, decidedly prove, that in many fluids the particles assume a particular arrangement, analogous to that which is exhibited in some of the crystals of the mineral kingdom, and that they may also be made to assume another arrangement, similar to that which is produced in glass, &c. by compression and dilatation. When these fluids are inclosed in a vessel, the particles uniformly affect a certain arrangement, which is unequivocally indicated by their action upon polarised light. See OPTICS and POLARISATION.

Fluids are divided into *elastic* and *inelastic*, or *compressible* and *incompressible* fluids. The class of elastic and compressible fluids consists of atmospherical air, and the various gaseous or aëriform bodies with which chemists have made us acquainted; while the class of inelastic or incompressible fluids comprehends water, mercury, alcohol, and the various oils and liquid acids. The first class, in virtue of their elasticity, are capable of expanding themselves when they are unconfined, so as to fill any given space, or of having their bulk greatly diminished by mechanical compression;* while the second class possess this property in such a small degree, that the diminution of their bulk by mechanical force is scarcely susceptible of accurate mensuration. The science of PNEUMATICS considers the mechanical properties of the first class, and that of HYDRODYNAMICS those of the second class.

Till within the last fifty years, it was considered as an established fact, that the class of incompressible fluids could not be reduced in bulk by the application of the most powerful forces. This conclusion was deduced from an

* Air is said to have been reduced to $\frac{1}{1837}$ of its bulk in Hales's experiments.

experiment by Lord Bacon, who filled a leaden globe with water, and attempted to compress it by a great external force. The fluid, however, made its way through the pores of the metal, and stood like dew upon the surface of the globe. The Florentine academicians repeated the same experiment with a silver globe, and, by violent hammering, they succeeded in altering its form, and expelling the water through the pores of the silver. These trials seem to have established the doctrine of the incompressibility of fluids in its most strict acceptation; but Lord Bacon deduced from them the very opposite conclusion, for, after giving an account of the experiment which we have mentioned, he tells us, that he afterwards computed into how much space the water was driven by this violent pressure.*

Although the experiment of the Florentine Academy of Del Cimento was considered as decisive of this point, yet it occurred to Mr Canton, about the year 1761, that it was not hostile to the idea of a small degree of compressibility; for the academicians were unable to determine whether or not the water forced into the pores, and through the gold, was exactly equal to the diminution of the internal space by pressure. He accordingly set about a series of experiments on this subject. Having procured a small glass tube about two feet long, and $1\frac{1}{4}$ inch in diameter, and with a ball at one end of it, he filled the ball and part of the tube with mercury, brought the whole to the temperature of 50° of Fahrenheit, and observed that the mercury stood at a point exactly $6\frac{1}{2}$ inches above the ball. The mercury was then raised by heat to the top of the tube, and the tube was hermetically sealed. The mercury was then brought to the same degree of heat as before, and it now stood in the tube $\frac{32}{100}$ of an inch higher than it did before. By performing the same experiment with water exhausted of air, instead of mercury, he found that the water stood in the tube $\frac{43}{100}$ of an inch above the mark. Hence it is obvious, that the weight of the atmosphere, or 73 pounds avoirdupois, pressing on the outside of the ball, and not on the inside, had squeezed it into less compass, and that, by this compression of the ball, the mercury and the water would be equally raised in the tube. But the water rose $\frac{11}{100}$ of an inch more than the mercury, and consequently the water must have expanded so much more than the mercury by removing the weight of the atmosphere. In order to determine how much compression was produced, either by the weight of the atmosphere, or by a greater weight, he took a glass ball about 1.6 inch in diameter, joined to a cylindrical tube 4.2 inches long, and $\frac{1}{100}$ of an inch in diameter, and, by weighing the quantity of mercury that exactly filled the ball, and also the quantity that exactly filled the whole length of the tube, he found that the mercury in $\frac{23}{100}$ of an inch of the tube was the 100,000th part of that contained in the ball, and he divided the tube accordingly with the edge of a file. When the ball and part of the tube was filled with water exhausted of air, he placed it in the receiver of an air pump, and also in the receiver of a condensing engine, and he observed the degree of expansion of the water that corresponded with any degree of rarefaction, and the degree of compression that corresponded with any degree of condensation. In this way he found, from repeated trials, that, when the mercury was at a mean height, and the temperature of the air 50° of Fahrenheit, the water rose four divisions and 6-10ths, or one part in 21740, by removing the weight of the atmosphere; consequently the compressinn of water, under twice the weight of the atmosphere, is one part in 10870 of its own bulk.

In combining these experiments, Mr Canton found, that water was more compressible in winter than in summer, while, on the contrary, alcohol and oil of olives were more compressible when expanded by heat, and less so when contracted by cold. The results were, as expressed in the following Table, suited to the mean weight of the atmosphere.

| Temperature in Fahrenheit's scale. | Compression in millionth parts of their own bulk. Water. | Alcohol. |
|---|---|---|
| 34° | 49 | 60 |
| 64° | 44 | 71 |

The following Table contains all the results which Mr Canton obtained. It is suited to a temperature of 50° of Fahrenheit, and to $29\frac{1}{2}$ inches of the barometer.

| Names of fluids. | Compression in millionth parts of their own bulk by the weight of $29\frac{1}{2}$ inches of mercury. | Specific gravities at the same temperature. |
|---|---|---|
| Alcohol | 66 | 0.846 |
| Oil of olives | 48 | 0.918 |
| Rain water | 46 | 1.000 |
| Sea water | 40 | 1.028 |
| Mercury | 3 | 13.595 |

From these results it appears, that the compressions are not, as might have been imagined, in the inverse ratios of the specific gravities. If the law of compression in water is the same as that in air, it would follow, that, at a depth of 100 miles, the density of the water would be doubled, and at the depth of 200 quadrupled.

In the year 1774, the Ex-Jesuit Herbert published at Vienna a treatise, entitled *De Aquæ Elasticitate*, in which he confirmed the general result of Canton's experiments, and in 1779 M. Zimmerman published an account of similar experiments at Leipsic, under the title of *Traité de l'Elasticité de l'eau et d'autres fluides*. He found, that sea water, when inclosed in the cavity of a strong iron cylinder, and pressed by a force equal to a column of sea water 1000 feet high, was compressed $\frac{1}{340}$th part of its own bulk, a result much greater than we should have expected from the experiments of Canton. A number of results similar to these were obtained by the Abbé Mongez, who has printed an account of them in the 9th volume of Rozier's Journal.

As the doctrine of the compressibility of water has long been considered as a fact rigorously established, we were surprised to find its incompressibility stated by the Abbé Hauy, without the slightest reference to any of the preceding experiments. "One of the experiments," he observes, "which has served to shew the incompressibility of water, consists in charging that liquid with a column of mercury, by employing a bent tube in the form of a syphon, the shortest branch of which is closed at its superior part, and contains water, at the same time that the longest branch is occupied by the mercury, which presses the surface of the

* See Bacon's *Works*, by Shaw, vol. ii. p. 521, or the *Novum Organum*, Part II. Sect. ii. Aphorism 45, § 222. Bacon seems to have considered all bodies as in some measure elastic; for after having explained what he calls the motion of liberty, and applied it to the phenomena of tension, he says, "that this motion was unscientifically called by the schools the motion of the *elementary forms*: for it does not only apply to air, water, and flame, but to all the diversities of consistent bodies, as wood, iron, lead, cloth, skins, &c. each body having its own measure of extent or dimension, from whence it is with difficulty stretched to any considerable distance." Bacon's *Works*, vol. ii. p. 725. Aph. 48. § 245.

water. The column formed by this latter fluid was not shortened by the smallest perceptible quantity, even when that of the mercury was 227 centimetres, or about seven feet high, in which case it exerted upon the water an effect triple of that of a column of water 33 feet high."* In this experiment, which must have been carelessly made, the compression ought to have been thrice as great as in the experiments of Canton.

Fluids have also been divided into *perfect* and *imperfect;* but this division is quite arbitrary, as there is no body which possesses the character of perfect fluidity. Boiling water approaches nearer to a state of perfect fluidity than water in any other state. As its temperature diminishes, its viscidity increases, and its fluidity becomes less perfect. In many of the oils, varnishes, and in melted glass, the fluidity is extremely imperfect; whereas it may be considered as nearly perfect in water, alcohol, mercury, &c.

## CHAP. I.

### On the Pressure and Equilibrium of Fluids.

#### FUNDAMENTAL PRINCIPLE.

*When a mass of fluid, in a state of equilibrium, is subjected to the action of any forces, every particle of the fluid mass is pressed equally in every direction, and,* vice versa, *if every particle of the fluid mass is pressed equally in every direction, the whole mass will be in equilibrio.*

This principle, which has been adopted as the foundation of hydrostatics by Euler, D'Alembert, Bossut, and Prony, is a necessary consequence of the definition which we have already given of fluidity; for, since the parts of a fluid yield to the smallest pressure, any particle, which is more pressed in one direction than another, would move to the side where the pressure was least, and consequently the equilibrium would be destroyed. If the particles are equally pressed in every direction, it is equally evident, that the mass of which they are composed must be in equilibrium.

Although the preceding principle is rigorously true only of perfect fluids, yet, in the case of water, alcohol, &c. where the cohesion of the particles is not very great, the inequality of pressure, under which an equilibrium might exist, must be extremely small; and it is accordingly found, that the principle is experimentally true in these fluids. For if, at a given depth below the surface of water in a vessel, an aperture be made, and a piston be applied to the aperture to prevent the water from flowing out, it will be found, that the piston will be pressed outwards with the same force, whether the aperture is horizontal or vertical, or inclined at any angle to the horizon.

*Cor.* If a number of pistons E, F, G, are applied to apertures of different sizes in the sides of a vessel ABCD full of water, the forces with which the pistons are applied will be in equilibrio, if they are proportional to the apertures to which they are applied. Plate CCCXIII. Fig. 1.

Since the pressure of every part of the piston E is transmitted to every part of the piston F, and *vice versa*, it follows, that these pressures will be in equilibrio, if they are equal. But the sum of the pressures propagated by E is proportional to the area of the aperture E, and the sum of the pressures propagated by F proportional to the area of the aperture F; consequently there must be an equilibrium between these opposing pressures, when E : F = area of E : area of F. The same is true of any number of apertures.†

### Sect. I. *On the Pressure and Equilibrium of Fluids of Uniform Density.*

#### Prop. I.

When any fluid, influenced by the force of gravity, is in equilibrio in any vessel, its surface is horizontal, or at right angles to the direction of gravity.

Let the surface of the fluid have the curvilineal form A *p* B, Fig. 2, and let the force of gravity with which any particle *p* is influenced be represented by the vertical line *p o*. This force *p o* may be resolved into the forces *p m*, *p n*, coinciding with the elementary portions of the surface on each side of *p*. Now, the particle *p* being in equilibrium, it is pressed equally in every direction; and, therefore, the equal and opposite forces *m p*, *n p*, exerted against *p* by the neighbouring particles, must be equal to *p m*, *p n*; hence the force *p m* is equal to *p n*, the angle *m p n* must be bisected by *p o*, (See Dynamics, Sect. III.) and the elementary portion of the curve must be perpendicular to *p o*. As the same is true of every other part of the fluid surface, it follows that this surface must be a *horizontal straight line*, if the directions of gravity at different points are considered as parallel, or a portion of a spherical surface, if the directions of gravity meet in one point.

*Cor.* It follows from this proposition, that the surface of a fluid must be perpendicular to the resultant of all the forces which act upon it. Hence the general surface of the ocean will not be perpendicular to the direction of gravity, but to a line which is the resultant of the action of gravity, of the centrifugal force, and of the attraction of the planetary bodies.

The effect of the centrifugal force, combined with gravitation, is such, that the surface of the water assumes a parabolic form, as shewn in Fig. 3. When any number of fluids of different densities are put in the same vessel, and are made to revolve round an axis, or if they are put into a glass globe, and turned by the whirling table, their separating surfaces always assume the form of parabolic conoids, when the axis of rotation is vertical.

#### Scholium.

The depression of the surface of a fluid or D beneath a horizontal straight line for any given length L, may be found from the following simple formula: $D = \frac{2 L^2}{3}$.

#### Prop. II.

If a fluid influenced by the force of gravity is inclosed in a syphon, or in any number of communicating vessels,

* Hauy's *Elementary Treatise on Natural Philosophy*, translated by Dr O Gregory, vol. i. § 174.

† In the two following sections, as well as in other parts of this article, our readers will perceive that we have been under great obligations to the admirable work of the Abbé Bossut, to which we must refer those who wish to obtain a more profound and extensive view of the subject.

the surface of the fluid in each branch will be in the same horizontal plane.

Let ABCD, Plate CCCXIII. Fig. 4, be a syphon with three branches, AB, CB, DB, communicating with each other at B. If water is poured into this vessel till it rises to A in one branch, it will rise to the same height in the other branches, so that ADC is a horizontal line perpendicular to the direction of gravity. Let the syphon be removed, and let the water which it contained form part of the fluid in the vessel *a b c d*, in which it has the horizontal surface *a* ADC *b*, it is easy to suppose that a portion of the water, of the same form and thickness as the syphon, may be converted into ice, without changing its place or its volume. The equilibrium of the water is obviously not affected by such a change; and, therefore, the water will stand at the same height ADC, in a syphon of ice; and, consequently, the same will happen, whatever be the substance of which the syphon is composed. The same conclusion would have been obtained, by supposing all the water frozen, excepting that portion which was at first included in the syphon.

### Scholium.

The arts of levelling and of conducting water are founded upon the preceding proposition. As water will always rise to the same level as the spring from which it flows, it may be conveyed in pipes through the deepest vallies, and over the highest eminences, provided the pipe never rises to a greater height than the source of water. Had the ancients been acquainted with this simple principle, they might have saved the construction of those expensive aqueducts with which their towns were supplied with water.

Levels are sometimes made upon the principle contained in the proposition. Mr Keith's mercurial level is nothing more than a syphon filled with mercury, with a float on each branch, which supports two sights. See *Edinburgh Transactions*, vol. ii. p. 14; and our article Levelling.

### Prop. III.

If a mass of fluid contained in a vessel is in equilibrio, any one particle of the fluid is pressed in every direction, with a force equal to a weight of the column of the fluid, whose base is equal to that particle, and whose height is the depth of the particle below the surface.

Let $p$, Fig. 5, be the particle of fluid whose depth in the vessel of fluid ABCD is $ep$. We may suppose, as formerly, that a portion of the water is frozen, so as to form a tube of ice $ep$, whose diameter is equal to that of the particle $p$, without any change taking place in the pressure sustained by $p$. In this case, the particle $p$ is obviously pressed downwards with the weight of the column $ep$; and, consequently, the measure of this pressure is the absolute weight of the column $ep$. But as the particle is in equilibrio, it must be pressed with this force in every direction.

The proposition is also true of a particle situated at $m$, for drawing the horizontal line $mg$; and supposing a syphon of ice $fghm$ to be formed, it is obvious that the column of fluid in the branch $mh$ is in equilibrio with, or balanced by, the column in $gh$; consequently the particle of water at $m$ is pressed with the same force as the particle at $g$, that is, with a column of water whose height is $fg$.

*Cor.* Hence it follows, that every particle of a vessel containing fluid is pressed with a force equal to a column of fluid, whose base is the particle, and whose height is the depth of the particle below the surface; for, since the particle of fluid adjacent to this particle of the vessel is pressed in every direction with this force, it must exert the same force against that particle of the vessel.

### Prop. IV.

The pressure exerted by a fluid upon any given portion of the vessel which contains it, is equal to a column of the fluid whose base is the area of the given portion, and whose altitude is the depth of the centre of gravity of the portion below the fluid surface.

Let $mn$ be the given portion of the vessel ABCD, Fig. 6. filled with fluid, and let us conceive this portion to be occupied by any number of particles $m, o, p, n$, &c. then the pressure sustained by each of these particles, by Prop. III. will be $\overline{m \times mu} + \overline{o \times ox} + \overline{p \times py} + \overline{n \times nz}$, &c.; but, by the property of the centre of gravity or inertia, (See Mechanics,) the sum of these products is equal to the distance EF of the centre of gravity E, from the surface at F, multiplied into the number of particles $m, n, o, p$; that is, $\overline{m \times mu} + \overline{o \times ox} + \overline{p \times py} + \overline{n \times nz} = \text{EF} \times m, n, o, p$; consequently, since $m, n, o, p$, represents the area, or the number of particles in the given portion $mn$, the pressure upon $mn = \text{EF} \times mn$.

*Cor.* 1. It follows from this proposition, that the pressure sustained by the bottom of the vessel is not the same as the weight of the fluid contained in the vessel. In the cylindrical vessel shewn in Fig. 7, or in any vessel, whatever be its shape, in which the sides are perpendicular to its bottom, the pressure upon the bottom is accurately measured by the weight of the water which it contains; but in vessels of all other shapes, such as Fig. 8, 9, the pressure on the bottom is measured by $mn \times mx$, which in Fig. 8 is much less than the weight of water in the vessel, and in Fig. 9 much greater.

*Cor.* 2. The truth of what is called the Hydrostatic Paradox is easily deduced from the preceding proposition. Let ABCDEFGH, Fig. 10, be a vessel filled with water, then, by the proposition, the pressure upon GF $=$ GF $\times$ GI, however narrow be the column ABCD; that is, *the pressure exerted upon the bottoms of vessels filled with fluid does not depend upon the quantity of the fluid which they contain, but solely upon its altitude.* In like manner, it is obvious from Prop. II. that the water will stand at the same level *a b* AB, Fig. 11, in the two communicating vessels *a b c d*, ABCD, consequently, *any portion of fluid* abcd, *however small, will balance any portion of fluid* ABCD, *however great.*

*Cor.* 3. The pressure exerted upon the sides of a vessel, perpendicular to its base, is equal to the weight of a rectangular prism of the fluid, whose height is equal to that of the fluid, and whose base is a parallelogram, one side of which is equal to the height of the fluid, and the other to half the perimeter of the vessel.

*Cor.* 4. The pressure against one side of a cubical vessel is equal to half the pressure against the bottom; and the pressure against the sides and bottom together, is equal to three-times the pressure against the bottom alone. Hence, by Cor. 1. the pressure against both the sides and bottom together, is equal to three times the weight of fluid in the vessel.

*Cor.* 5. The pressure exerted upon the surface of a hemisphere full of fluid, is equal to the product of that surface multiplied by its radius.

*Cor.* 6. The pressure sustained by different parts of the sides of a vessel are as the squares of their depths below the surface. Hence, these pressures will be represented by the ordinates of a parabola, when the depths are represented by its abscissæ.

DEFINITION.

The *centre of pressure* is that point of a surface exposed to the action of a fluid, to which, if a force equal to the whole pressure upon the surface were applied, the effect would be the same as it is when the pressure is distributed over the whole surface.

PROP. V.

To find the centre of pressure.

Let it be required to find the centre of pressure P, Fig. 11, on the side of a cubical vessel ABCD. Let G be the centre of gravity of the surface, then the pressure exerted against this surface will be $BC \times BC \times GB$, or $\frac{BC^3}{2}$, since in the case of a cube or rectangle, $GB = \frac{BC}{2}$, and since the pressure must be equal to the sum of all the elementary pressures upon the elementary portions $Ff$, we have $\frac{BC^3}{2} \times PB = \int BC \times Ff \times FB \times FB$, or $\frac{BC^2}{2} = \int Ff \times FB^2$. But the sum of the elementary pressures $Ff \times FD^2$ compose a pyramid whose base is $= BC^2$, and whose altitude is BC, consequently, by the property of the centre of inertia (See MECHANICS) $\frac{DC^2 \times PB}{2} = \frac{DC^3}{3}$, and $PB = \frac{2\,DC}{3}$, that is, the centre of pressure is two-thirds of the depth of fluid in the vessel.

COR. The centre of pressure coincides with the centre of percussion, as the centre of percussion is also two-thirds of the height of the body.

SECT. II. *On the Pressure and Equilibrium of Fluids of Variable Density.*

DEFINITION.

THE absolute weights of different bodies that have the same bulk are called their *specific gravities* or *densities*, and any body, that, under the same bulk, is heavier than another, is said to be *specifically heavier.*

PROP. I.

If two fluids of different densities are included in the separate branches of a syphon, they will be in equilibrio, when the altitudes above their common junction are reciprocally proportional to their specific gravities.

Let ABCD, Fig. 12, be the syphon, and AB, CD the heights of the two fluids of different densities, which may be supposed separated from each other by the common junction $m\,n$. Then, if G is the centre of gravity of the surface $m\,n$, the pressure exerted by the fluid in AB is, by Prop. IV. $mn \times Gs$, and that of the fluid in CD, $mn \times GB$; but since their specific gravities S, S′ are, by the hypothesis, reciprocally as their altitudes, that is, $S : S' = Gr : Gs$, we have $S \times Gs = S' \times Gr$; but the pressure of the one column is $mn \times Gs \times S = mn \times Gr \times S$, the pressure of the other, consequently they will be in equilibrio.

If $op$ be the junction of the two fluids, then, by drawing the horizontal line $op\gamma tv$, we may regard the columns $opmn$, $tvnm$ as balancing one another, since they are composed of the same fluid, and then consider the columns $ABpo$, $CDvt$ of different densities, as resting upon the surfaces $op$, $tv$. In this case, $\gamma s \times S' = \gamma r \times S'$, and consequently the pressures $op \times \gamma s \times S = op \times \gamma r \times S'$.

In the case of water and mercury, the values of S, S′ are 1 and 13.58 at a temperature of 60°, consequently $Gs : Gr = 13.58 : 1$; and therefore, to balance 33 feet of water, a column of mercury 29.16 inches will be required.

PROP. II.

The pressure on the bottom of a vessel containing horizontal strata of fluids of different densities, is equal to the area of the bottom multiplied by the sum of the products of the thickness of every stratum and their specific gravities.

Let ABCD, Fig. 13, be the vessel, and $ABfe$, $efhg$, $ghlk$, and $klcD$ strata of different densities, S, S′, S″, S‴. Then since, by the last Prop. any column of fluid is in equilibrio with another, or has the same pressure when their heights are reciprocally as their densities, calling H, H′, H″, &c. the heights of the strata, we have $S : S' = H' : H$, and $H = \frac{S' \times H'}{S}$. We may therefore substitute a column of fluid of the same kind as the lower stratum $k$C, and having an altitude $\frac{S' \times H'}{S}$ instead of the column $gl$, and in like manner, instead of the other columns $eh$, $Af$ we may substitute columns whose heights are $\frac{S'' \times H''}{S}$ $\frac{S''' \times H'''}{S}$, and therefore calling DC the area of the bottom, the whole pressure on the bottom will be $= S \times DC \times H + \left( \times H + \frac{S' \times H'}{S} + \frac{S'' \times H''}{S} + \frac{S''' \times H'''}{S} \right) = DC \times (S \times H + S' \times H' + S'' \times H'' + S''' \times H''')$, which is the truth announced in the proposition.

PROP. III.

If a fluid contained in a vessel consists of an infinite number of strata, whose densities vary according to any law, the fluid will be in equilibrio, when the surfaces of the strata are perpendicular to the direction of gravity.

If the lower stratum of $klc$ D (Fig. 13.) were placed alone in the vessel, its surface $kl$ would be horizontal. Let us now suppose that every point of the surface $kl$ is pressed downwards by equal forces, which it will be, when it is pressed down by the weight of the superior strata with horizontal surfaces, then since there can be no reason why one point should yield more than another to these forces, it follows that the stratum $k$ C will still be in equilibrio. In like manner, it may be shewn, that the stratum $ghlk$ will be in equilibrio, and so on with all those above it, so that we may conclude that the whole fluid in the vessel is in equilibrio.

### Prop. IV.

To find the pressure exerted by a fluid composed of an infinite number of strata of variable density against any part of the vessel which contains it.

Let S, S′, S″, &c. be the specific gravities of the different strata $q\,p$, $p\,o$, $o\,n$, &c. then since the point $q$ sustains the weight of all the columns $q\,p$, $p\,o$, &c. above it, it will be pressed down by a force equal to $S \times q\,p + S' \times p\,o + S'' \times o\,n$, &c. $= S \times \left(\frac{q\,p + S' \times p\,o}{S} + \frac{S'' \times o\,n}{S} \times \text{\&c.} = S' \times \right.$ $\left(p\,o + \frac{S \times q\,p}{S'} + \frac{S'' \times o\,n}{S'} + \text{\&c.} = S'' \times (o\,n + \frac{S \times q\,p}{S''} + \frac{S' \times p\,o}{S''} + \text{\&c.}\right)$ Hence it follows, that we may substitute in place of the fluid of variable density a fluid whose density is uniform through the whole height $q\,m$.

Let us take an infinitely small elementary stratum $e\,n\,f\,\varphi\,\varphi\,\varepsilon$ contained between the horizontal lines $e\,n\,f$, $\varepsilon\,\nu\,\varphi$, then the pressure upon $e\,\nu$ is the absolute weight of the column $m\,\nu$; but making $m\,n = x$, and $\Sigma =$ the specific gravity of the fluid in $n$, the weight of $m\,n$ will be $\int \Sigma\,x$, and therefore the sum of the pressures against A $e$ will be $\int A\,e \times \int \Sigma\,x$. Thus to find the pressure upon the bottom DC, let $q\,m = a$, and $S =$ the specific gravity of the fluid in DC, then $\Sigma = \frac{S\,x}{a}$, and $\int \Sigma \dot{x} = \int \frac{S\,x\,\dot{x}}{a} = \frac{S x^2}{2a}$; and since, in the case of a pressure upon the bottom, $x = a$, we have $\frac{S\,x^2}{2\,a} = \frac{S\,a}{2}$ and the whole pressure upon the bottom $= \frac{S\,a}{a} \times \text{DC}$.

## CHAP. II.

### On Specific Gravities.

### Prop. I.

If any object floats upon a fluid, or is wholly immersed in it without sinking, it is pressed upwards with a force equal to the weight of the fluid displaced.

Let EF (Fig. 14.) be a body floating in the vessel ABCD. Then by Prop. III. Chap. I. any point or particle $n$ is pressed upwards with a force equal to a column of particles whose height is $m\,n$, and as this is true of every part of the surface E $n$ F, then since the part of the solid immersed is made up of these elementary columns, it follows that the sum of all the pressures exerted upon E $n$ F is equal to a quantity of fluid of the same size as the immersed part, which is the same as the quantity of fluid displaced.

When the body EF is wholly immersed, as in Fig. 15, it is obvious, that any part $o$ is pressed downwards with a column of fluid whose height is $m\,o$, while any part $n$ is pressed upwards with a column of fluid whose height is $m\,n$; consequently the point $n$ is pressed upwards with a column $n\,o = m\,n - m\,o$. But the sum of all the elementary columns $n\,o$ make up a quantity of fluid equal to that which is displaced by the body.

*Cor.* When a solid floats on a fluid, the quantity of fluid which it displaces is equal to the weight of the body. Since the whole weight of the solid pressing upon the surface of water E $n$ F is in equilibrio with the fluid mass, it must be equal in weight to the quantity of fluid E $n$ F, which is also in equilibrium with the same fluid mass, but this quantity of fluid is the quantity which is displaced.

### Prop. II.

When a body floats upon a fluid, the centre of gravity of the body and of the fluid displaced are in the same vertical line.

For since the upward pressure which supports the floating body is the same as if it were applied to the centre of gravity of the part immersed, or of the quantity of fluid displaced, then since the whole floating body is in equilibrio, its centre of gravity must be supported by this upward pressure; that is, the centres of gravity of the fluid displaced and of the floating body must be in the same vertical line.

### Prop. III.

The specific gravity of any floating body is to that of the fluid, as the volume of the part immersed is to the whole volume of the body.

Calling S the specific gravity of the fluid, and $s$ that of the solid, we have by Cor. Prop. I. $S \times E\,n\,F = s \times E\,p\,F\,n$, and therefore $s : S = E\,n\,F : E\,p\,F\,n$; that is, as the part immersed is to the whole volume of the body.

### Prop. IV.

If a solid is weighed in a fluid, it will lose as much of its weight as is equal to the quantity of fluid displaced.

It appears from Prop. I. that the body is pressed upwards with a force equal to the weight of the fluid displaced; and as this force acts in opposition to the natural gravity or absolute weight of the body, its absolute weight must be diminished by a quantity equal to the weight of the fluid displaced. The weight which the body in this case loses is not destroyed, but is sustained by an equal and opposite force.

If we call $s$ the specific gravity of the solid, S that of the fluid, B the bulk of the solid, and $m$ B the part of it which is immersed; then since $B \times s$ is the absolute weight of the solid, and $m\,B \times S$ the absolute weight of the quantity of fluid displaced, in order that an equilibrium may take place, we must have $B \times S = m\,B \times S$, and $S : S = m\,B : B$. Hence if $s = S$, we have $m\,B = B$; that is, *if the specific gravity of the solid is equal to that of the fluid, the part immersed is equal to the whole body;* or, in other words, *the solid will be completely immersed, and will remain wherever it is placed.* If $s > S$, then $m\,B > B$; that is, *when the specific gravity of the solid is greater than that of the fluid*, the body will sink to the bottom: and if $S > s$, then $m\,B < B$; that is, *when the specific gravity of the fluid is greater than that of the solid, then the part immersed is less than that of the whole solid*, or the body will float.

### Prop. V.

If a body is held beneath the surface of a fluid, the force with which it will ascend, if it is lighter than the fluid, or with which it will descend if it is heavier, is equal to the difference between its own weight and the weight of an equal quantity of the fluid.

The body held beneath the water obviously descends with its own weight $= B \times s$, while it is pressed upwards with the weight of the quantity of fluid displaced $= B \times S$; consequently the force with which it ascends must be $\overline{B \times S - B \times s}$, and the force with which it descends $= \overline{B \times s} - B \times S$, which are the differences between the weight of the body and the weight of the fluid displaced.

### Scholium.

On the truth contained in this proposition is founded the construction of the Camel for raising sunk vessels, or for lifting ships over high sand banks. (See our article Camel.) A similar effect is exhibited in some of the American rivers, where the ice is formed upon the stones at their bottom. Ice is specifically lighter than water, and therefore, when it accumulates to a certain degree round the stones, the upward pressure upon the stones exceeds their pressure downwards, and they are brought to the surface, having been sometimes torn up with great force. Huge masses of stones appear in many cases to have been floated by the ice adhering to them, and carried to a great distance from the place of their formation.

### Prop. VI.

The specific gravity of a solid is to that of the fluid in which it is weighed, as the absolute weight of the solid is to the loss of weight which it sustains.

In the equation $B \times s = m B \times S$, we have $B = m B$ when the body is weighed in a fluid, and of course wholly immersed; consequently if W be the weight of the body in the fluid, or the weight necessary to keep it in equilibrio with the fluid, then $B \times s = B \times S + W$, (and transposing and multiplying by $s$,) we have $s \times \overline{B \times s - W} = s \times B \times S$, and (Euclid, Book VI. 16.) $s : S = B \times s : B \times s - W$; consequently since $B \times s - W$ is the loss of weight which it sustains, the specific gravity of the solid is to that of the fluid, as the weight of the solid is to its loss of weight.

This Proposition may also be demonstrated, by considering that the weight lost, or $B \times s - W$, is the weight of a bulk of fluid equal to the bulk of the solid, whose weight is $B \times s$; and therefore, as the specific gravities are to one another, by the definition, as the weight of equal bulks, we have $s : S = B \times s : B \times s - W$.

### Prop. VII.

If the same solid body is weighed in two fluids, the specific gravities of the fluids are to one another as the losses of weight which the solids respectively sustain in each.

Making B the bulk of the body as before, S, S′ the specific gravities of the two fluids, and W, $w$ the weights of the solids in each fluid, then the weight of the quantities of fluid displaced will be $B \times S$, $B \times S'$, and since these weights are the weights lost by the body, if we add the weights of the body in the fluid, viz. W, $w$, to these weights, we shall have an expression which will be equal to $B \times s$, the real weight of the body. Thus:

$$B \times S + W = B \times s \text{ and } B \times S' + w = B \times s.$$

Hence we have the two equations,

$$B \times S = B \times s - W \text{ and } B \times S' = B \times s - w; \text{ hence}$$

$S \times B : S' \times B = B \times s - W : B \times S' - w$, consequently, (Eucl. B. V. 16.) $S : S' = B \times s - W : B \times s - w$, that is the specific gravities, or as the losses of weight sustained by the solid, for these losses must always be equal to the difference between the real weights and the weights W, $w$ in the fluid.

*Cor.* Hence, if two solid bodies lose equal parts of their weights in the same fluid, they have equal volumes.

### Prop. VIII.

If a solid body is immersed in two fluids of different specific gravities, so as to be partly in the one and partly in the other, it will be in equilibrio, if the part in the lighter fluid is to the part in the heavier fluid, as the difference between the specific gravities of the solid and the heavier fluid is to the difference of the specific gravities of the solid and the lighter fluid.

Let E F, Fig. 16, be the solid immersed in two fluids, and having the part M in the lighter fluid, whose specific gravity is S, and the part N in the heavier fluid, whose specific gravity is S′, and let $s$ be the specific gravity of the solid. Now the weight of the solid is $s \times \overline{M + N}$, the weight of the heavier fluid displaced by N is $S' \times N$, and the weight of the lighter fluid displaced by M is $S \times M$. But as the solid is, by the hypothesis, suspended in the fluids, the whole of its weight is lost; and consequently the part lost in the lighter fluid, added to the part lost in the heavier fluid, must be equal to its whole weight, that is, $S \times M + S' \times N = s \times \overline{M + N}$; then, by transposition, and Euclid, B. VI. 16, we have $M \times \overline{S - s} = N \times S' - s$ and $M : N = S' - s : S - s$.

*Cor.* 1. Since $M : N = S' - s : S - s$ then, by inversion and composition, Eucl. B. V. prop. B and 18, $M : M + N = S' - s : S' - S$, that is, *the part in the lighter fluid is to the whole solid, as the difference between the specific gravities of the solid and the heavier fluid is to the difference between the specific gravities of the two fluids.*

*Cor.* 2. If the specific gravity S of the lighter fluid is very small when compared to S′, as in the case of air and water, then we may, for ordinary purposes, take the analogy $M : N = S' - s : s$.

### Prop. IX. Prob.

To detect the adulteration of the precious metals.

Let us suppose, as in the case of Hiero's crown, that a mass of pure gold is adulterated by the admixture of silver. If we take a quantity of pure gold of the same weight as the adulterated mass, it will obviously have less bulk, as its specific gravity is greater than that of the mixture, (silver having a less specific gravity than gold) and therefore the quantity of pure gold, when weighed in water, will displace less of the fluid than the adulterated mass. Hence it follows, that we have only to weigh the suspected mass, and a mass of pure gold of the same weight; and if there is any difference in their weight, we must conclude that the mass is adulterated.

If the gold is heavier in water than the suspected mass, it has obviously lost less weight, and has therefore less bulk than the mass; consequently the adulterating mixture has a less specific gravity than gold. If, on the contrary, the gold loses more weight than the mass, it will have a greater bulk, and therefore the adulterating metal must have a higher specific gravity than gold, such as platinum.

### Prop. X.

If two substances of any kind be compounded together, the bulk of the heavier of the two ingredients is to the bulk of the lighter ingredient, as the difference between the specific gravities of the compound and the lighter ingredient is to the difference between the specific gravities of the compound and the heavier ingredient.

Calling S, S′ the specific gravities of the ingredients, B, B′ their bulks and Σ the specific gravity of the compound, then the weight of the compound is $\Sigma \times B + B'$, and as the weight of the compound must be equal to the sum of the weights of its ingredients, we have $\Sigma B + \Sigma B' = B \times S + B' \times S'$, and by transposition, &c. we have $B \times \Sigma - S = B' \times S' - \Sigma$ and (Eucl. VI. 16.) $B : B = S' - \Sigma : \Sigma - S$.

Scholium.

The supposition in the preceding reasoning, that the bulk of the compound is equal to the sum of the bulks of its ingredients, is not physically true. A pint of alcohol or of sulphuric acid, mixed with a pint of water, will not make so much as two pints of the compound fluid; and, on the other hand, a cubical inch of tin, mixed with a cubical inch of lead, will make a compound containing more than two cubical inches of metal. A certain bulk of water is diminished by the addition of $\frac{1}{61}$ of sal ammoniac; and 40 parts of platinum and 5 of iron will make but 39 parts by measure.

Prop. XI. Prob.

To determine accurately the specific gravity of gaseous or aeriform bodies.

As the specific gravities of gaseous bodies are measured in relation to that of air, we must first determine the weight of a given volume of this gas. In order to do this, take a large glass vessel, containing at least five or six litres, and having exhausted it of its air by a good air-pump, weigh it in a delicate balance, and call its weight W. Let the air be now admitted to the glass vessel, and let its weight, as ascertained by the balance, be now called W′. The difference between these weights, or W—W′, will obviously be the weight of the atmospherical air contained in the vessel. Let it now be required to measure the specific gravity of another gas. Weigh the glass vessel when empty as formerly, and also when full of the gas, and let these weights be $w$, $w'$, then $w-w'$ will be the weight of the gas, and $\frac{w-w'}{W-W'}$ will be its specific gravity compared with that of the air, which is taken at 1.000. This specific gravity is that which corresponds with the state of the atmosphere at the time when the experiment was made.

It is obvious, however, that all these measures are affected by a variation in the density, the temperature, and the humidity, of the external atmosphere. The weight, too, of the gases, when they are introduced into the receiver, is affected by the temperature and pressure of the air. The contraction and dilatation of the glass vessel requires also to be computed; and the weight of the gas itself is affected by the temperature and the degree of drying which it has experienced. These various sources of error likewise affect the results, in so far as they affect the external atmospherical air in which both the air itself and the gas must be weighed. Some allowance must also be made for the imperfect exhaustion of the glass vessel, which is always visible by its effect upon the barometer.

It will readily be seen, that it must require no small degree of trouble to calculate the combined influence of these different causes, though, in order to obtain accurate results, such a calculation becomes absolutely necessary. As it would be impracticable in the present article to enter into any lengthened examination of the subject, we must refer such of our readers as wish to study it profoundly, to the 19th, 20th, and 21st chapters of M. Biot's valuable work, entitled *Traité de Physique*, which not only contain the method of deducing the necessary formulæ, but also many excellent remarks and suggestions which could only have been given by one who had investigated the subject both theoretically and practically. The following are his principal formulæ, which are suited to a temperature of 32° of Fahrenheit, or that of melting ice, and to a state of the atmosphere when the barometer stands at 0.76 metres, or 29.94 English inches.

In these formulæ,

$X$ = the absolute weight of atmospheric air contained in the glass vessel at a temperature of 32°, and under a pressure of 29.94 inches of mercury, as calculated from the formulæ.

$Y$ = the absolute weight of any gas under the same circumstances.

$V$ = the interior volume of the glass vessel at the same temperature.

$K$ = the cubical dilatation of glass for every degree of the centigrade thermometer.

At the time when the glass vessel is weighed empty:
- $P$ = the absolute weight of the glass vessel, which never changes.
- $h$ = the atmospherical pressure.
- $t$ = the temperature of the air.
- $p$ = the state of the hygrometer.
- $\theta$ = the tension in the interior of the glass vessel, after a vacuum is made by the air pump.

At the time of the introduction of the gas into the glass vessel:
- $p$ = external pressure exerted upon the gas.
- $t'$ = temperature of the gas.
- $p'$ = its hygrometric state.

At the time when the glass is weighed full of gas:
- $P''$ = the weight of the glass vessel filled with gas.
- $p''$ = the atmospherical pressure.
- $t''$ = the temperature of the external air.
- $h''$ = the state of the hygrometer.

When the glass vessel is weighed empty a second time, after it has been weighed full of gas:
- $P'''$ = the weight of the glass vessel empty observed in air.
- $p'''$ = atmospherical pressure.
- $t'''$ = temperature.

1. *Formulæ suited to the case where the Gases are perfectly dry.*

$$X = \frac{P'' - P\ 0^m.76}{\frac{(1+Kt)p}{1+t.0,00375} + \frac{(1+Kt')p'}{1+t.0,00375} - \frac{(1+Kt'')p''}{1+t''.0,00375}} \qquad \text{(No. 1.)}$$

$$2Y = \frac{(2P'' - P - P''')\ 0^m.76 + \frac{2X(1+Kt'')p''}{1+t''.0,00375} - \frac{X(1+Kt)p}{1+t.0,00375} - \frac{X(1+Kt''')p'''}{1+t'''.0,00375}}{\frac{(1+Kt)p}{1+t'.0,00375}} \qquad \text{(No. 2.)}$$

In the ordinary state of the atmosphere, the barometer and thermometer indicate only very small and progressive changes, so that in the short time which can elapse between the different weighings of the gas, we may safely suppose the atmospherical pressure $p''$, and the temperature $t''$, corresponding to the intermediate weighing of the glass vessel, as arithmetical means between the extreme pressures $p$, $p'''$, and the extreme temperatures $t$, $t'''$. In proportion, therefore, as the variations in these elements have been inconsiderable, we may consider them as compensating themselves in the terms of X: These terms will consequently disappear, and the formula will be reduced to the following simple form:

$$Y = \frac{\left(P'' - \frac{(P+P''')}{2}\right)(1+t'.)0,00375\ .0''',76}{(1+Kt')p'}. \qquad \text{(No. 3.)}$$

This formula will be found sufficiently exact when the gases and the atmospherical air are perfectly dry; but as this is never the case, and as the aqueous vapour has a very considerable influence upon the weight at a temperature above 50° of Fahrenheit, it is necessary to compute its effect.

2. *Formulæ suited to the case where the Gases are perfectly saturated with Water.*

In the following formulæ, X is the weight of a volume of a dry atmospherical air contained in the glass vessel, at the temperature of 32°, and the barometrical pressure of 0.76 metres, or 29.994 English inches.

T = the real tension of aqueous vapour at the weighing of the glass vessel empty.
T′ = the tension at the introduction of the gas.
T″ = the tension at the weighing of the glass vessel full of gas.

$$X = \frac{P'' - P\ .0_m.76}{\frac{(1+Kt)\ (p - \frac{3}{8}T)}{1+t\ .0,00375} + \frac{(1+Kt')\ (p' - \frac{3}{8}T')}{1+t'\ .0,00375} - \frac{(1+Kt'')\ (p'' - \frac{3}{8}T'')}{1+t''\ .0,00375}} \qquad \text{(No. 4.)}$$

$$Y = \frac{(P''-P)_m 0.76 - \frac{5X\ (1+Kt')\ T')}{8(1+t'\ .0.00375)} + \frac{X(1+Kt'')\ (p'' - \frac{3}{8}T''}{1+t''\ .0,00375} - \frac{X(1+Kt)\ (p - \frac{3}{8}T)}{1+t\ .0,00375}}{\frac{(1+Kt')\ (p' - T')}{1+t'\ .0,00375}} \qquad \text{(No. 5.)}$$

These formulæ will answer, when the external air, in which the air and the gas are weighed, are not saturated with moisture. In this case, T′ and T″ will express the tension of the aqueous vapour really suspended in this air.

The preceding results may be rendered independent of the quantity of aqueous vapour contained in the atmosphere at the time of the experiment, by the method employed above, namely, by weighing a second time the glass vessel empty, immediately after it has been weighed full of the gas. Then, if $t'''$ is the temperature at which this is done, $p'''$ the atmospherical pressure, T‴ the tension of the aqueous vapour, and P‴ the weight observed, the resulting formula will be

$$Y = \frac{\left(P'' - \frac{(P+P''')}{2}\right)0^m.76 - \frac{5X\ (1+Kt')\ T'}{8(1+t'\ .0,00375)}}{\frac{(1+Kt')\ (p' - T')}{1+t'.0,00375}} \qquad \text{(No. 6.)}$$

This formula becomes exactly the same as No. 3, when T′ = .0; that is, when the gases are perfectly dry.

3. *Formulæ suited to the Case when the Gases are perfectly dry, but the exhaustion not complete.*

The above formulæ will be sufficiently correct, if the exhaustion of the glass vessel is made with a very fine air pump, but as this is not generally to be met with, let us suppose $\theta$ to be the tension of the little air which remains in the glass vessel, as marked by the gauge. Then

$$Y = \frac{(P'' - P''')\,0^m.76 + \frac{X(1+Kt'')\,(p''-\frac{3}{8}T'')}{1+t''\,.0{,}00375} - \frac{X(1+Kt''')\,(p'''-\frac{3}{8}T''')}{1+t'''\,.0{,}00375}}{\frac{(1+Kt')\,(p'-\theta}{1+t'\,.0{,}00375}} \qquad \text{(No. 7.)}$$

which, by the means formerly described, may be reduced to

$$Y = \frac{\left(P'' - \frac{(P+P''')}{2}\right)(1+t'\,.0{,}00375)\,0^m.76}{(1+Kt')\,(p'-\theta)}.$$

M. Biot has exemplified the use of the formula No. 5. by an experiment which he made on the 3d July 1806, for the purpose of determining the specific gravity of hydrogen gas. In this experiment, the different quantities had the following values.

At the weighing of the empty glass vessel, $P = 662.262$ grammes; $t = 20°\,9$ centigrade; $p = 0.7616$ metres.

At the introduction of the gas into the glass vessel $t' = 21°\,4$ centigrade; $p' = 0.7630$ metres.

At the weighing of the glass vessel when full $P'' = 662.823$ grammes; $t'' = 20°\,6$; $p'' = 0.7622$

The gas was saturated with water, and the hygrometer indicated a state of the atmosphere approaching to extreme humidity.

Weight of the atmospherical air in the glass vessel, as determined by preceding experiments $X = 7.2532$ grammes.

Log. $X = 0.8605315$

Cubical dilatation of glass for one degree of the centigrade thermometer $K = 0.0000262716$

Log. $K = 5.4194865$

Elastic forces of the aqueous vapour at the temperatures $t, t', t''$, calculated from a formula given by Biot, vol. i. p. 27. $T = 0.0185$ metres. $T' = 0.0190$; $T'' = 0.0182$. Consequently $\frac{3}{8}T = 0.0069$. $\frac{3}{8}T'' = 0.0068$. Hence

$$p - \tfrac{3}{8}T = 0.7547 \text{ metres};$$
$$p' - \tfrac{3}{8}T' = 0\,7440;$$
$$p'' - \tfrac{3}{8}T'' = 0.7554;$$

But as the pressures $p, p', p''$, or the altitude of the mercury in the barometer, were observed at different temperatures, they must be reduced to that of 32° of Fahrenheit, by subtracting from each of them the corresponding dilatation of mercury. Hence we shall have

$$p = \frac{0.7547\ .\ 20°.9}{5412} = 0.0029 \text{ metres.}$$
$$p' = \frac{0.7440\ .\ 21°4.}{5412} = 0.0029.$$
$$p'' = \frac{0.7554\ .\ 20°.6}{5412} = 0.0029;$$

so that the barometrical columns thus reduced, will be

$$p - \tfrac{3}{8}T = 0.7518;\ p' - \tfrac{3}{8}T' = 0.7411;\ p'' - \tfrac{3}{8}T'' = 0.7525.$$

We have also . . . . $1 + Kt = 1.000549$; $1 + t\ .0{,}00375 = 1.078375$
$1 + Kt' = 1.000562$; $1 + t'\ .0{,}00375 = 1.080250$
$1 + Kt'' = 1.000541$; $1 + t''\,.0{,}00375 = 1.077250$

With these elements, and with X, which has been found, we have

$$\frac{X\,(1+Kt'')\,(p''-\frac{3}{8}T'')}{1+t''\,.0{,}00375} = 5.088935 \text{ grammes.}$$
$$\frac{X\,(1+Kt)\,(p-\frac{3}{8}T)}{1+t\,0.00375} = 5.078947$$

Difference . . 0.009988

Hence we have the difference of these two terms, or

$$\frac{X(1+Kt'')\,(p''-\frac{3}{8}T'')}{1+t''\,0.00375} - \frac{X(1+Kt)\,(p-\frac{3}{8}T)}{1+Kt\,.0{,}00375} = 0.009988 \text{ grammes.}$$

By adding to this $(P'' - P)$ .0.76 metres . . . . . . . . . . . . $= 0.43016$

we have . . . . . . . . . . . . . . . . . . . . . . . 0.440148

which is the sum of all the positive terms of the numerator.

By subtracting the negative term, or $\frac{5\,X\,(1+Kt')\,T'}{8\,(1+t'\,.0.00375)}$ . . . $= 0.0797783$

The difference is . . . . . . . . . . . . . . . . . . . . 0.360370

which is the value of the numerator of the formula.

$$\text{The denominator, or } \frac{(1+K\,t')\,(p'-T')}{1+t'.0.00375} \quad . \quad . \quad = 0.6891163$$

$$\text{we have } Y = \frac{0.36037}{0.6891163} \quad . \quad . \quad . \quad . \quad . \quad = 0.522945 \text{ grammes,}$$

which is the weight of the volume of hydrogen gas contained in the glass vessel at 32° of Fahrenheit, and 0.76 metres, or 29.994 inches of the barometer. Hence we have the specific gravity of hydrogen gas, or

$$\frac{Y}{X} = \frac{0.522945}{7.25323} = 0.720982.$$

PROP. XII. PROB.

To determine accurately the specific gravity of liquids.

The accurate determination of the specific gravity of liquids is, like that of gaseous bodies, attended with considerable difficulty. As the specific gravities of the gases are referred to that of atmospheric air, so in liquid and solid bodies the specific gravities are referred to that of water, when at the temperature of + 3°.42 of the centigrade scale, or 38°.15 of Fahrenheit, which corresponds to the maximum density of that fluid.

In measuring the specific gravities of liquids, a glass vessel with a narrow neck, after having been accurately weighed when empty, is successively weighed when filled with distilled water, and with the liquid whose specific gravity is required, and the temperature and atmospherical pressure are carefully marked. The volume of water and of fluid may then be obtained by the following formulæ which have been given by M. Biot. In these formulæ,

V = the interior capacity or volume of the glass vessel in cubic centimetres, at the temperature of 32° of Fahrenheit, or that of melting ice.
L = the apparent weight of the liquid when it is weighed.
$\lambda$ = dilatation of the liquid at 32° of Fahrenheit, taking its volume at this temperature for unity.
$\delta'$ = the dilatation of water from its maximum density to the temperature $t'$.
F = the apparent weight of the water at the temperature $t'$.
$t$ = the temperature when the liquid is weighed.
$t''$ = the temperature reckoned from the point of maximum density, or $t'' = t - 3°.42$.
$a$ = the weight of a volume of dry or moist air in the glass vessel at the time the liquid is weighed.
$(a)$ = the weight of a cubic centimetre of dry air, at the temperature of 32°, and the pressure of 0.76 metres, or 29.994 inches.
K = the cubical dilatation of glass for every degree of the centigrade thermometer.
$p$ = the height of the column of mercury when the liquid is weighed.
$p'$ = the height of the column of mercury in the barometer, reduced to the temperature of 32° of Fahrenheit.
$\alpha'$ = the relation of the weight of air to that of water, at the temperature $t'$.
T = the tension of the vapour of water in the air where the liquid is weighed.
$\pi$ = the weight of a cubic centimetre of the liquid at the temperature of 32° of Fahrenheit.

Then we have

$$\delta = 0.00000634750\, t''^2 - 0.00000002708\, t''^3 \quad \text{No. 1.}$$

$$\alpha' = \frac{(a)\, p'\, (1+\delta')}{(1+t'\,.\,0.00375)\, 0^m.76} \quad \text{No. 2.}$$

$$V = E + E\alpha' + \frac{E\,(1+\delta')\,(\alpha' - K\,t' + \alpha'\,K\,t')}{(1-\alpha')\,(1+K\,t')} \quad \text{No. 3.}$$

$$\alpha = \frac{(a)\, V\, (1+K\,t)\,(p - \frac{3}{8}\,T)}{(1+t\,.\,0.00375)\, 0^m.76} \quad \text{No. 4.}$$

$$\pi = \frac{(L+a)\,(1+\lambda)}{V\,(1+K\,t)} \quad \text{No. 5.}$$

The use of these formulæ will be best seen by applying them, as M. Biot has done, to the following experiments on mercury and water by him and M. Arago.

| Liquids. | Apparent weight of air in grammes, or values of L. | Temperature in degrees of the centigrade or values of $t$. | Height of the mercury in the barometer, or values of $p$. |
|---|---|---|---|
| | | | Metres. |
| Exp. 1. Mercury | 1342,989 | 12°.5 | 0.7439 |
| Exp. 2. Mercury | 1340,893 | 20 .6 | 0.7580 |
| Exp. 3. Water | 98,721 | 20 .1 | 0.7600 |
| Exp. 4. Water | 98,716 | 20 .9 | 0.7589 |

In calculating the value of V, from the formula No. 3, we have

$(a) = 0.001299541$ grammes, and Log. $(a) = \bar{3}.1137902$, and by the formula No. 1.

$\delta' = 0.0017017$ for Exp. 3. since $t'' = 20°.1 - 3°.42 = 16°.68$
$\delta' = 0.0018654$ for Exp. 4. $\quad t'' = 20\ .9 - 3\ .42 = 17\ .48$

The height of the mercurial columns, or $p$, being reduced to the temperature of 32° of Fahrenheit, we have

$$p' = 0.760 - 0.0028 = 0.7572 \quad \text{Exp. 3.}$$
$$p' = 0.7589 - 0.0029 = 0.7560 \quad \text{Exp. 4.}$$

With these values, and the temperature $t'$ observed at the time of the weighing, we have by the formula No. 2.

$$\alpha' = 0.001206079$$
$$\alpha' = 0.001192953$$

$$\text{Now } K\,t' = 0.0005281 \quad \text{Exp. 3.}$$
$$K\,t' = 0.0005491 \quad \text{Exp. 4.}$$

$$\text{Hence } \alpha'\,K\,t' = 0.0000006369, \quad \alpha' + \alpha'\,K\,t' - K\,t' = 0.00067861 \quad \text{Exp. 3.}$$
$$\alpha'\,K\,t' = 0.0000006551, \quad \alpha' + \alpha'\,K\,t' - K\,t' = 0.00064451 \quad \text{Exp. 4.}$$

By substituting these values in the formula No 3, we have, in cubic centimetres,

$$V = 98.721 + 0.1679935 + 0.0671518 = 98.9561453 \quad \text{Exp. 3.}$$
$$V = 98.716 + 0.1841449 + 0.0637819 = 98.9639268 \quad \text{Exp. 4.}$$

The arithmetical mean between these results is $V = 98.960036$. The capacity of the glass vessel at the temperature of 32° of Fahrenheit.

The absolute weight of mercury or any other liquid weighed in the same glass vessel, at a given temperature, may now be easily deduced from the formula No. 5. We shall follow M. Biot in applying the formula to Experiments 1. and 2. on mercury.

In order to calculate the value of $a$, we have $(a)$ $V = 0,1286201$ grammes, or the weight of dry air contained in the glass vessel at the standard temperature of 32° of Fahrenheit, and $0^{m}.76$ or 29.994 inches of atmospherical pressure.

Hence we shall have by the formula No. 4.

$a = 0,12004$ Exp. 1. and $a = 0.11872$. Exp. 2. Hence

$$\text{Exp. 1.} \begin{cases} L = 1342,989 \text{ grammes} \\ a = \phantom{134}0,12004 \\ \hline L + a \quad 1343,10904 \end{cases} \qquad \text{Exp. 2.} \begin{cases} L = 1340,93 \text{ grammes} \\ a = \phantom{134}0,11872 \\ \hline L + a \quad 1341,01172 \end{cases}$$

As these weights contain a great number of grammes, it is necessary to calculate the corrections with regard to $K\,t$ and $\lambda$ more exactly than would otherwise have been necessary. We have

$$\frac{L + a}{1 + K\,t} = L + a - \frac{(L + a)\,K\,t}{1 + K\,t}$$

The second of these terms, which is always very small, is the correction sought. Now

$$\frac{L + a}{1 + K\,t} = \overset{\text{grammes.}}{1343,10904} - 0,440919 = 1342,66812 \quad \text{Exp. 1.}$$

$$\frac{L + a}{1 + K\,t} = 1341,01172 - 0,725363 = 1340,286357 \quad \text{Exp. 2.}$$

By adding to each of these results its product by the dilatation $\lambda = \frac{t}{5412}$ in mercury we have

$$\frac{(L + a)\,(1 + \lambda)}{1 + K\,t} = 1342,66812 + 3,10113 = 1345,7692 \quad \text{Exp. 1.}$$

$$\frac{(L + a)\,(1 + \lambda)}{1 + K\,t} = 1340,28636 + 5,10160 = 1345,3880 \quad \text{Exp. 2.}$$

The arithmetical mean between these results is 1345,5786 grammes, which, being divided by V, already found to be 98,960036, we have

$$\pi = \frac{1344,5786}{98,960036} = 13,597190$$

which is the weight of a cubic centimetre of mercury in grammes, at the temperature of melting ice.

If we wish to compare this weight with that of water, we have only to calculate the last for the temperature of melting ice, or for —3°.42 of the centigrade thermometer. But if $\delta$ is the dilatation of water from its maximum density to its freezing point, or for 3°.42, the weight of water required will be $\frac{1}{1+\delta}$, and the relation between the weights of mercury and water at the temperature of melting ice will be $\pi\,(1+\delta)$. But, by substituting —3°.42 in the formula of dilatation, No. 1. we shall have $\delta = 0,0000748$. Hence

$$\pi\,(1+\delta) = 13,597190 + 0,001017 = 13,598207,$$

which is the exact ratio between the weights of equal volumes of mercury and water at the temperature of melting ice.

Prop. XIII. Prob.

To determine accurately the specific gravities of solid bodies.

In determining the specific gravities of solid bodies, we may adopt two methods. 1. We may weigh them successively in air and in some other fluid, which is the ordinary method; and then, if P is the apparent weight of the solid in air, and $p$ the weight of the volume of water which it displaces, we have $\frac{P}{p}$ for the specific gravity of the body, neglecting the necessary reductions; or, 2. After having weighed the solid in air, we may place the solid in a glass vessel, and weigh them conjointly, and then weigh the same glass vessel when filled only with water. If then D is the weight of the solid in air, $p$ the weight of the vessel containing the water and the solid, and $p'$ the weight of the vessel containing water alone; then $p - p'$ is the weight of the quantity of water displaced, and $\frac{P}{P - p + p'}$ will be the specific gravity required.

If the substance is soluble in water, like many of the salts, it is necessary to use alcohol, or some other fluid, such as the essential or fat oils, which are not capable of dissolving it. The specific gravity of the oil being known, that of the salt will be immediately found.

If the solid imbibes water, without either dissolving or decomposing it, it is necessary first to weigh the body when perfectly dry, which weight we may call P, and then weigh it when it has imbibed as much water as possible. Let this weight be P′. We must next find how much water the body displaces, which we may call $a$, then the apparent specific gravity of the body is $\frac{P}{a}$, as it has really displaced the quantity of water $a$. But, in order to know the specific gravity of the solid parts of the body which do not admit water, such as the real fibrous part of sponges, then we must consider, that the quantity of water displaced is not merely $a$, but $a—P'$, and therefore $\frac{P}{a-P'}$ is the real specific gravity, neglecting the necessary reductions.

In order to explain the formulæ given by M. Biot for solid bodies, let us take

$t$ = temperature at which the solid is weighed.
V = the volume of the solid body in cubic centimetres at the temperature $t$.
$(s)$ = the absolute weight of a cubic centimetre of its substance at the temperature of melting ice.
K = the cubical dilatation of the solid for one degree of the centigrade thermometer.
$(e)$ = the weight of a cubical centimetre of water at the temperature of melting ice.
$\delta$ = the dilatation of water from 32° to $t$.
$\alpha$ = the ratio of the weight of air to that of water in the circumstances under which the experiment is made.
$\lambda$ = the dilatation of any other liquid employed instead of water.
$(\pi)$ = the weight of a cubical centimetre of another liquid at the temperature of melting ice.
S = the weight of the solid in air.
S' = the weight of the solid in water.

*Case* 1. When the body is weighed successively in air and water,

$$(s)=\frac{(1+K\,t)\left(\frac{S(\pi)}{1+\lambda}-\frac{S'\,(e)\alpha}{1+\delta}\right)}{S-S'} \quad \text{No. 1.}$$

If the body has been weighed successively in water and in air at the same temperature, then $(\pi)=(e)$ and $\lambda=\delta$, consequently

$$(s)=\frac{(e)\,(1+K\,t)\,(S-S'\,\alpha)}{(1+\delta)\quad(S-S')} \quad \text{No. 2.}$$

*Case* 2. When there are three weighings, 1st of the solid body, 2d of the glass in a vessel filled with a liquid, and 3d of the same vessel containing the solid and the liquid;

$$\text{Then } (s)=\frac{(1+Kt)\left(\frac{S(\pi)}{1+\lambda}-\frac{(P-L)(e)\,\alpha}{1+\delta}\right)}{S-P+L} \quad \text{No. 3.}$$

If the body has been weighed successively in water and in air, then $(\pi)=(e)$ and $\lambda=\delta$, and the formula is reduced to

$$(s)=\frac{(e)\,(1+K\,t)\,[S-(P-L)\alpha]}{(1+\delta)\,(S-P+L)} \quad \text{No. 4.}$$

*Case* 3. When there are only two weighings, 1st of the solid in air, and 2d of the solid in liquid in the same vessel: In this case let M be the weight of the solid and liquid,

$$(s)=\frac{(e)\,(1+K\,t)\,[S-(P-M+S)\alpha]}{(1+\delta)(S-P+M-S)} \quad \text{No. 5.}$$

This formula differs from No. 4. only in the substitution of M — S in place of L.

## CHAP. III.

### On the Theory and Construction of Areometers, or Hydrometers, for measuring Specific Gravities.

### Sect. IV. *On the Construction of different Hydrometers.*

The names *areometer*, *hydrometer*, *gravimeter*, have been indiscriminately applied to those instruments which are employed, when very great accuracy is not required, for determining the specific gravities of spirituous liquors, and other fluids.

Before we enter upon the description of these instruments, we shall first explain the general principles of their construction, as exhibited in the hydrometer of Fahrenheit.

#### 1. *Fahrenheit's Hydrometer.*

This instrument is represented in Plate CCCXIV. Fig. 1. It may be constructed either of glass or metal, and consists of a cylindrical stem AB, Fig. 1. connected with two hollow balls C, D. A small quantity of mercury, or of leaden shot, is introduced into the lower ball D, so as to prevent it from overturning, and to make it float steadily when it is immersed in a fluid. In using this instrument, we may either load it with different weights, or have a scale of equal parts engraven upon its stem. Fahrenheit adopted the first of these methods. He made a mark $w$ upon the stem AB, and having immersed it in the lightest liquor, (Fahrenheit used spirits of wine and spirits of turpentine,) such as ether, he introduced mercury into the ball D, till the surface of the light fluid stood at the mark $w$. The tube AB was then hermetically sealed, and the instrument weighed in a nice pair of scales. This weight will obviously be the weight of the quantity of fluid which it displaces. When the instrument was placed in a denser fluid, such as water, he placed weights in the small box at A, till the hydrometer sunk to the same mark $w$. By again weighing the hydrometer with the additional weights, he obtained the weight of a quantity of the denser fluid which was displaced; but as the part immersed was the same in both cases, the two weights which he had obtained were the absolute weights of equal quantities of two fluids, and were, therefore, the ratios of their specific gravities. Thus if W be the weight of the loaded instrument in distilled water at the temperature of 60° of Fahrenheit, when it has sunk to any mark upon the stem, and $w$ the weight, which must either be taken from the box at A, or added to it, in order to make the instrument sink to the same point in another fluid, and B the volume or bulk of the part immersed, then S, $s$, being the specific gravities, we have $W = S \times B$, and $W \pm w = s \times B$. Hence $B = \frac{W}{S}$ and $B = \frac{W \pm w}{s}$, and $\frac{W \pm w}{s} = \frac{W}{S}$, and by reduction $s = \frac{S \times W \pm w}{W}$; or since $S = 1.00$ in water, $s = \frac{W \pm w}{W}$. In the thermometer of Fahrenheit which we have described, the stem AB is made very short, and is only one-third of the length of a tube which he places between the balls C and D.

The results obtained with this hydrometer, may be reduced to the temperature of 32° of Fahrenheit, and allowance made for the effects of heat, both upon the liquid and the hydrometer itself. The following formula, given by M. Biot, includes these effects.

$$(\pi) = \frac{(P + P')(1 + \lambda)}{(P)(1 + K\,t.)}$$

In this formula, $(\pi)$ is the weight in grammes of a cubic centimetre of the liquid subjected to experiment, $\lambda$ is the dilatation of this liquid from 32° to the temperature $t$, P is the absolute weight of the hydrometer when weighed *in vacuo*, or its weight in air diminished by the weight of the quantity of air which it displaces, and it also expresses, in cubic centimetres, the value of the part immersed in the liquid; (P) is the absolute weight of the part immersed at 32° of Fahrenheit; and K the cubic dilatation of the substance of the areometer.

### 2. *Clarke's Hydrometer.*

The hydrometer invented by Mr Clarke, and described in the Philosophical Transactions by Dr Desaguliers, was made of metal instead of glass. The principal ball was made hollow and of copper, and the brass wire of about $\frac{1}{4}$th of an inch thick, was soldered into it. Upon the stem a mark is made, to which the instrument sinks when it is placed in proof spirits, and another mark is made above and below this, at which it sinks when the spirit is $\frac{1}{10}$th under proof, or $\frac{1}{10}$th above proof. The lower ball could be screwed off, and other balls of different weights screwed on, for liquors that differ more than $\frac{1}{10}$th from proof, so as to give the specific gravities of all the mixtures of spirituous liquors that are used in trials. See the *Phil. Trans.* 1730, No. 413, p. 277.; and Desaguliers' *Course of Experimental Philosophy*, edit. 3d, vol. ii. p. 233.

### 3. *Desaguliers' Hydrometer.*

The object of this instrument was, to ascertain the specific gravities of different kinds of water; and in order to give it a high degree of sensibility, Dr. Desaguliers made the hollow glass ball less than three inches in diameter, while the stem to which it was attached was a long slender wire, whose diameter was only the 40th part of an inch, and whose length was 10 inches. Under the great ball is placed a small ball, about one inch in diameter, to contain shot for floating the instrument in a vertical position. In river or soft spring water, the hydrometer sinks to a fixed point in the middle of its stem. If a single grain weight is added, the stem will descend a whole inch. Now, as the hydrometer weighs 4000 grains, and as one inch of the stem weighs *ten* grains, the part of it immersed must weigh 4000—50=3950 grains, 50 grains corresponding to half the length of the stem. But the quantity of water displaced must weigh 4000 grains, equal to the whole weight of the hydrometer; consequently the instrument will serve to compare together the different bulks of 4000 grains of water; and since one tenth of an inch in the scale corresponds to one tenth of a grain, it will obviously distinguish the strength of a grain in 4000, or the 40,000th part of the whole bulk of water. By altering the quantity of shot in the ballast ball, this hydrometer may be fitted for comparing any other two liquors that have nearly the same specific gravity. See Dr Desaguliers' *Course of Experimental Philosophy*, vol. ii. p. 234.

### 4. *Deparcieux's Hydrometer.*

This instrument, which was intended by its author for measuring the specific gravities of different kinds of water, is represented in Plate CCCXIV. Fig. 2. where AB is a glass phial about seven or eight inches long, and two inches in diameter. It is loaded with shot at the bottom to prevent it from overturning, and its lower part is rounded to prevent the air from lodging below. A brass wire AC, about 30 inches long, and $\frac{1}{12}$ of an inch in diameter, is fixed in the cork of the phial, which is well varnished to prevent the penetration of the water. The length of the wire ought to be such, that, when the phial is loaded and immersed in spring water at a medium temperature, the whole phial, and about an inch of the wire, should be below the scale, while, when it is plunged in very light river water, the wire should be immersed about 20 inches. To the summit of the wire is fixed a cup C, which contains the small weights with which it may be found necessary to load the instrument in order to make it sink to a fixed point in different kinds of water. A tube of white iron DEFG, about 3 feet long, and 3 inches in diameter, is used to hold the water whose specific gravity is to be determined, and there is attached to it a scale EH, divided into inches and parts of an inch, for the purpose of measuring the different depths to which the instrument sinks. This instrument is so sensible, that, if a small quantity of spirits of wine, or a pinch of sugar or salt, are added to the water in the tin tube, the phial will ascend or descend a very sensible quantity. M. Deparcieux made use of a hydrometer which weighed 23 ounces, 2 gros, and 26 grains (French). A weight of 38 grains made it descend through a height of 19 inches, 6 lines, which was equal to $6\frac{3}{19}$ lines for every grain, or the $\frac{1}{17428}$th part of the volume of water displaced. The results given in our general Table of specific gravities, p. 455, for different waters in France, were obtained by means of this instrument. See Prony's *Architecture Hydraulique*, tom. i. § 614—627.

### 5. *Jones's Hydrometer.*

This hydrometer, which was invented by Mr William Jones of Holborn, is constructed so as to apply the correction which is necessary from a change of temperature. This correction had hitherto been applied only in a rough manner; but upon considering that 32 gallons of spirits in winter will expand to nearly 33 gallons in summer, Mr Jones fixed a thermometer to his instrument, and by adjusting the divisions experimentally, he has obtained it pretty correctly. Mr Jones has also taken into account the diminution of bulk which takes place in mixing alcohol and water, which is so great as to produce a loss of four gallons in the 100. Thus, if to 100 gallons of spirit of wine, which are 66 gallons in the 100 over proof, 66 gallons of water are added to reduce it to proof spirit, the compound of water and alcohol will consist only of 162 gallons instead of 166, four gallons having been lost by the mutual penetration of the two fluids.

Mr Jones' hydrometer is represented in Plate CCCXIV. Fig. 3. It consists of a stem AC of the form of a parallelopiped, on the five sides of which the different strength of spirits are marked. One of these sides is shewn in Fig. 3. and the other three separately. This stem is fixed to the oval ball CD, which is made of hard brass, and has its conjugate diameter about one and a half inches. A thermometer DE is attached to the stem DB below the ball, and the whole length AB of the instrument is about 9½ inches. Three weights W, W′, W″ are suited to the three sides of the stem shewn separately. Let us now suppose that the instrument is plunged in a spirituous liquor; then, if it floats, so that the surface of the liquor is somewhere between A and C, the division on the side of the stem marked 0 (viz. the side of the stem attached to the instrument) will indicate the strength of the liquor if it is between 74 gallons in the 100, and 47 in the 100 above proof. But if the surface of the fluid stands below the extremity C of the scale, it must be loaded with any of the weights W, W′, W″, till the surface of the liquor rises above C; then, if the weight W, or No. 1. is required to produce this effect, the side of the stem marked No. 1. will shew the strength of the spirituous liquor from 46 gallons in the 100 to 13 in the 100 above proof. If the weight No 2. is required to raise the surface of the spirits above C, the divisions on the side marked No. 2. will shew the strength from 13 gallons in the 100 above proof to 29 gallons in the 100 under proof; and if the weight No. 3. is required, the division on the side marked No. 3. will shew the strength of the spirits from 29 under proof down to water, which is marked W at the bottom of the scale No. 3. The thermometer DE has four scales engraven upon it, marked No. 1, 2, 3, corresponding with the similarly numbered scales on the stem. Two of these scales only are seen in the figure. The zero or 0 of each scale is at the middle of each column, and corresponds with a temperature of 60° of Fahrenheit; then whatever number of divisions the mercury in the thermometer stands above the zero, so many gallons in the 100 must the liquor be reckoned weaker than the hydrometer indicates; and whatever number of divisions the mercury in the thermometer stands below the zero, so many gallons in the 100 must the spirits be reckoned stronger than the hydrometer indicates.

The diminution of bulk occasioned by the mutual penetration of the two fluids, is marked by the small figures on the different scales of the stem. Thus the figures $2\frac{1}{2}$ at 48, $3\frac{1}{2}$ at 61, and 4 at 66, indicate, that if the spirit be 48 gallons in the 100 over proof, the bulk of the compound will be $2\frac{1}{2}$ gallons less than the sums of the two ingredients, that is, instead of being 148 it will be $145\frac{1}{2}$. This instrument is adjusted, like other hydrometers, to the temperature of 60° of Fahrenheit, and requires only three different weights to determine the strength of spirituous liquors from alcohol to water.

### 6. *Dicas's Hydrometer.*

The hydrometer constructed by Mr Dicas of Liverpool, possesses all the advantages of Jones' hydrometer, but exhibits, with more accuracy, the correction which it is necessary to apply for a change of temperature. It is constructed of metal, with a stem and ball of the ordinary form. It has 36 different weights, which are valued from 0 to 370, including the divisions on the stem; but the chief improvement which distinguishes this hydrometer is its ivory sliding scale, which adjusts it to different temperatures, and indicates the diminution of bulk arising from the mutual penetration of the combined fluids.

### 7. *Quin's Universal Hydrometer.*

The object of this hydrometer is to ascertain with the greatest expedition the strength of any spirit from alcohol to water, the diminution of bulk, and the specific gravity of each different strength, and also the specific gravity of worts. In its general appearance, it is nearly the same as Jones' hydrometer, shewn in Fig. 3. The stem has four sides, one of which indicates the strength of any spirit, from alcohol to water, while the other three shew the specific gravities of worts. The stem has a conical form, in order to make the degrees upon it more equal than they would otherwise have been. A sliding rule, differing very little from that of Mr Dicas, exhibits the variations of density arising from changes of temperature. In using this instrument, place any of the weights, if necessary, upon the top of the part of the stem below the ball; observe the temperature of the spirit with a thermometer, and bring the star of the sliding rule to the degree of heat on the thermometric scale; then the strength of the spirit will be found opposite to the number of the weight and the letter on the stem. See a full account of this hydrometer in the *Transactions of the Society of Arts*, vol. viii. p. 98.

### 8. *Nicholson's Hydrometer.*

The hydrometer invented by the late Mr Nicholson, is superior to the ordinary instruments, both in its general construction, and from its being capable of ascertaining the specific gravities of solids. This instrument, which is shewn in Fig. 4. of Plate CCCXIV. consists of a hollow copper ball CD attached to the dish AB by means of a stem AC, made of hardened steel, and about $\frac{1}{40}$th of an inch in diameter. An iron stirrup E, fixed to the lower extremity of the ball, carries another dish F, sufficiently heavy to keep the instrument in a vertical position. The parts of the instrument are so adjusted, that when 1000 grains are placed in the upper dish AB, the whole will sink in distilled water at the temperature of 60° of Fahrenheit, to the point $m$ in the middle of the stem.

In order to find the specific gravity of a fluid, immerse the instrument in it, and place weights in the dish AB till it sinks to the point $m$; then, since the quantity of fluid displaced is always the same, we shall have $W + 1000 : W \pm w = S : s$; W being the weight of the instrument, $w$ the weight necessary to make it sink to $m$, S the specific gravity of water, and $s$ that of the fluid.

To determine the specific gravities of solids that do not exceed 100 grains in weight, place the instrument in distilled water, and, having put the solid in the dish AB, throw weights into the same dish till the instrument sinks to $m$. The sum of the weights added being subtracted from 1000 grains, will obviously be the weight of the solid, which we may call W. Let the solid be now placed in the lower dish F, and weights added in the upper dish AB till the instrument again sinks to $m$. The weights now added, which we may call $w$, will be the loss of weight which the solid sustains, or the weight of an equal bulk of distilled water, consequently $s : S = W : w$. As the cylindrical stem of this instrument is only $\frac{1}{40}$th of an inch in diameter, the instrument will rise or fall nearly one inch by the subtraction or addition of $\frac{1}{10}$th of a grain. It will therefore indicate changes in weight less than $\frac{1}{20}$th of a grain, or $\frac{1}{620000}$th of the whole; which will give the specific gravities correct to five places of figures. See *Manchester Memoirs*, vol. ii. p. 570; and Nicholson's *Natural Philosophy*, vol. ii. p. 16.

### 9. *Atkins' Hydrometer.*

This instrument, which is of brass, consists of an eliptical bulb and stem, with a small loaded bulb below, for keeping it in a vertical position. The total length is 8 inches, the elliptical bulb is $1\frac{1}{2}$ inches in diameter, and 2 inches long, and the square stem is $\frac{1}{8}$th of an inch wide. One of the faces of the scale is used for liquors that are specifically lighter than water. On this face are engraven the 26 letters of the alphabet, with an 0 or zero at the beginning and end of the letters, thus—0, A, B, C, D, &c. Z, 0.

Opposite to each letter, and between each of them, is a division for marking the point of the stem to which the instrument sinks, so that the total number of divisions is 55. The weight of the hydrometer is 400 grains, and it is furnished with four weights, viz. No. 1, 2, 3, 4, which weigh respectively 20, 40, 61, and 84 grains, which are placed on the instrument, below the elliptical bulb, as occasion requires. These weights are adjusted in such a manner, that when with one of them, such as No. 2, the instrument emerges to the lower division 0, it will, upon changing the weight for the next heavier one, No. 3, sink exactly to the other division 0, at the top of the stem. Hence the stem is virtually extended to five times its real length, and the number of divisions increased to 272; thus, without any weight at all, it will sink exactly to the upper division 0 in a liquor whose specific gravity is .806, and to the lower division 0 in a liquor whose specific gravity is .843, the intermediate specific gravities being indicated by intermediate divisions on the scale. By applying the weight No. 1. we obtain all the specific gravities from .843 to .880; No. 2. gives them from .880 to .918; No. 3. from .918 to .958; and No. 4. from .950 to 1.000. When the last weight is used in water, the instrument sinks to the lower 0 at 55 degrees of Fahrenheit. Each of the divisions on the stem will be found to correspond considerably less than an unit in the third place of the specific gravity, and to indicate a difference of about one-half per cent. or two quarts in a hundred gallons. The correction for temperature is obtained from a sliding rule, by an ingenious application of two scales of equal parts to each other; and the diminution of bulk, or penetration as it is called, is obtained by the same rule. The specific gravities, corresponding to the divisions on the stem, are likewise pointed out by the sliding rule.

Mr Atkins afterwards made considerable changes upon this instrument. Instead of making the weights circular, he made them of different figures, viz. round, square, triangular, and pentagonal, so as to prevent any mistake being committed; and he stamps upon the sliding rule, the figure of the weight opposite to every letter in the series to which it belongs. He has also made the form of the great bulb cylindrical, and rounded off at the upper and lower sides; and instead of the alphabetical scale, he has engraven the real specific gravities on the stem of the instrument. A full account of this instrument will be found in Mr Atkins' pamphlet on the *Relation between the Specific Gravities and the Strength of Spirituous Liquors*, Lond. 1803; and in Nicholson's *Journal*, 8vo. vol. ii. p. 276, and vol. iii. p. 50.

### 10. *Guyton's Gravimeter.*

This instrument, which was invented by the late celebrated chemist M. Guyton Morveau, is made of glass, and carries two basins like the hydrometer of Nicholson. The bulb is cylindrical, and is connected with the upper basin by a slender stem, in the middle of which is the fixed point of immersion. The lower basin, which terminates in a point, contains the ballast, and is attached to the cylinder by two branches. The cylinder is 6.85 inches long, and 0.71 in diameter. The upper basin carries an additional constant weight of 115 grains. To this apparatus, M. Guyton has added another piece, which he calls the *Plongeur*, or plunger, which is a ball of glass loaded with mercury, till its total weight may be equal to the additional weight of 115 grains, added to the weight of the volume of water displaced by the plunger. The plunger is always placed in the lower basin when it is used; and it will readily be seen, that the gravimeter will sink to the same mark on the stem, whether it is loaded with the constant weight of 115 grains in the upper basin, or with the plunger in the lower basin.

The object of this instrument is to ascertain, 1st, The specific gravities of solids, whose absolute weight is less than 115 grains; 2d, Of liquids inferior to water in specific gravity; 3d, Of liquids of greater specific gravity than water; 4th, The absolute weight of bodies below 115 grains; and, 5th, The degree of rarefaction and condensation of water in proportion to its bulk, the purity of the water being previously known.

In order to find the specific gravity of any solid by this instrument, place the solid in the upper basin, and add weights till the instrument sink to the fixed point of immersion. Subtract these weights from the constant weight of 115 grains, and the remainder is the absolute weight of the solid. Multiply this by the specific gravity of the fluid, and reserve the product, place the solid in the lower basin, and add weights in the upper basin till the instrument sinks to a fixed point of immersion; and subtracting these additional weights from the additional weights when the body was in the upper basin, the remainder will be the loss of weight by immersion. Divide the reserved product by this loss of weight, and the quotient will be the specific gravity of the solid with regard to distilled water at the standard temperature and pressure.

In order to find the specific gravity of a fluid, immerse the gravimeter in the fluid, and having observed the weight which is necessary to sink it to the fixed point of immersion, add this weight to that of the gravimeter. To the weight required to sink it in distilled water, add also the weight of the gravimeter. Divide the first sum by the second, and the quotient will be the specific gravity of the fluid. See the *Annales de Chimie*, vol. xxi. p. 3; and Nicholson's *Journal*, 4to, vol. i. p. 110.

### 11. *Speer's Hydrometer.*

This instrument consists of a ball and stem, with a counterpoise underneath. The stem is cut into an octagonal form; and upon each of the eight faces of the octagon is engraved a scale of per centages, by the inspection of which the strength of the spirit may be found. The scale upon each of the faces is suited to the temperatures of 35°, 40°, 45°, 50°, 55°, 60°, 65°, and 70°. When the temperature of the spirits is found by the thermometer, their strength must be sought on that face of the octagon which corresponds with the temperature. As the temperature is indicated only to every five degrees, there is an index which performs the office of a weight, for pointing out the effect for intermediate temperatures. The precision of a single degree of the thermometer may also be obtained by four small pins, which are inserted in the holes in the counterpoise below, where they operate as weights of adjustment, and produce the same effect as a variation of temperature. For a full account of this hydrometer, see Speer's *Enquiry into the Causes of the Errors and Irregularities which take place in ascertaining the Strength of Spirituous Liquors by the Hydrometer.* Lond. 1802; *Philosophical Magazine*, vol. xiv. p. 151; and the *Repository of Arts*, 2d series, vol. iii. p. 81.

### 12. *Mr Adie's Statical Hydrometer.*

This hydrometer, which is one of the neatest and most correct instruments that we have seen, was first constructed about the year 1799 by Mr Adie, optical instrument maker in Edinburgh. It is made entirely of brass, and consists of a lever AB $10\frac{1}{2}$ inches long, resting upon a fulcrum C, so that the shorter arm AC is $2\frac{1}{2}$ inches, and the longer one CB 8 inches long. At the extremity A of the shorter arm is suspended a brass ball, whose solid content is $\frac{1}{100}$ of a gallon. This ball is immersed in the fluid which is held in the cylindrical brass jar FG. Two moveable weights *m*, *n*, slide along each arm of the balance. When the temperature of the spirits is found by the thermometer, the weight *m* is set to the corresponding degree upon the thermometric scale AC. The weight *n* is then moved along the other arm CB, till the ball E is in equilibrium in the fluid, which is indicated by the coincidence of the arm CB with the horizontal index *o*, fixed to the bar *b*. The whole of this instrument is nicely packed into a mahogany box 11 inches long and $2\frac{1}{2}$ square, which serves as a stand for the balance.

### 13. *Mr Adie's Sliding Hydrometer.*

The sliding hydrometer, invented by Mr Adie, differs from all other hydrometers, in requiring no weights whatever for its adjustment. It is a floating hydrometer, of the usual form; but instead of being adjusted by weights, the volume of the instrument is increased by drawing out a tube, while its weight is invariable. If the instrument sinks to the fixed point of immersion in distilled water, before the tube is drawn out, it is obvious that in spirituous liquors, it may be made to sink to the same point, merely by drawing out a tube below the principal bulb; for the same effect is thus produced by increasing the volume of the instrument, as if its weight were diminished.

### 14. *Charles's Thermometrical Hydrometer.*

This instrument, which, we believe, has been described for the first time by M. Biot in his *Traité de Physique*, tom. i. p. 414, was invented by M. Charles, to whom experimental philosophy is under great obligations. It is called a thermometrical hydrometer, from its being employed to measure the densities of water at different temperatures. In order to give a very high degree of sensibility to the instrument, M. Charles makes the ball very large, and the stem very small; the augmentation of the ball rendering the absolute effects of the dilatation more considerable, and the smallness of the stem enabling us to measure these dilatations upon a greater scale. The whole instrument, with the basin for holding the weights, weighed in air 90.303 grammes, or 90.4209 when reduced to a vacuum. An account of the results obtained with this instrument will be found in M. Biot's work.

### 15. *Charles's Balance Areometer.*

This hydrometer, which is intended to measure the specific gravities of solids, does not differ very essentially from the hydrometer of Nicholson. It has a contrivance, however, for inverting the lower basin, when the solid whose specific gravity is required is lighter than water. In this case the basin is inverted, and the solid presses upwards against its bottom, and tends to elevate the hydrometer. See Biot's *Traité de Physique*, tom. i. p. 435.

### 16. *Dr Wilson's Hydrometer with Glass Beads.*

The late Dr Wilson, professor of astronomy in the university of Glasgow, proposed to measure the specific gravities of fluids by a series of small glass beads, or hollow balls, differing from each other in specific gravity. When any of the beads are thrown into the fluid, all those that are heavier than the fluid sink to the bottom, while those that are lighter float upon the surface. By holding the vessel either in the warm hand, or near a fire or candle, the fluid will dilate, and one of the glass beads will sink. Hence it follows, that the specific gravity of this bead, which is marked upon it, was either equal to, or a little less than that of the fluid before the heat was applied. If any of the beads should happen to be broken, the specific gravity of the liquor may be determined by the other beads; for the liquor in which No. 4. sinks will also allow No. 2. to sink by heating it a few degrees, so that No. 3. may be dispensed with. Complete sets of these bubbles, with a small treatise pointing out the method of using them, were made by Mr Brown, an artist in Glasgow, and have been pretty generally used by spirit-dealers. In some of these sets, the numbers upon each bead are the number of gallons of proof spirits contained in 100 gallons of the liquor; while in other sets, the number expresses the gallons of water which will make a liquor of that strength, if added to 14 gallons of alcohol.

### 17. *Lovi's Patent Areometrical Beads.*

The patent areometrical beads have been brought to a very high degree of perfection by Mrs Lovi. They are now used by many of the first distillers and practical chemists, and have been honoured with the highest approbation of some of the principal philosophers and chemists in Scotland. The patent beads are fitted up in boxes, containing different quantities, according to the purposes for which they are wanted, and they are always numbered to every two units in the 3d place of specific gravity; for example, 920, 922, 924, &c. If they are required merely for spirituous liquors, thirty beads will be sufficient; but if they are required for all fluids, from ether to the most concentrated sulphuric acid, three hundred at least will be required. As these beads are marked with their respective specific gravities, we have only to throw a parcel of them into the fluid till we find the one that stands in the middle of the liquid without either rising to the top or sinking to the bottom. The number marked upon this bead will indicate the specific gravity of the fluid. The beads are accompanied by a sliding rule and a thermometer for making the corrections for differences of temperature, and for finding the strength of the spirits, in the language of spirit dealers and excise officers. The superiority of this hydrometer to every other instrument with which we are acquainted, is very great. If the ordinary hydrometer meets with any accident, it is incapable of being repaired; but if any of the areometrical beads are broken, they can easily be replaced, and the specific gravity may be determined with sufficient accuracy, if one or even two beads of the series are destroyed.

The areometrical beads have been applied with great success by Mr Hutton to an improved method of ascertaining the quantity of spirituous liquors by weighing instead of measuring them.

"The weight of a very large quantity," says Mr Hutton, "may be ascertained at one operation, in a short time, and comparatively with little trouble. Now, if the weight of a cask be ascertained when empty, and afterwards when filled with spirits, the difference of these weights will be the weight of the spirits the cask contains; and since the specific gravity of spirits is easily found by means of the patent beads, we can thus obtain with the greatest facility both the weight and specific gravity of the spirits; and from these data, it is easy to calculate the quantity which a cask may contain, in terms of any given measure,

| | C. | Qr. | lb. | oz. |
|---|---|---|---|---|
| Thus, suppose that a cask weighs, when empty, . . . . . . | 1 | 3 | 2 | 2 |
| And when filled with spirits, | 12 | 3 | 0 | 0 |
| The difference or weight of the spirits will be . . . . . | 10 | 3 | 25 | 14 |

And suppose that the spirit is of the specific gravity 920, and that it is required to find the number of wine gallons which the cask contains,

We may proceed in this manner:

Since a cubic foot, or 1728 cubic inches, of spirit of this strength weighs 920 ounces, and a wine gallon contains 231 cubic inches; to ascertain the weight of a wine gallon of such spirits we have this proportion:

$$\overset{\text{In.}}{1728} : \overset{\text{Oz.}}{920} : : \overset{\text{In.}}{231} : \overset{\text{Oz.}}{\frac{920 \times 231}{1728}}$$ the weight of a wine gallon of spirits of the specific gravity 920.

And to ascertain the number of wine gallons or quantities of the weight $\frac{920 \times 231}{1728}$ ounces, contained in 10 C. 3 qrs. 25 lb. 14 oz. or 19,678 ounces, we have this proportion:

$$\overset{\text{Oz.}}{\frac{920 \times 231}{1728}} : \overset{\text{Gall.}}{1} : : \overset{\text{Oz.}}{19{,}678} : \overset{\text{Gall.}}{\frac{19\,678}{\frac{920 \times 231}{172.8}}} = \frac{1728 \times 19678}{920 \times 231} = \overset{\text{Gallons.}}{160.}$$

A quantity of spirits, therefore, of the specific gravity 920, and which weighs 10 C. 3 qrs. 25 lb. 14 oz. will measure exactly 160 wine gallons.

It is easy also, the number of wine gallons and specific gravity being given, to calculate the weight. Thus, in the above example, all the alteration that this state of the question would have occasioned, would have been in the second proportion, which would have stood thus:

$$\overset{\text{Gall.}}{1} : \overset{\text{Oz.}}{\frac{920 \times 231}{1728}} : : \overset{\text{Gall.}}{160} : \overset{\text{Oz.}}{\frac{160 \times 920 \times 231}{1728}} = \overset{\text{C.}}{10} \quad \overset{\text{Qr.}}{3} \quad \overset{\text{lb.}}{25} \quad \overset{\text{oz.}}{14}$$

In this manner Mr Hutton has calculated a series of tables for giving the quantity of spirits by inspection. At the top, in the centre, is the specific gravity of the spirits, commencing at 906, and ending with 934, and embracing the different specific gravities at which spirits are usually met with in commerce. On the right of the number denoting the specific gravity, and on the same line with it, is the approximate weight of one gallon of spirits of that specific gravity, expressed in pounds and ounces. The tables consist of two sets of columns; one contains the number of gallons, and the other their weight: they begin with 30 gallons, being the smallest quantity it is considered necessary to weigh, and increasing by single gallons, they extend to 185 gallons, being the contents of the largest cask used in trade.

### 18. *Dr Brewster's Capillary Hydrometer.*

This instrument is founded upon a principle which was never before employed in hydrometrical measurements. It is well known that alcohol is a much more perfect fluid than water, possessing much less viscidity, in consequence of the small force of cohesion which exists between its particles. Hence it follows, that if a vessel containing alcohol is emptied through a capillary tube, so as to discharge the fluid only by drops, the drops will be much smaller, and consequently much more numerous, than when the same vessel is filled with water and emptied through the same tube. The capillary hydrometer, which is founded on this principle, is represented in Fig. 6. where ABC is a glass vessel three, or four, or five inches long, having a hollow bulb B about half an inch or an inch in diameter. This instrument is filled by suction at the lower end C, and the water is discharged at C till it stands nearly at the point $m$, the zero of the scale. By removing the finger from the lower end C, the water is discharged by drops, and the number of drops which fall till the fluid descends to another fixed point $n$ are accurately counted. This experiment is carefully repeated at different temperatures, so that the number of drops of distilled water contained in the vessel between the points $m$ and $n$ is known for various temperatures. Hence, if N is the number of drops of water whose specific gravity is S, and $n$ the number of drops of alcohol whose specific gravity is $s$, and $d$ the number of drops given by any other mixture of alcohol and water, then $n - \text{N} : \text{S} - s = d - \text{N} : \frac{(d-\text{N})(\text{S}-s)}{n-\text{N}}$, and therefore $\text{S} - \frac{(d-\text{N})(\text{S}-s)}{n-\text{N}}$ will be the specific gravity of the mixture required. The same experiment is made with the purest alcohol, and the number of drops carefully marked. With an instrument of this kind, the number of drops necessary to empty it when filled with water was 724, whereas, when it was filled with ordinary proof spirits, the number of drops amounted to 2117. This experiment, which was performed rudely, for the purpose of obtaining a general idea of the magnitude of the scale, was made nearly at the temperature of 60°. Now as the specific gravity of the spirit was about .920, and that of water 1.000, we have in the present case no less than a scale of 1393 drops for measuring specific gravities between .920 and 1.000: that is, a variation in the fifth figure, or in the fourth place of decimals of the specific gravity, nearly corresponds with a variation of two drops. With another instrument made on a very small scale, the number of drops amounted to 47 with water and 122 with spirit, whose specific gravity was 928. As this instrument was too large, I was obliged to incline it, in order to prevent the fluid from issuing in a continued stream. In the first experiment, N = 724, $n$ = 2117, S = 1.000, $s$ = 920. Hence if $d$ = 1500, we have $\text{S} - \frac{(d-\text{N})\ (\text{S}-s)}{\text{N}-n} =$ $\frac{1.000 - 776 \times 0.080}{1393} = .9555.$

The bulk of a drop of water will be about 2.93 times as large as the bulk of a drop of the spirit used in the first experiment. In the 2d experiment, the drop of water was 2.6 times greater than the drop of the spirit. See Chapter V. p. 473 of this article.

### 19. *Sikes' Hydrometer.*

As this hydrometer is now universally used in the collection of the revenue in both kingdoms, we shall lay before our readers a drawing and description of it, although it does not differ much in principle from the ordinary hydrometers. It is represented in Plate CCCXIV. Fig. 7. where AB is a flat stem 3.4 inches long, which is divided on both sides into 11 equal parts, each of which is subdivided into 2, the scale being numbered from 0 to 11. This stem is soldered into a brass ball 1.6 inch in diameter, into which is fixed a small conical stem CD, 1.13 inch long, at the end of which is a pear-shaped loaded bulb DE, half an inch in diameter. The whole instrument, which is made of brass, is 6.7 inches long. The instrument is accompanied with 8 circular weights, numbered 10, 20, 30, 40, 50, 60, 70, 80, and another weight of the form of a parallelopiped. Each of the circular weights are cut into their centre, so that they can be placed on the conical stem C, and slide down to D; but in consequence of the enlargement of the cone they cannot slip off at D, but must be brought up to C for this purpose. The square weight, of the form of a parallelopiped, has a square notch in one of its sides, by which it can be placed upon the summit A of the stem. In using this instrument, it is immersed in the spirit, and pressed down by the hand to 0, till the whole divided part of the stem be wet. The force of the hand required to sink it will be a guide in selecting the proper weight. Having taken one of the circular weights which is necessary for this purpose, it is slipped on the conical stem at C. The instrument is again immersed and pressed down as before to 0, and is then allowed to rise and settle at any point of the scale. The eye is then brought to the level of the surface of the spirit, and the part of the stem cut by the surface, *as seen from below*, is marked. The number thus indicated by the stem is added to the number of the weight employed, and with this sum at the side, and the temperature of the spirits at the top, the strength per cent. is found in a Table of six quarto pages. "The strength is expressed in numbers denoting the excess or deficiency per cent. of proof spirit in any sample; and the number itself (having its decimal point removed two places to the left) becomes a factor whereby the gauged content of a cask or vessel of such spirit being multiplied, and the product being added to the gauged content if over-proof, or deducted from it if under proof, the result will be the actual quantity of proof spirit contained in such cask or vessel."

The instrument is also accompanied with three sliding rules made of boxwood, which may be used instead of the Table. "The officers of excise are directed to estimate the temperature by the nearest degree *above* the surface of the mercury, when it stands between any two degrees of the thermometer, and the indication or (numbers on the stem) by the nearest division *below* the surface of the sample, when its level cuts the stem of the hydrometer between one division and another; thus giving the difference in favour of the trader in both cases. The square weight or cap shews the difference between the weight of proof spirit and that of water, as described in the first clause of the hydrometer act, and being one-twelfth part of the total weight of the hydrometer and weight 60. If this weight is placed upon the top of the stem at A, and if the hydrometer is loaded with weight No. 6, it will sink in distilled water at the temperature of 51° to the proof Point P, at that temperature, as marked on the narrow edge of the stem."

### 20. *On the Hydrostatic Balance.*

Although the hydrostatic balance can scarcely be called a hydrometer, yet as it is employed for measuring specific gravities when great accuracy is required, we shall give a description of it in this place. The hydrostatic balance, of which we have given a front and a side view in Figs. 8. and 9, of Plate CCCXIV. Figs. 8, 9. is nothing more than a good balance, with some additional apparatus for enabling it to measure specific gravities with accuracy and expedition. The support of the balance is a pillar AB, fixed into a stand or base CD. By a silken string P*pe*, Fig. 9, attached to a screw S, and passing over the pullies P, *p*, is suspended the balance by means of the horizontal arm EF, on which the hook *e* is hung: *af*, *fb*, are the arms of the balance, *ef* its tongue, *c d*, the scales, and *m n* a slender curved rest, which prevents any of the arms from descending too far on either side. By means of the screw S, a vertical ascent or descent of the balance can be obtained; but when it is necessary to raise it much higher or lower, the whole sliding-piece into which the screw S is fixed, may be moved either forward or backward in a groove, or upon a brass rod placed upon the stand CD. A board GH is fixed upon the projecting arm L beneath the two scales, and being moveable up and down in a groove, it can be fixed in any position by a screw. In the middle of the lower surface of each scale is fixed a hook, to which are suspended brass wires *c k*, *d g*, which pass freely through two openings in the board GH. To the wire *c k* is suspended a cylindrical wire K *k*, about 5 inches long, perforated at each end, and covered with paper, containing a scale of equal parts. A brass tube MN is fixed on the corner of the board GH, on which a wire MN is made to move. On the lower part of the wire moves another tube W, carrying an index NO, which can be moved either horizontally by turning round the tube, or vertically by pushing it up or down; so that the index MN can be made to point to any division on the scale K *k*. A weight *k* is suspended to the wire K *k*, to which is fixed the wire *k l*, (of such a size that one inch of it will weigh about 4 grains,) with a small brass ball *l* about ¼ of an inch in diameter. A large glass bubble *h*, is in like manner suspended by a horse hair to the wire *dg*. The length of these wires is such, that the ball *l*, and the bubble *h*, hang about the middle of the cylindrical glass vessels X, Y, in the ordinary position of the balance. Since brass is nearly eight times heavier than water, it is evident, that for every inch that the wire *k l* sinks in the water in the vessel X, it will become half a grain lighter, and for every inch that it rises out of the water it will become half a grain heavier: consequently if it sinks 2 inches below its middle point $x$, or rises two inches above it, the wire will become one grain lighter or heavier. Let the middle point $x$, therefore, be brought to the surface of the water, and the index NO set to the middle of the scale K *k*, and let the distances OK, O *k* be each divided into 100 parts, then if it is required to weigh bodies to the accuracy of the 100th part of a grain, it may be done in the following manner. Let the body to be weighed be placed in the scale *c*, and let its weight be between 52 and 53 grains, as determined by the weights in the opposite scale, then if we move the balance gently up and down by the screw S, till the tongue of the balance *ef* indicates a perfect equilibrium, the distance of the index NO from *k*, as measured upon the scale, will indicate the number of hundredth parts of a grain which the real weight of the body is above 52, or below 53, according as either of these weights is placed in the scale *d*. If 52 be the weight in the scale *d*, then since the weight of the body in the scale *c* exceeds 52, the scale *c* will preponderate, and the balance being let down until the equilibrium is restored by the loss of weight sustained by the immersed wire *k l*, the index NO will rise as it were from the middle part of K *k*. Hence if it points to 12 divisions above the middle of K *k*, the weight of the body will be 52.12 grains. Had the weight 53 been placed in the scale, it would have been necessary to raise the balance, so that the scale *c* might acquire an equilibrium with 53 grains, by an addition to the weight of the wire *k l* in consequence of its ascent from the water. In this case, the index NO would have pointed to division 88 below the middle point of the scale, and the weight of the body would have been $53.00 - 0.88 = 52.12$, as before.

The weight of the body in air being thus obtained with the utmost accuracy, it is next to be suspended to the hook g by means of the horse hair, and weighed when immersed in the water in the jar Y. The difference between these two weights, when they have been corrected by the methods formerly described,* will lead to an accurate determination of the specific gravity of the body. The wire *k l* should always be oiled, and the oil wiped off, so that a thin film may adhere to it, in order to prevent the adhesion of the water.

Sect. II. *On the Table of Specific Gravities.*

The determination of the specific gravities of bodies is of the greatest use, not only in many of the sciences, but also in most of the practical arts of life. Hence it has been the object of philosophers to determine, with all the accuracy in their power, the specific gravities of the various solid and fluid substances which occur in nature. The following Table, which we have collected with great labour from the tables of Brisson and other sources, contains the most important specific gravities that have been determined. All the measures are related to that of water, whose specific gravity is 1.000, excepting the gases or aëriform bodies, whose specific gravities are determined in relation to that of atmospheric air, which is taken at 1.00. The bodies are arranged in an alphabetical order, for the sake of more easy reference.

* The specific gravities of the gases are taken from Biot's *Traité de Physique*, tom. i. p. 383; from Gay Lussac's Table in the *Annales de Chimie et de Physique*, vol. i. p. 218; and from Thomson's *Annals of Philosophy*, vol. i. p. 118. The measures for the gases, taken by M. M. Biot and Arago, are calculated from Biot's formulæ, which we have given in p. 432, 433 of this article. They are given in relation to atmospheric air which is supposed to be unity. Their relation to water is easily computed.

## CHAP. IV.

### On the Equilibrium and Stability of Floating Bodies.

We have already seen, (Chap. II. Prop. I. p. 429,) that when a body is in equilibrium in a fluid, its weight is always equal to that of the fluid displaced; and that the centre of gravity of the floating body when homogeneous, must be situated in the same vertical line with the centre of gravity of the part submersed, or of the fluid displaced, Prop. II. p. 430. From the equality between the weight of the body and that of the displaced fluid, the upward pressure of the fluid is exactly capable of balancing the downward tendency of the body; but unless these two forces are directly opposed to each other by passing through the same point, the solid body will have a rotatory motion, instead of a position of perfect equilibrium. In order, therefore, to determine the positions in which a body will float permanently on the surface of a fluid, we have only, after the specific gravity of the body has been ascertained, to discover in what positions the solid can be placed, in order that the centre of gravity of the solid and of the part immersed may be in the same vertical line. The solid, however, will not float permanently in every case, when these centres of gravity are situated in the same vertical line; for there are examples, in which the body cannot remain in this position of equilibrium, but will actually assume another, in which it will continue to float permanently. Mr Atwood has illustrated this by the case of a cylinder, whose specific gravity is to that of the fluid on which it floats as 3 to 4, and whose axis is to the diameter of its base as 2 to 1. When the cylinder which we suppose to be 2 feet long, and its base 1 foot in diameter, is held in the fluid, with its axis in a vertical line, it will sink to a depth of $1\frac{1}{2}$ feet: but as soon as it ceases to be supported, it instantly oversets, and remains floating with its axis horizontal. If the cylinder, instead of being 2 feet long is only 6 inches, or one-half the diameter of its base, it will sink to the depth of $\frac{3}{8}$ths of its diameter, or $4\frac{1}{2}$ inches, and will float permanently in that position. In this last case, if the axis of the cylinder is not exactly in a vertical line, but a little inclined to it, the cylinder will still settle permanently with its axis in a vertical line.

Hence it is obvious, that there are different kinds of equilibrium.

1st, The *equilibrium of stability*, or that which is exhibited in the short cylinder 6 inches long, which floats permanently in a given position.

2d, The *equilibrium of instability*, or that which is exhibited in the cylinder 2 feet long, which oversets, although the centre of gravity of the solid and that of the part immersed are in the same vertical line. In this case the equilibrium is as perfect as in the first case; for while the centres of gravity are in the same vertical line, the solid must continue erect; but the slightest deviation of the centres of gravity from that line creates a rotatory motion, from which the solid necessarily oversets.

3d, The *equilibrium of indifference*, or the insensible equilibrium in which the solid floats indifferent to motion, and without any tendency to recover its position when inclined from it, or to incline itself farther. The equilibrium of indifference takes place, when the proportion between the axis of the cylinder and the diameter of its base is greater than 1 to 2, and less than 2 to 1. This kind of equilibrium is exhibited in a homogeneous sphere, or in a homogeneous cylinder, floating with its axis horizontal.

If a solid floats permanently on a fluid surface, and if it is moved from its position of equilibrium by any external force, the resistance which the solid opposes to this inclination is called the *stability of floating*; and the horizontal line round which it moves is called the *axis of motion*.

It would be impossible in a work like this, to enter at great length into a subject so difficult and profound as the present. We shall, therefore, content ourselves with stating the general principles relative to the stability of floating bodies, and with investigating the different positions of stability and instability which they assume; and in doing this shall freely avail ourselves of the labours of Mr Atwood, whose papers on the stability of floating bodies are remarkable for their perspicuity. In arranging, abridging, and sometimes simplifying his demonstrations, we trust we shall do an important service to the reader.

### Prop. I.

To determine the stability of bodies floating on a fluid at any angle of inclination from a given position of equilibrium.

Let EDHF be a vertical section through the centre of gravity G, of a homogeneous solid, whose figure is symmetrical with regard to the axis of motion, and let it float on the surface HABL of the fluid, O being the centre of gravity of the part immersed. Plate CCCXV. Fig. 1. The line GOC will therefore be perpendicular to AB. If by an external force the solid is inclined through an angle KGS, the solid will take the position IRLMN, and the part immersed will now be WRMNP. Hence, as the part XWI is raised out of the water, and the corresponding and equal part XNP immersed, the centre of gravity which would otherwise have been at E (taken so that GO = GE) will now be transfered to some other point Q. Having drawn QS parallel to GO, and EY and ZG$z$ perpendicular to SQ, it is obvious that the upward pressure of the fluid will be exerted in the line QS, with a force equal to the weight of the body, or that of the fluid displaced, and this force will have the same tendency to turn the body round its axis of motion, as if it were applied at the point Z. In determining, therefore, the position which bodies assume on a fluid surface, and the stability with which they float, it is necessary only to find the perpendicular distances GZ, between the two vertical lines which pass through the centre of gravity of the solid and the part immersed.

Since the weight of the body continues the same, the portion IXW, elevated from the fluid in consequence of the inclination, must always be equal to the portion PXN which is immersed. Hence, supposing $a$ to be the centre of gravity of IXW, and $f$ that of NXP, then the centre of gravity Q will be at a distance from E, corresponding to the change produced, by removing the fluid IWX to the position NXP. In order to determine, by a geometrical construction, the line, GZ, let fall the perpendiculars $a\,b$, $f\,c$, and in the line EY drawn parallel to AB, take ET, so that ET : $b\,c$ = volume IWX : volume WRMP. Through T draw FTS parallel to GO, then the centre of gravity required will be somewhere in FS, and because ER : EG = sin. KGS : rad. the line GO = EG being supposed given, the line ER will be determined, and being taken from ET already found, will leave RT or GZ the perpendicular distance required.

Now, when one body of a system is removed from its place, the corresponding motion of the common centre of gravity, estimated in any given direction, is to the motion of the body moved and estimated in the same direction as the weight of that body is to the weight of the whole system. Hence, considering IRMN as a system of bodies whose common centre of gravity is E, and that the body IWX, whose centre of gravity is $a$, has moved, or been transferred to NXP, whose centre of gravity is $f$, we shall have volume WRMP or ADHB : volume IWX or WXP = $b\,c$ : ET, the motion of one body, the motion of the centre of gravity of the system. Calling, therefore,

- V = volume of the part of the floating body immersed,
- A = the volume NXP, or the part immersed in consequence of the inclination,
- $h$ = GO the distance between the centre of gravity of the whole solid and that of the part immersed,
- $s$ = sine of the angle of inclination KGS,
- $b$ = $b\,c$ the space through which A has been transferred.

Then, by the proposition $b : \mathrm{ET} = \mathrm{V} : \mathrm{A}$, and $\mathrm{ET} = \frac{b \times \mathrm{A}}{\mathrm{V}}$. But ER : EG or GO = $s$ : 1, we have ER = $h\,s$; consequently, RT=ET—ER, or $\mathrm{GZ} = \frac{b\,\mathrm{A}}{\mathrm{V}} - h\,s$.

If the floating solid should be of an irregular form, the same demonstration will hold good; but we must, in this case, consider that the volume or space immersed by the inclination will no longer be WXP, but a space which must be obtained by calculation from the shape and dimensions of that volume. The centres of gravity of the volumes PXN, IXW, will in that case be no longer $a$ and $f$ the centres of gravity of the areas, but must be found by the usual rules. This proposition is applicable either to homogeneous or heterogeneous bodies, and enables us to determine the stability of vessels or other bodies, at any angle of inclination from a given position of equilibrium; for the stability is measured by a force equal to the upward pressure of the fluid, or the weight of the loaded vessel applied perpendicularly at the end of the lever GZ moving round the axis of motion.

### Prop. II.

To ascertain the different positions of equilibrium in which a body will float permanently on the surface of a fluid, and to discover in which of these positions the equilibrium is permanent or stable, and in which of them it is momentary or instable.

In order to do this, we must attend to the species of equilibrium in which the solid is placed previous to its being inclined from it. Assuming that the body is in a state of stable equilibrium, let it be inclined through an angle till it is again placed in a position of equilibrium. Then since during this inclination the upward pressure of the fluid acts with a force proportional to GZ to diminish the angular distance from the primitive position of equilibrium, it follows that the same force must act on the solid, so as to increase the inclination or angular distance from the second position of equilibrium to which the body arrives after revolving through the angle A, or any part of it. Hence it is obvious, that the second position of equilibrium must be that of instability, and, in general, that when a floating body is caused by an external force to revolve round its axis of motion, and pass through different positions of equilibrium, the positions of stability and instability must alternate, and no position of either species can follow a position of the same species.

In determining, therefore, the position which a solid will assume, after it has been overset from any situation of instable equilibrium, we must ascertain the angle of inclination through which the solid must revolve, so that the distance GZ may become evanescent, and we must also determine whether any position of equilibrium originally given is stable or instable. This may easily be done from the value of GZ already given; for if we take any point $t$ in the line ER, and through $t$ draw $q\,t\,z$ parallel to GO, then it is obvious,

1. That while $\frac{b\,\mathrm{A}}{\mathrm{V}} = \mathrm{ET}$ is *greater* than $h\,s$ = ER, the part Z and the line of support QZ, will be between the axis and the parts of the solid immersed in consequence of the inclination, which gives a *stable equilibrium*.

2. That while $\frac{b\,\mathrm{A}}{\mathrm{V}} = \mathrm{ET}$ is *less* than $h\,s$ = ER, the part $q$ and the line of support $q\,z$ will be on the opposite

side of the axis, and will give an *instable equilibrium.* Hence we can always determine, from the value of GZ, what is the particular kind of equilibrium with which the body will float when the angle of inclination, and consequently its sine, are assumed to be evanescent.

### Prop. III.

To find an expression for the stability or instability of floating, when the floating solid is not of an uniform figure and dimensions with respect to its axis of motion.

Let us suppose in Fig. 1. that another section of the solid is drawn parallel to ADHB, and very near it. A small portion of the solid will be comprehended between these planes; now, since the sine $s$ of the angle KGS is evanescent, and since WXP=IXW, and the angle NXP=the angle IXW, the point X will bisect the line AB, and the points P, B, N will be coincident. Hence, the evanescent area $NXP = \frac{XB^2 \times s}{2} = \frac{AB^2 \times s}{8}$; and if we represent by $z$ a line drawn through the middle of the solid, on a level with the surface of the fluid, and parallel to the larger axis, the evanescent portion of the solid comprehended between the adjacent vertical planes ADHB, and the one supposed extremely near it, will be $\frac{AB^2 \times s}{8} \times dz$; the perpendicular distance of the centre of gravity of this evanescent solid from the point X is $\frac{AB}{3}$. In order to find the distance from X of the centre of gravity of the whole volume immersed by the inclination, or the common centre of gravity of the elementary solids $\frac{AB^2 \times sdz}{8}$ corresponding to the length $z$, we must multiply each elementary solid by the distance of its centre of gravity from the horizontal line passing through X, and divide the sum of these products by the sum of the elementary solids. Hence, in the present case, since the distance from X of the centre of gravity of the elementary solid is $\frac{AB}{3}$, the product arising from multiplying the distance by the solid itself will be $\frac{AB^3 \times sdz}{24}$, and the sum of the products corresponding to the whole line $z$ will be fluent of $\frac{AB^3 \times sdz}{24}$; and since A represents the volume of the part immersed by inclination, and also of the part elevated by inclination, the distance of the centre of gravity of the immersed part or $c$ X, also of the part elevated, or $b$ X, will be fluent of $\frac{AB^3 \times sdz}{24A}$, and the distance between the two centres of gravity in the line $b\,c$ will be twice this quantity, or fluent of $\frac{AB^3 \times sdz}{12A}$. Substituting this value for $b$ in the general equation, we have $GZ =$ fluent of $\frac{AB^3 \times s\,d\,z}{12\,V} - h\,s$, which is the general expression required.

Now it follows, 1. That if the first member of this equation, viz. fluent of $\frac{AB^3 \times s\,d\,z}{12\,V}$, is greater than the second $h\,s$, the line of support QZ will be between the axis of motion and the part immersed by inclination, and the solid will float permanently; and, 2. That if the first member is less than the second, the line of support $q\,z$ will be on the contrary side of the axis, and the body will overset. Hence it is obvious, that between these limits, we must have the equilibrium of indifference which takes place when fluent of $\frac{AB^3 \times s\,d\,z}{12\,V} = h\,s$.

If the solid has an uniform figure and dimensions, then putting D for the area of any of the sections immersed under the fluid, the solid contents of the volume immersed will be D$z$, hence V=D$z$; and since AB is now a constant quantity, we have fluent of $\frac{AB^3 \times sdz}{12Dz} = \frac{AB^3 \times s\,z}{12Dz} = \frac{AB^3 \times s}{12\,D}$, consequently $GZ = \frac{AB^3 \times s}{12\,D} - h\,s$.

### Prop. IV. Prob.

To determine the limits of stability and instability in a parallelopiped depending on the dimensions and specific gravity of the solid.

In applying the preceding expressions to a parallelopiped, let EFDC be its vertical section, with its flat surface EF upwards, and IK the surface of the fluid. Through its centre of gravity G draw SGL parallel to CE, and let us take

$c =$ CE

$a =$ CD

$n =$ specific gravity of the solid, or $n : 1 =$ SN : SL. Fig. 2. Then if O be the centre of gravity of the part immersed, and since $n : 1 =$ SN : SL, or CL, we have SN$=$ $nc$; $GO = \frac{c}{2} - \frac{n\,c}{2}$, and ABCD $= a\,c\,n$. Substituting these values in the general expression already found, we have $GZ = \frac{a^3\,s}{12\,acn} - \frac{s \times \overline{c - nc}}{2}$; and since the equilibrium is one of indifference, when the first member of the expression is equal to the second, or when $\frac{a^3\,s}{12\,acn} = \frac{s \times \overline{c - n\,c}}{2}$, we have, by the resolution of this quadratic equation, $n^2 - n = -\frac{a^2\,s}{6\,c^2}$, and

$$n = \tfrac{1}{2} \pm \sqrt{\tfrac{1}{1} - \frac{a^2}{6\,c^2}}.$$

*Cor.* 1. From this proposition, we may infer, that whenever $\frac{a^2}{6\,c^2}$ is less than $\frac{1}{4}$, or when the height $c$ of the solid has a greater proportion to the base than that of $\sqrt{2}$ to $\sqrt{3}$, two values may be assigned to the specific gravity of the solid, which will cause it to float in the equilibrium of indifference. If, for example, $c=a$, we have $n = \frac{1}{2} \pm \sqrt{\frac{1}{4} - \frac{1}{6}}$, which gives

$$n = \tfrac{1}{2} + 0.28868 = 0.78868$$
$$n = \tfrac{1}{2} - 0.28868 = 0.21132.$$

*Cor.* 2. If the specific gravity of the solid is very small compared with that of the fluid, the term $\frac{a^3\,s}{12\,a\,c\,n}$ must be greater than $\frac{s \times \overline{c - c\,n}}{2}$, and the solid will float permanently with the line EF parallel to the horizon.

*Cor.* 3. If the specific gravity of the solid is increased beyond .21132, then, since this is the limit at which it ceases to float with stability, if it is placed with its flat surface upward, its equilibrium will be instable, and it will therefore assume a position of permanent equilibrium. By increasing the specific gravity from .21132 to .78868, the instability increases at first, and reaches its maximum, when $n = \frac{1}{\sqrt{6}}$; it then diminishes and vanishes at the second limit, when $n = .78868$. When $n$ is between .78868 and 1, the body will float permanently with its flat surface EF horizontal. The maximum of instability is found by putting the least increment of the quantity $\frac{a^3 s}{12\,acn} - \frac{s \times \overline{c - c\,n}}{2} = 0$, considering $n$ as variable, and making $a = c$.

*Cor.* 4. If the height SL of the parallelopiped is in a less proportion to its base CD than that of $\sqrt{2}$ to $\sqrt{3}$, there is no value of $n$ at which the stability will vanish; for in this case the quantity $\sqrt{\tfrac{1}{4} - \frac{a2}{6\,c2}}$ become impossible. The solid will therefore always float permanently with its surface EF horizontal.

PROP. V.

To determine the limits of stability and instability of a square parallelopiped, when one of its diagonals is in a vertical position.

Let EDCF be a vertical section of the parallelopiped floating on the surface AB of the fluid, and let G, as formerly, be the centre of gravity of the solid O, that of the part immersed, and $n$ the specific gravity of the solid. Fig. 3. Then if DC $= a$, we shall have GC $= \frac{a}{\sqrt{2}}$. But since HB=HC, we have ABC=HB$^2$; and since ABC : DEFC $= n : 1$, we have ABC $= a^2 n$, HB$^2$ $= a^2 n$, HC $= a \times \sqrt{n}$; AB$=2a\sqrt{n}$; OC $= \frac{2a\sqrt{n}}{3}$

and GO $= \frac{a}{\sqrt{2}} - \frac{2a\sqrt{n}}{3} = \frac{a \times 3 - \sqrt{8n}}{\sqrt{2} \times 3}$

If we now apply the general expression GZ $= \frac{\text{AB}^3 \times s}{12\,\text{D}} - h\,s$ to the present case, we shall obtain AB$^3 =$ $8\,a^3\,n^{\frac{3}{2}}$; D $= a^2\,n$; $h = \frac{a \times 3 - \sqrt{8\,n}}{\sqrt{2} \times 3}$, and consequently

GZ $= \frac{8\,a^3\,n^{\frac{3}{2}}\,s}{12\,a^2\,n} - \frac{a \times 3 - \sqrt{8\,n}}{\sqrt{2} \times 3}$. In order, therefore, to obtain the limit between the stability and instability of floating, we must make $\frac{\text{AB}^3 \times s}{12\,\text{D}} = h\,s$, as in Prop. IV. or making $\frac{8\,a^3\,n^{\frac{3}{2}}}{12\,a^2\,n} = \frac{a \times 3 - \sqrt{8\,n}}{\sqrt{2} \times 3}$, we shall have $\tfrac{2}{3}\sqrt{n} = \frac{3 - \sqrt{8\,n}}{\sqrt{2} \times 3}$ or $n = \tfrac{9}{32} = .28125$, the specific gravity at which the equilibrium of indifference begins, or the limit between the specific gravities at which the solid will float with stability and instability.

*Cor.* 1. It follows from the value of GZ given above, that when $n$ is evanescent, or extremely small, the solid will overset when placed on the fluid with the angle uppermost; for the first term of the value of GZ must necessarily be less than the second.

*Cor.* 2. If $n : 1 = 9 : 32$ the solid will float with the equilibrium of indifference; and therefore if $n : 1$ in a less ratio than that of 9 to 32, the solid will overset; but if $n$ exceeds that limit, then the solid will float permanently, with the angle E uppermost.

PROP. VI.

To determine the limit of stability and instability in a square parallelopiped with one of its angles upwards, when its specific gravity is greater than one half of the specific gravity of the fluid.

Let EDCF, Plate CCCXV. Fig. 5. be the square parallelopiped, which having a greater specific gravity than $\frac{1}{2}$, that of the fluid will sink so that the diagonal FD is below the surface of the water IK. Using the same symbols as in the last proposition, we have the area ABDCFA $= a^2\,n$, and the area EAB $=$ EH$^2$ $= a^2 - a^2\,n$, and consequently EH $= a\sqrt{1-n}$, and AB $= 2$ EH $= 2\,a\sqrt{1-n}$, and GH $= a \times \overline{\frac{1}{\sqrt{2}} - \sqrt{1-n}}$. Now if P be the centre of gravity of the area AEB, then from the property of the centre of gravity we have GH $\times$ area EDCF $=$ area ABDCFA $\times$ OH $-$ area AEB $\times$ HP, or $a^3 \times \overline{\frac{1}{\sqrt{2}} - \sqrt{1-n}} = a^2\,n \times \text{OH} - a^3 \times \frac{\overline{1-n}^{\frac{3}{2}}}{3}$, and by reduction

$$\text{HO} = \frac{a \times 3 - \sqrt{18} \times \sqrt{1-n} + a \times \sqrt{2} \times \overline{1-n}^{\frac{3}{2}}}{\sqrt{18} \times n}$$

Subtracting from this expression the value of HG $= a \times \overline{\frac{1}{\sqrt{2}} - \sqrt{1-n}} = \frac{3n - \sqrt{18\,n^2} \times \sqrt{1-n}}{\sqrt{18} \times n}$, we shall have the line

$$\text{GO} = \frac{a \times 3 - 3n\ \sqrt{18} \times \overline{1-n}^{\frac{3}{2}} \times \sqrt{2} \times \overline{1-n}^{\frac{3}{2}}}{\sqrt{18} \times n}$$

By inserting these values in the general formula GZ $= \frac{\text{AB}^3 s}{12\,\text{D}} - h\,s$, we have AB$^3$ $= 8\,a^3 \times \overline{1-n}^{\frac{3}{2}}$; D $= a^2\,n$, and since GO $= d$ we obtain GZ $= \frac{8\,a^3 \times \overline{1-n}^{\frac{3}{2}}}{12\,a^2\,n} - \frac{a \times 3 - 3n - \sqrt{18} \times \overline{1-n}^{\frac{3}{2}} + \sqrt{2} \times \overline{1-n}^{\frac{3}{2}}}{\sqrt{18} \times n}$. This value of GZ being put $= 0$ to obtain the limit, and the whole being multiplied by $\frac{3\,n \times \sqrt{2}}{\overline{1-n} \times a}$ we shall have

$$2\sqrt{2} \times \sqrt{1-n} = 3 - 3\sqrt{2} \times \sqrt{1-n} \times \sqrt{2} \times \sqrt{1-n}$$

or $\sqrt{1-n} = \frac{3}{4\sqrt{2}}$, and $1 - n = \frac{9}{32}$ and $n = \frac{23}{32}$ the limit required.

*Cor.* Hence from this, and the preceding propositions, we have the four limiting values of the specific gravities, viz. $\frac{1}{2} - \sqrt{\frac{1}{4} - \frac{1}{6}}$; $\frac{9}{32}$; $\frac{23}{32}$ and $\frac{1}{2} + \sqrt{\frac{1}{4} - \frac{1}{6}}$, or .211, .281, .718, and .789; that is, if the specific gravity is less than 211, the parallelopiped, with its flat surface upward and horizontal, will float permanently in that position, but will overset if the specific gravity is greater than .211 and less than .789. If the parallelopiped has one of its angles upward, when the specific gravity is less than .281, it will overset; if greater than .281, and less than .718, it will float permanently with an angle upward; but if the specific gravity exceeds .718, it will overset when placed in the fluid with an angle upward.

### Prop. VII.

If the parallelopiped is placed in the fluid in a position of instable equilibrium, so as to overset or change its position, it is required to ascertain the position which it will assume when it continues to float permanently; or to ascertain through what angle the solid will revolve, till its centre of gravity and the centre of gravity of the part immersed are again in the same vertical line.

Let EFDC, Fig. 5. be the vertical section of the parallelopiped when in its position of instable equilibrium; IK the surface of the water; G its centre of gravity; O the centre of gravity of the part immersed. Let the solid, after oversetting, have revolved through an angle UGS into the position YWVH, the part immersed will now be ZHVR, and QXR will be the part now immersed in consequence of the inclination. Bisect PZ and RQ in $m$ and $n$, join $m$ X, $n$ X, and taking X $a = \frac{2}{3}$ X $m$, and X $f = \frac{2}{3}$ X $n$, $a$ and $f$ will be the centres of gravity of the triangles PXZ, and QXK. Let fall the perpendiculars $a\,b$, $f\,c$ upon the line AB. In applying the general equation $GZ = \frac{b\,a}{V} - f\,s$ to the present case, we have QXR = A; ZHVR or ACDB = V; $b\,c = b$; OG $= f$; sine of UGO $= s$. Make $t$ equal the tangent of the angle UGO. Then from the similarity of triangles QX = XP; ZP = QR; ZX = XR. Making SL $= c$, and VU or XQ $= a$: then QR $= a\,t$; and Q $n = \frac{a\,t}{2}$; X $n = \sqrt{a^2 + \frac{t^2 a^2}{a}} = \frac{a}{2}\sqrt{4 + t^2}$. Now, since R $n$ or Q $n$ : X $n$ = sin. $n$ XR$n$, we have $\frac{t\,a}{2} : \frac{a}{2} \times \sqrt{4 + t^2} =$ sin. $n$ XR : sin. XR $n$, consequently sin. $n$ XR $= \frac{\text{Sin.}\,n\,\text{RX} \times t}{\sqrt{4 + t^2}}$ and substituting in place of sin. $n$ RX its value $\frac{1}{\sqrt{1 + t^2}}$, we obtain sin. $n$ XR $= \frac{t}{\sqrt{4 + t^2} \times \sqrt{1 + t^2}}$, and cos. $n$ XR $= \frac{2 + t^2}{\sqrt{4 + t^2} \times \sqrt{1 + t^2}}$ and since X $d = \frac{2\,\text{X}\,n}{3} = \frac{a \times \sqrt{4 + t^2}}{3}$, we have X $c = \frac{a \times \sqrt{4 + t^2} \times \overline{2 + t^2}}{3n\sqrt{4 + t^2} \times \sqrt{1 + t^2}} = \frac{a}{3} \times \frac{2 + t^2}{\sqrt{1 + t^2}}$. But X $b$ = X $c$ by similar triangles, and therefore $b\,c = 2\,\text{X}\,c = \frac{2a \times \overline{2 + t^2}}{3 \times \sqrt{1 + t^2}} = b$. Now the immersed part ACDB $= 2\,a\,c\,n =$ V, and the volume QXR $= \frac{a^2\,t}{2} =$ A. Substituting, therefore, these values in the equation $GZ = \frac{b\,A}{V} - h\,s$, we have $GZ = \frac{2a \times \overline{2 + t^2}}{3 \times \sqrt{1 + t^2}} \times \frac{a^2\,t}{4\,a\,c\,n} - h\,s = \frac{a^2\,t \times \overline{2 + t^2}}{6\,c\,n \times \overline{1 + t^2}} - h\,s$; but since $h = \frac{c - c\,n}{2}$; $GZ = \frac{a^2\,t \times \overline{2 + t^2}}{6\,c\,n\sqrt{1 + t^2}} - \frac{\overline{c - c\,n} \times s}{2}$. By substituting for $t^2$ its equal $\frac{s^2}{1 - s^2}$, the formula becomes $GZ = \frac{a^2\,s \times \overline{2 - s^2}}{6\,c\,n \times \overline{1 - s^2}} - \frac{\overline{c - c\,n} \times s}{2}$. As it may be more convenient to make $a$ express the whole breadth AB or PQ, instead of the half breadth, the equation will, by this change, become $GZ = \frac{a^2\,s \times \overline{2 - s^2}}{24\,c\,n \times \overline{1 - s^2}} - \frac{\overline{c - c\,n} \times s}{2}$. By making this value $= 0$, we obtain $s^2 = \frac{2\,a^2 - 12\,c^2\,n + 12\,c^2\,n^2}{12\,c^2\,n^2 - 12\,c^2\,n + a^2}$, or $s^2 = \frac{12\,c^2\,n - 12\,c^2\,n^2 - 2\,a^2}{12\,c^2\,n - 12\,c^2\,n^2 - a^2}$.

In the case of a square parallelopiped, we have $a = c$, and therefore $s^2 = \frac{12\,n - 12\,n^2 - 2}{12\,n - 12\,n^2 - 1}$. In order, therefore, to ascertain from this equation the angle through which the solid revolves, let us take $n = .24$, which being between .211 and .789, will place the solid with a flat surface upward and horizontal, and in an instable equilibrium, consequently $s^2 = \frac{.1888}{1.1888}$, and $s = \sqrt{\frac{.1888}{1.1888}} =$ the sine of 23° 29′, the angle of revolution, after which the solid will settle in a position of stable equilibrium.

The preceding equation determines also the specific gravity $n$, which will make the solid float at the angle $s$; for, by resolving that equation, we obtain $n = \frac{1}{2} \pm \sqrt{\frac{1 - 2\,s^2}{12 - 12\,s^2}}$, and applying this to the particular angle of 23° 29′, we have $n = 0.5 \pm 0.26 = 0.76$ and 0.24, the two specific gravities, which will cause it to float in stable equilibrium at the angle of 23° 29′.

### Prop. VIII.

To ascertain the position of equilibrium, &c. as in Prop. VII. when the surface of the fluid passes through one of the extremities of the base of the floating solid.

The preceding proposition is applicable only to the case where the surface of the water intersects the parallel sides YH, WV. In order to obtain the angle of inclination from a position of equilibrium, with the flat surface horizontal, and the specific gravity of the solid, when the fluid surface passes through one extremity of the base, let AECD, Fig. 6, be a vertical section of the square parallelopiped, and let the water line IK pass through D. Then putting CD $= a$, and $t =$ tangent of KDC, the angle required, we have KC $= a\,t$, and area KCD $= \frac{a^2\,t}{2}$; but area KCD : area AECD $= n$ : 1, we have $n = \frac{t}{2}$. Substituting this value of $n$ in the formula, or value of $s^2$ in the preceding proposition, we obtain $s^2 = \frac{6\,t - 3\,t^2 - 2}{6\,t - 3\,t^2 - 1}$, but $s^2 = \frac{t^2}{1 + t^2}$, consequently $\frac{t^2}{1+t^2} = \frac{6t-3t^2-2}{6t-3t^2-1}$, or $6t^3-3t^4-t^2 = 6t-3t^2-2+6t^3-3t^4-2t^2$, or $4t^2 = 6t-2$, which gives $t = \frac{3}{4} \pm \frac{1}{4}$, that is $t = \frac{1}{2}$, and $t = 1$. The first of these values corresponds to an angle of 26° 33′ 51″, and the second to an angle of 45°, as shewn in Fig. 7. In the first of these cases, KCD : ABCD, $= 1:4$, and therefore $n = \frac{1}{4}$, and the equilibrium is that of stability; in the second case $n = \frac{1}{2}$, and the position of equilibrium is also one of stability.

### Prop. IX.

To find the position of equilibrium as in Prop. VIII. when the fluid surface intersects one of the extremities of the upper side, as shewn in Fig. 8.

Putting ABK $= t$, we have areas ABK $= \frac{a^2 t}{2}$, and KCDB $= \frac{2a^2 - a^2 t}{2}$, consequently $n = \frac{2-t}{2}$, which, being substituted for $n$ in the equation of Prop. VIII. gives $\frac{t^2}{1+t^2} = \frac{6t-3t^2-2}{6t-3t^2-1}$, the same as formerly. Hence since $t = \frac{3}{4} \pm \frac{1}{4}$, we have $n = \frac{2-t}{2} = \frac{3}{4}$, or $n = \frac{1}{2}$.

### Prop. X.

To determine the position in which the parallelopiped will float permanently with a plane angle obliquely upward, when the specific gravity is between $\frac{8}{32}$ and $\frac{9}{32}$, or betwen $\frac{23}{32}$ and $\frac{24}{32}$.

It follows from Prop. VI. that when $n$ is between $\frac{8}{32}$ and $\frac{9}{32}$, or between $\frac{23}{32}$ and $\frac{24}{32}$, the solid will float permanently with the diagonal inclined to a vertical line. In order to find the angle, let IVCF, Fig. 9. represent the square parallelopiped floating with its angle I placed obliquely, and let its inclination to a vertical line be OGT. Let DE be the surface of the fluid, and taking CB a mean proportional between EC and CD, draw BA parallel to FV, and cutting IC in H, CH will be the depth to which the solid sinks when IV is vertical, and therefore area BXE = area XDA. Make CO $= \frac{2}{3}$ CH, and O will be the centre of gravity of the volume ABC. Bisect EB in K and AD in R, and draw KX, RX, and take XM $= \frac{2}{3}$ XR and XL $= \frac{2}{3}$ XK, and M, L will respectively be the centres of gravity of the triangles XAD, BXE. Let fall the perpendiculars MP, QL upon the horizontal line DE, then making PQ $= b$, sin. BXE $= s$; tang. BEX $= t$, and EC $= a$, we have CD $= ta$; CB $= \sqrt{ta^2}$; CH $= \sqrt{\frac{ta^2}{2}}$; CO $= \frac{2}{3}$ CH $= \sqrt{\frac{2ta^2}{9}}$; area ABC $=$ CH² $= \frac{ta^2}{2}$. Putting area BXE $= u$, we have area CDE or ABC : area BXE = PQ : OT or $\frac{ta^2}{2} : u = b :$ OT $= \frac{2bu}{ta^2}$, and OG $= \frac{2bu}{ta^2 s}$. Adding CO to CG, we obtain CG $= \frac{2bu}{ta^2 s} + \sqrt{\frac{2ta^2}{9}}$, and since GC : CV $= 1 : \sqrt{2}$, we have CV $=$ GC $\times \sqrt{2}$ and CV $= \frac{\sqrt{8} \times bu}{ta^2 s} + \sqrt{\frac{4ta^2}{9}} = \frac{\sqrt{72} \times bu + \sqrt{4t^3 a^6 s^2}}{3ta^2 s}$. But since $1 : n =$ area CAHB : IFCV, or as CH² : CV², we have $\sqrt{n} = \frac{\text{CH}}{\text{CV}}$ and $\sqrt{n} = \sqrt{\frac{ta^2}{2}} \times \frac{3ta^2 s}{\sqrt{72} \times bu + \sqrt{4t^3 a^6 s^2}} = \frac{3t^{\frac{3}{2}} a^3 s}{12bu + 2\sqrt{2}t^{\frac{3}{2}} a^3 s}$.

If we assume the angle OGT or BXE $= 15°$, and take CE $= 1$, we shall find BXE $= u = .039395$, and PQ $= b = 0.73089$, which being substituted in the above value of $n$, gives $\sqrt{n} = \frac{.34063}{.34552 + .32114} = 0.51094$ and $n = 0.261$, the specific gravity with which the solid will float in stable equilibrium, when its diagonal is inclined 15° to a vertical line.

The preceding solution is applicable to all cases in which $n$ is between $\frac{8}{32}$ and $\frac{9}{32}$; and by a similar process we may obtain an equation for the case when the specific gravity is between $\frac{23}{32}$ and $\frac{24}{32}$. In this case, the solid will float permanently with the line IC upward, but inclined to the vertical at some angle between 0° and 18° 26′ 9″.

Mr Atwood has collected into the following abstract, the various positions which the square parallelopiped assumes as depending upon its specific gravity.

1. If $n$ is between 0 and $\frac{1}{2} - \sqrt{\frac{1}{4} - \frac{1}{6}}$, (as shewn in Figs. 10, 11, and 12,) or between 0 and 0.211, the solid will float permanently with a flat surface upwards, and parallel to the horizon.
2. If $n$ is between .211 and 25, (as shewn in Figs. 12, 13, 14), it will float permanently with a flat surface upward, but inclined to the horizon at different angles from 0° corresponding to .211 to 26° 34′ corresponding to .25.
3. If $n$ is between .25 or $\frac{8}{32}$ and .281 or $\frac{9}{32}$, (as shewn in Figs. 14, 15, 16), the solid will float with only one angle immersed, the diagonal being inclined to the vertical at various angles from 18° 26′, corresponding to .25 or $\frac{8}{32}$, and 0° corresponding to .281 or $\frac{9}{32}$.
4. If $n$ is above .281 or $\frac{9}{32}$, (as in Figs. 16, 17,) the solid will float permanently with its diagonal vertical, till the specific gravity becomes .718 or $\frac{23}{32}$.
5. If $n$ is below .718 or $\frac{23}{32}$ and .75 or $\frac{24}{32}$, (as in Figs. 17, 18,) the solid will float with the diagonal inclined to the vertical at angles varying from 0° corresponding to .718 to 18° 26′ corresponding to .75, three angles of the solid being immersed.
6. If $n$ is between .718 or $\frac{24}{32}$ and .789 (as in Figs. 19, 20, 21,) the solid will float with a flat surface upward, and inclined to the horizon at various angles between 26° 34′ corresponding to .75 and 0° corresponding to .789.
7. If $n$ is between .789 and 1.000, the solid will float permanently with a flat surface parallel to the horizon.
8. When the solid revolves round its larger axis, or axis of motion, so as to complete an entire revolution of 360°, it will pass either through 16 or 18 positions of equilibrium. If $n$ is between .211 and .281, or between .719 and .789, the positions of equilibrium will be *sixteen*, eight of which will be positions of stable and the other eight of instable equilibrium, alternating with each other. If $n$ is not within these limits, the solid in the course of its revolution will pass only through *eight* positions, four of which are positions of stable, and the other four of instable, equilibrium.

In the preceding propositions, the solid is supposed to have a uniform figure in respect to the axis of motion, so that all its vertical sections are equal. But when the solid has such a form that the sections are unequal, a different process of investigation, though depending on the same principles, must be employed for determining its positions of equilibrium. We shall content ourselves with giving Mr Atwood's application of the preceding principles to a cylinder.

PROP. XI.

To determine the positions of stable and instable equilibrium, in a cylinder placed on the surface of a fluid, with its axis in a vertical position.

Let EFCD represent the cylinder with its axis NP, Fig. 22. vertical, and let it sink to the depth QP. Make $QA = r$, the distance between the centres of gravity G and O, viz. $GO = h$, and let AIBHSKA represent the circular section of the cylinder formed by the surface of the fluid. Draw any diameter IS, and another diameter AB, perpendicular to IS, and let IS be the direction of the axis round which the cylinder is moveable. Through any point W draw the double ordinate KH, and make $QW = z$, $NP = l$, and $\pi = 3.14159$, the ratio of the circumference to the diameter of a circle. Now, from Prop. III. it follows, that the solid will float permanently with the axis vertical, when fluent of $\frac{\overline{KH}^3 \times dz}{12\,V}$ is greater than $h$, and that the equilibrium will be instable if $h$ is the greater of the two, and therefore, when these two quantities are equal, the equilibrium will be the limit between stability and instability. To apply this to the present case, we must find the fluent of $\frac{KH^3 \times dz}{12\,V}$. Now since $QS = r$, $QW = z$, we have, by Euclid, B. III. Prop. 35. $WH = \sqrt{r^2 - z^2}$, $KH = 2 \times \sqrt{r^2 - z^2}$, and $KH^3\,dz = 8 \times \overline{r^2 - z^2}^{\frac{3}{2}} \times dz$, the fluent of which quantity, when $z$ increases from 0 to $r$, is $8 \times \overline{\frac{\pi r^4}{4} - \frac{\pi r^4}{16}} = \frac{8 \times 3\,\pi r^4}{16}$, and for both semicircles fluent of $\overline{KH}^3 \times dz = 3\,\pi r^4$; and since $PQ = l\,n$, and the area of the circle $AIBS = \pi r^2$, we have $V = \pi r^2\,l\,n$. But $GP = \frac{l}{2}$, and $OP = \frac{l\,n}{2}$, consequently $GO = \frac{l - l\,n}{2} = h$; and since $\frac{\text{fluent } KH^3 \times dz}{12\,V} = \frac{3\,\pi r^4}{12\,\pi r^2\,l\,n}$, by making $\frac{\text{fluent } \overline{KH}^3 \times dz}{12\,V} = h$, we shall obtain the limits between the stable and instable equilibriums. Thus $\frac{3\,\pi r^2}{12\,\pi r^2\,l\,n} = \frac{l - l\,n}{2}$, or $n^2 - n = -\frac{r^2}{2\,l^2}$. But since $2\,r = b$, or the diameter of the base, we have $n^2 - n = \frac{-b^2}{8\,l^2}$, and $n = \frac{1}{2} \pm \sqrt{\frac{1}{4} - \frac{b^3}{8\,l^2}}$.

Hence, if the diameter of the base bears a greater proportion to the length of the axis than that of $\sqrt{2}$ to 1, there is no value of the specific gravity $n$, which will cause the solid to float in the equilibrium of indifference: It follows, therefore, from the preceding investigations, that in this case it will always float permanently with its axis in a vertical line.

If the diameter of the base bears a less proportion to the length of the axis than $\sqrt{2}$ to 1, then there are always two values of $n$, which will be the limits of stability and instability. In order to determine the ratio between the length and diameter of the cylinder which limits the case of stability and instability when the specific gravity is given, we obtain from the equation $n - n^2 = \frac{b^2}{8\,l^2}$, the equation $\frac{b}{l} = \sqrt{8\,n - 8\,n^2}$, from which it follows, that since $n$ is given, the diameter of the base should be to the length of the axis of the cylinder in a greater proportion than that of $\sqrt{8\,n - 8\,n^2}$ to 1, in order that the solid may float permanently with its axis upwards; but if the diameter of the base should be to the length of the axis in a less proportion to that, the solid will overset. For example, if $n = \frac{3}{4}$, then $\sqrt{8\,n - 8\,n^2} = \sqrt{\frac{3}{2}} = 1.2247$; that is, the diameter of the base should be in a greater proportion to the length of the axis than 1.2247 to 1, in order that it may float permanently. If the proportion is less than this, it will overset.

We shall now conclude this Section, by following Mr Atwood in his application of the preceding principles to the stability of ships. We have already seen that the force of stability of a ship or any other body is represented by $W \times GZ$, W being the weight of the vessel and its lading. When the angle of inclination is so small as to be considered evanescent, we have seen that $GZ = \frac{\text{fluent of } AB^3 \times dz \times s}{12\,V} - h\,s$; but since the first member of this equation is equal to ET, and since $h = OG = EG$, it follows that $\frac{\text{fluent } AB^3\,dz}{12\,V} = ES$, and $\frac{\text{fluent } AB^3\,dz}{12\,V} - h = GS$, which is an invariable quantity, whatever be the inclination of the floating body, provided it is very small; that is, the point S is immoveable with respect to G. This point S is called the *Metacentre*, or centre of equilibrium; for if the centre of gravity G coincides with the point S, the stability, or $GZ \times W = W \times SG \times s$, will be $= 0$, or the solid will float in all positions alike, without any effort to restore itself if it is inclined, or to incline itself farther. If the centre of gravity G is situated beneath the metacentre S, the solid will always float with stability, as the measure of that stability $W \times SG \times s$ tends always to turn the body in a direction contrary to that in which it is inclined. If the centre of gravity is placed above the metacentre, the force $W \times SG \times s$ having passed through 0, tends to turn the vessel in the same direction as that in which it is inclined, and it will therefore float with an instable equilibrium.

When the angles of inclination, however, are large, the stability of the vessel will, as has already been shewn, be measured by $W \times GZ = \frac{\overline{b\,A}}{V} - d\,s \times W$. In the application of this formula to practice, $b\,A$ is the only quantity which requires to be determined; for all the other values can be easily ascertained from the nature of the case. In order to find $bA$, the following observations must be attended to. If a line parallel to the horizon passes from the head to the stern of the vessel when the ship floats uprightly, this line is called the *longer axis*, to distinguish it from the *shorter axis*, which passes through the same centre, but in a direction perpendicular to the former. If we conceive a vertical plane to pass through the longer axis when the ship floats uprightly, it will divide the vessel into two parts perfectly similar and equal. A ship in equilibrium may also be conceived to be divided into two parts by the horizontal plane which passes through the surface of the water, and this section is called the *principal section of the water*, represented in section by AB, Fig. 1, which will be transferred to IN when the vessel is made to heel or revolve through the angle SGK. The real section of the water will now be AB, which may be called the *secondary section of the water*. These two planes inclined at the angle of heeling SGK, intersect each other in X, and this line of intersection will obviously be parallel to the longer axis.

The position of the point X clearly depends on the shape of the sides of the vessel. In a parallelopiped, with two plane angles immersed, as in Fig. 5, the point X bisects the lines ZR, PQ, corresponding to AB, IN, in Fig. 1; but, when the same solid floats with only one plane angle immersed, as in Fig. 10, the point X no longer bisects these lines, but is removed towards the parts immersed by the inclination. As the breadth of vessels, therefore, has no regular proportion from the head to the stern, the position of X, which is necessary to the determination of $bA$, must obviously be determined practically by approximation. We must therefore conceive the equal volumes NXP, LXW, Fig. 1 and 25, one of which is immersed, and the other raised by the heeling of the ship, to be divided into segments by vertical lines, perpendicular to the longer axis, and at distances of two or three feet. These segments will therefore have the form of wedges, as shewn in Fig. 25, NXP being the inclination of the planes on the faces of the wedges.

The solid contents of the immersed wedges NXD must now be found by approximation; and making $XI = AB - NX$, and $XW = AB - PX$, the solid contents of all the wedges, IXW raised by heeling, must also be obtained. If the size of the immersed wedges is not equal to the size of the elevated wedges, the position of the point X must be altered, till this equality is obtained. To find $bA$, therefore, let the area PXNTP, and its centre of gravity $f$, be determined by approximation. Draw $dc$ perpendicular to PX, and $Xc$ will be the distance of the centre of gravity from the point X, estimated in the horizontal direction PX; and $ex$ being found in a similar manner, $\frac{Xc + ex}{2}$ will be the mean distance of the centre of gravity of the solid segment XPN $xpn$ from the line $Xx$, estimated in the horizontal direction XP. By finding similar distances of the centre of gravity of all the other wedges or segments, from $Xx$, estimated in the same direction, the sum of all these products will be the value of $bA$ required. Hence the measure of the vessel's stability $W \times \overline{\frac{bA}{V} - ds}$ for an angle whose sine is $s$, is obtained.

## CHAP. V.

### On Capillary Attraction, and the Cohesion of Fluids.

In our articles on Adhesion and Capillary Attraction, we have already given an account of the principal facts relative to the cohesion of fluids, and the ascent of water in capillary tubes. In the present chapter we propose to resume the subject, and after tracing the progress of discovery in this interesting branch of physics, to lay before our readers an account of additional experiments which have either been made since the publication of these articles, or which appear to us necessary for completing the view of the subject which might be expected in the present work.

The earliest experiments on the ascent of water in capillary tubes, appear to have been first made at Florence,* but we are not acquainted with the name of the philosopher who made them, or with the results which he obtained. The editor of the posthumous tracts of Pascal informs us, that capillary attraction was not known in France when Pascal wrote his posthumous treatise *Sur l'Equilibre des Liqueurs*, which could not have been composed more than a few years before his death in 1662; and he mentions it as if it were a fact well known, that the ascent of water in narrow tubes was first discovered by M. Rohault, a celebrated Cartesian philosopher, who taught mathematics and natural philosophy at Paris. In 1671, Rohault published in 4to his *Traité de Physique*, which was translated into Latin by Dr Clark. This work contains an account of the ordinary experiments on capillary attraction, which Rohault ascribes to the unequal pressure of the air within and without the tube. He states distinctly, that water rises between all bodies which are capable of being wetted with it, whereas it is depressed between substances that are not capable of being wetted. He observed the ascent of water between two plates of glass, and the spherical concavity of the upper surface in capillary spaces; but he no where gives the least hint, that he was the discoverer of these phenomena.†

In the year 1660, our celebrated countryman, Robert Boyle, published at Oxford his *New Experiments Physico-Mechanical touching the Spring of the Air*, &c. in which he has treated of the ascent of water in capillary tubes. He ascribes the discovery to some men of science in France,

* This is stated on the authority of Fabri.

† See Rohaultii *Physica*, edit. 1710, § 69, 70, 71, 80, 81, &c.

on the authority of a celebrated mathematician from whom he received it; and he repeated the experiment with a tube of very small bore, drawn out by means of the blow-pipe. In this tube, the water is said to have sprung instantaneously to the height of *five* inches, to the great surprise of several mathematicians that were present. When the tube was inclined, the water occupied a greater part of it, and it always rose higher in the tube when the inside of it was wetted beforehand. These experiments succeeded equally well, when the tubes were placed in an exhausted receiver. Mr Boyle observed also the concavity of the upper surface of the water, the convexity of the surface of mercury, and its depression in capillary tubes. See the above work, p. 262.

Dr Hooke seems to have been one of those who was present at the exhibition of this experiment; and he *is said* to have explained the phenomenon by affinity. In a tract published in 1660, and entitled "An attempt for the explication of the Phenomena observable in an experiment published by the Right Hon. Robert Boyle, in the 35th experiment of his Epistolical Discourse touching the Air, in confirmation of a former conjecture made by R. H."* Dr Hooke† accounts for the ascent of water in capillary tubes, by the unequal pressure of the atmosphere on the column of fluid within and without the tube. He supposes that there is a greater incongruity between air and glass than between water and glass, and that, on this account, the air is admitted with more difficulty into the tube than the water, the difficulty always increasing as the diameter of the tube diminishes. This hypothesis Dr Hooke endeavours to support, by the fact which he has determined experimentally, that a much greater force is necessary to force a bubble of water into a narrow tube than into a wide one; and he has illustrated it at great length, in the VIth Observation of his *Micrographia*, which appeared in 1667. This observation is entitled, *On Small Glass Canes*, and contains his most mature opinions on the subject. He states, that the water, when it enters small capillary tubes, rises rapidly to the height of 6 or 7 inches; that when the tube is extremely fine, it ascends slowly to a much greater height: and that he had never patience to wait till it rose higher than 21 inches, which must have been in a pipe, whose internal diameter was about the $\frac{1}{1428}$th part of an inch. He defines the term *Congruity*, which may be considered the same as affinity, as that "property of a fluid body, whereby any part of it is readily united with any other part, either of itself, or of any other similar fluid or solid body; and *Incongruity*, to be that property of a fluid, by which it is hindered from uniting with any dissimilar fluid or solid body." Dr Robison, and some other authors, are therefore mistaken in claiming for Dr Hooke the merit of explaining the phenomena of capillary attraction by affinity, by which they meant the affinity of water to glass. Dr Hooke, indeed, employs a term the same as this in his explanation of these phenomena; but it is employed for a quite different purpose; for he supposes that the water rises in the tube, not because it is attracted by the glass, but because there is a greater affinity between water and glass than between air and glass, in consequence of which, the column of air within the tube is not capable of balancing the corresponding atmospherical column without. "For since the pressure" says he, "of the air every way is found to be equal, that is, as much as is able to press up and sustain a cylinder of quicksilver of $2\frac{1}{2}$ feet high or thereabouts; and since of the pressure so many more degrees are required, to force the air into a smaller than into a greater hole that is full of a more congruous fluid; and, lastly, since these degrees that are requisite to press it in are thereby taken off from the air within, and the air within left with so many degrees of pressure less than the air without; it will follow, that the air in the less tube or pipe will have less pressure against the superficies of the water therein, than the air in the bigger. The conclusion, therefore, will necessarily follow, viz. that this unequal pressure of the air, caused by its ingress into unequal holes, is a cause sufficient to produce the effect, without the effect of any other concurrent; and therefore is probably the principal (if not the only) cause of these phenomena. This, therefore, being thus explained, there will be divers phenomena explicable thereby: as, the rising of liquors in a filtre; the rising of spirit of wine, oil, melted tallow, &c. in the wick of a lamp, though made of small wire, threads of asbestos, strings of glass, or the like; and the rising of liquors in a sponge, pieces of bread, sand, &c.; perhaps also the ascending of the sap in trees and plants, through their small and some of them imperceptible pores, at least the passing of it out of the earth into their roots." ‡This hypothesis of Dr Hooke's, which was received at the time with great applause, was afterwards shewn to be unsatisfactory and inconsistent with experiments by Roger Cotes.¶

In the year 1666, the learned Isaac Vossius published at the Hague his work, entitled *De Nili et Aliorum Fluminum Origine*, in the second chapter of which he describes the phenomena of capillary attraction, and endeavours to account for them by a theory which approaches more nearly than any other which had been given to the true theory of the action of capillary tubes. Since water, says he, is by its very nature viscid, it adheres to every thing which it touches, so that it adheres to glass, and is sustained by the glass. But since the water is sustained by the action of the glass, it does not press upon the water below it, as the same weight cannot press in two places, and as no body can be heavier than itself. The portion of water, therefore, which enters the tube, loads the glass tube to the sides of which it adheres, and is destitute of weight in respect of the subjacent water. Hence it follows, that if capillary tubes are immersed in water, and then taken out of it, the water which has entered them will not all flow out of the tube, but as much will remain as the surface of the tube can sustain. From this hypothesis Vossius concludes, that water will rise higher in narrow than in wide tubes, because the narrow tubes, in proportion to their capacity, present more points of contact of adherence to the water, and that mercury being destitute of viscidity, will not adhere to glass, and will therefore sink below its natural level in capillary tubes.

The first person in France who repeated these experiments, and attempted to investigate their cause, was M. Honoré Fabri, a learned Jesuit, who was born at Bellay near Lyons, in the year 1607. In the year 1669, he published a work, entitled *Dialogi Physici*, the fourth chapter of which is entitled, *De humoris elevatione per Canaliculum.* In this chapter, he observes that water, whether hot or

* In 1662, this work was translated into Latin, and published at Amsterdam, by M. Bohem, entitled *Conatus ad explicanda Phenomena notabilia in Experimenta publicata ab Honorabili Viro Roberto Boyle.*

† "In the year 1660," says Dr Hooke in his *Micrographia*, "I printed a little tract, entitled *An Attempt*, &c. and being unwilling then to publish this theory, as supposing it might be prejudicial to my design of watches, which I was then procuring a patent for, I only hinted the principle which I supposed to be the cause of these phenomena of springs, in the 31st page thereof in the English edition, and in 38th of the Latin edition, Amst. 1662; but referred the further explication thereof till some other opportunity."—Hooke *on Springs*, 4to, 1678.

¶ See Cotes' *Hydrostatical Lectures*, Lect. XI. Lond. 1738.

cold, ascends above the level of the water in the vessel; that it rises to a greater height in narrow than in wide capillary tubes; and that the water ascends highest in tubes of the same diameter when the tubes extend farthest above the surface of the water; that the water raised by capillary attraction will never flow out of the top of the tubes, however short; that the water will rise higher in a wet tube than in a dry one; that the water will not rise in a tube, if the finger is placed upon the upper end of its bore previous to immersion; and that in two concentric tubes, the water will rise sometimes higher and sometimes lower in the widest of the two tubes, according as the difference of their diameters is less or greater than the diameter of the inner tube. In explaining these phenomena, he maintains, that the external air, acting as a compressed body, has free access to press upon the surface of the water exterior to the tube, whereas it does not act so freely upon the surface of the water in the tube, and therefore the fluid will rise with a force proportional to the difference of these pressures. The cause of this unequal pressure of the air Fabri supposes to be, that only an inverted cone of air touching the fluid in the tube with its vertex, and having the upper orifice of the tube for its base, can press upon the surface contiguous to its vertex.

The celebrated Alphonso Borelli has attempted to explain the phenomena of capillary attraction in his Treatise *De Motionibus a Gravitate naturali pendente*, which was published at Lyons in 1670. He seems, like Vossius, to ascribe the elevation of water to its adhesion to the sides of the tube, and he considers the attractive force of the tube as extending to the particles of water placed in its axis. "In cavitatibus," says he, "subtilium fistularum internus aquæ contactus grandis est et amplus, respectu illius aquæ moleculæ ibidem existentis: ergo subito ac infimum fistulæ orificium attingit aquam, efficitur, in ejus interna et cava perimetro efficacissimus contactus a cujus adhesione fulciri sustinerique potest majus pondus, quam habet pusilla aquæ particula insinuata, et ideo gradus prædictæ virtutis suspensivæ et adhæsionis exercetur in aqua subjecta, et proinde ea reddetur aliquo pacto levis, seu minus ponderosa, quam sit aqua collateralis libere premens. Et, quia minimæ aquæ particulæ porositatibus et asperitatibus internis fistulæ innixæ efficiuntur operanturque ut totidem *vectes*, quæ flecti possunt et interne rotari, necesse est, ut partes aquæ, collaterales magis compressæ, a totali energia sui, ponderis vim faciant, impellendo sursum particulas aquæ, quæ minus comprimuntur a vectibus supra dictis; et ideo rotando excurrere possunt inferius efformando tumorem, vel monticulum aqueum, qui excurrendo lateraliter altioribus fistulæ porositatibus insinuabitur adhærebitque et ideo denuo imminuetur ejus vis compressiva, renovabiturque causa ulterioris suspensionis et proinde altius aqua intra fistulam impelletur, et sic de novo eminentioribus lateribus adhærendo successive altius impelletur quousque ad supremam et maximum illam altitudinem aqua perducta, in qua equilibrium, cum aqua collaterali libere premente efficiatúr: tunc quidem quies ejus subsequetur nec altius elevari poterit;" and in another place, prop. clxxxviii. p. 243, he accounts for the elevation of water to a greater height in small tubes: "Quia adhærentia et connexio aquæ parietibus internis canalium majorem proportionem ad molem aquæ insinuatæ *extensive* et *intensive* in canaliculis subtilissimis habet quam in amplis et capacioribus. *Extensive*, quia vis adhæsionis mensuratur a contactibus, et ideo a superficie interna canaliculorum; e contra resistentia iisdem canaliculis; estque proportio cylindrorum aquearum ejusdem altitudinis duplicata ejus rationis quam habent eorum perimetri internæ, &c. *Intensive*, quoniam facultas et energia adhæsionis minus efficax est quanto magis a parietibus removetur."

Similar experiments made by our countryman Sinclair, are described in his work, entitled *Ars Nova et Magna Gravitatis et Levitatis*, which was published at Rotterdam in 1669; and the experiments were repeated by Johannes Christopher Sturmius, who adopts the hypothesis of Fabri, and gives a full account of the opinions of Hooke, Boyle, Fabri, and Vossius, in the first part of his *Collegium Experimentale sive Curiosum*, which was published at Nuremberg in 1676.

The suspension of mercury in Toricellian tubes, far above the height of 28 inches, had been observed by several philosophers, and which was owing to the attraction of cohesion, and Huygens and Wallis attempted in vain to explain it. The former of these philosophers ascribes it to the pressure of a matter more subtle than air, which penetrates glass, water, quicksilver, and all other bodies, and which, added to the pressure of the air, enables it to sustain 75 inches of mercury. Wallis is equally unsuccessful in his explanation of the phenomena, which he ascribes to a particular spring of the air, which does not exist in the quicksilver.

The celebrated James Bernoulli appears to have paid some attention to the subject of capillary attraction. In his *Dissertatio de Gravitate Etheris*, which was published in 1683, he has endeavoured to explain the ascent of water, upon the supposition that the particles of air have a greater magnitude than those of water. In order to do this, he employs the diagram in Fig. 1. where ABCD is a capillary tube plunged in the vessel MN, and EFGH what he calls a similar atmospherical cylinder. He then supposes that the diameter of each tube will only receive a certain number of spherical particles of air, viz. seven for example, so that seven such particles placed in a straight line will exhaust the breadth of the tubes, as shewn at $i\,l$; but, according to our author, it will always happen that the *first* and *eighth* globules will rest upon the margin of the tube, as shewn at AB, and therefore only the six intermediate ones will rest upon the surface of the fluid, as seen at $q\,r$. Hence it will happen that the size of the globules of the air which occupies the circumference of the upper orifice of the tubes, with the superincumbent rows A $m$, B $n$, which rest upon that ring, will press upon the margin of the tubes, and will not produce the smallest pressure upon the surface $q\,r$ of the fluid. In the imaginary atmospherical cylinder or tube EFGH, nothing prevents the seven particles from acting freely upon the surface of the fluid EF. Hence Bernoulli concludes, that as the water without the tube is affected with a greater pressure than the water within the tube, it must necessarily rise to a height proportional to the excess of pressure. He then concludes from this hypothesis, that the water should not rise in wide tubes, as the portion of air prevented from acting by the margin bears a small proportion to the whole column;—that fluids specifically lighter than water ought to rise to a greater height; that the water cannot flow over the top of a capillary tube, however short; and that the surface of mercury ought to stand below its level in tubes of glass, if its particles are larger than those of water; (this effect he explains by Fig. 2. where the row of particles of mercury $s\,t$ is more pressed down by the weight of the air above than it is by the pressure of the mercury from below;) and finally, that the surface of water in capillary tubes ought to be concave, and that of mercury convex. Bernoulli next proceeds to deduce from this hypothesis the magnitude of a globule of air, and by assuming, from his own experiments, that water rises half an inch in a tube $\frac{1}{8}$ of an inch in diameter, he concludes that the magnitude of a particle of air, or rather the distance between the centres of two adjacent particles, is $\frac{1}{12500}$ of an inch. But having convinced himself by other means, that four particles of a very subtile matter is interposed between every two particles of air, he determines the real magnitude of a particle of air to be $\frac{1}{62500}$ of an inch!

A very interesting memoir on capillary attraction was published by M. Louis Carré in the Memoirs of the Academy of Sciences for 1705, entitled *Experiences sur les tuyaux Capillaires.* He ascribes the ascent of the water to its adhesion to the sides of the tubes, and to the mutual attraction of the particles of water. The portion of water contiguous to the sides of the tube is first raised and supported, and therefore presses less upon the bottom of the vessel than the collateral column. He attributes the higher elevation of the water within than without the tube to the mutual adhesion of the aqueous particles, which contributes to their elevation; and he says, that water rises higher in small tubes, since the force of adhesion is measured by the internal surface of the tubes, and the resistance by the supported column of fluid; and he supposes that water has a *greater contact* with glass than alcohol, and therefore rises higher. These views are supported by some new and curious facts: he found, that when the same surfaces were anointed with grease, the water would not rise above its level; that if only part of the surface was anointed, the water rose only on the side where there was no grease; that if the tube was plunged deeper than the point to which the grease reached, the water rose above its level; and that a drop of water descending on the outside of the tube was drawn into the tube when it was not greased, but refused to enter when the tube was greased.*

The following are the principal results which Carré obtained:

WATER.

| Diameter of tube, which was 12 inches long. | Height of ascent. |
|---|---|
| $0\frac{1}{3}$ of a line | 10 lines |
| $\frac{1}{6}$ | 18 |
| $\frac{1}{10}$ | 30 |

| Diameter of tube in parts of a line. | Fluids employed. | Height of ascent. |
|---|---|---|
| | Tube 12 inches long. | |
| $\frac{1}{3}$ | Water | $5\frac{3}{4}$ lines, 1st immersion.<br>7 lines, 2d immersion.<br>10 lines, 3d immersion. |
| $\frac{1}{3}$ | Alcohol | $3\frac{1}{2}$ lines. |
| $\frac{1}{3}$ | Spirit of turpentine | 4 |
| $\frac{1}{3}$ | Oil of tartar | 5 lines. |
| | Spirit of nitre | 4 |
| $\frac{1}{3}$ | Oil of olives | 5 |
| | Tube $9\frac{1}{2}$ inches long | |
| $\frac{1}{3}$ | Water | 10 lines. |
| $\frac{1}{3}$ | Alcohol | 4 lines. |
| | Tube 15 inches long | |
| $\frac{1}{6}$ | Water | 29 lines. |
| $\frac{1}{6}$ | Alcohol | 12 |
| | Tube 5 inches long | |
| $\frac{1}{6}$ | Water | 27 |
| $\frac{1}{6}$ | Alcohol | 12 nearly. |

The phenomena of capillary tubes were investigated with great care by our countryman Mr Hawksbee. In the year 1706, he communicated to the Royal Society an account of some experiments made at Gresham College, by which it was proved that water rose to the same height in capillary tubes *in vacuo* as in the open air; and he likewise observed in bending some small tubes by the flame of a candle in the manner of syphons, that it was necessary for the orifice of the longer leg to be at least so far below the surface of stagnant water as that water in the same tube would spontaneously ascend in it, before it would run. In 1709, Mr Hawksbee laid before the same learned body an account of his experiments on the rise of water between two plates of glass or polished marble, an experiment of which he has the exclusive merit. He shewed that the water rose between them whether the plates were placed *in vacuo* or in the open air; and having found that neither the figure of the vessel, nor the presence of the air, nor the quantity of matter in the tubes or plates, contributed to the production of the phenomena, he endeavours to explain the rise of the water, by supposing the glass to act upon water in the very same way as a magnet acts upon iron.† Mr Hawksbee's attention was next directed to the motion of a drop of oil of oranges between two glass planes. The drop always moved towards the sides of the planes that were nearest pressed together. The velocity of the drop increased as it approached the touching sides, and its surface of course increased in a similar manner, from the greater proximity of the planes. This experiment was also repeated with the same results *in vacuo.*‡ Mr Hawksbee next endeavoured to measure the angle required to suspend a drop of oil of oranges at certain stations, between two glass planes placed in the form of a wedge, as shewn in our Plate CX. Fig. 6. "I procured two glass planes," says Mr Hawksbee, "that measured a radius of 20 inches each; their breadth was about three inches; that which I used for the lower plane was placed with its surface parallel to the centre of its axis and to the horizon. The planes being very clean, they were rubbed with a linen cloth dipped in oil of oranges; then a drop or two of the same oil being let fall on the lower plane near the axis, the other plane was laid on it, and as soon as it touched the oil, the drop spread itself considerably between both their surfaces. Then the upper plane being raised a little at the same end by a screw, the oil immediately attracted itself into a body, forming a globule contiguous to both surfaces, and began to move toward the touching ends. When it arrived two inches from the axis, an elevation of 15 minutes at the

* See Mem. Acad. Par. 1705, p. 241, and 317, 8vo. edit.

† See Phil. Trans. 1707, vol. xxvi. p. 258.

‡ Id. 1711, vol. xxvii. p. 35.

touching ends stopped its progress, and it remained there without motion any way. The planes being let fall again, the drop moved forward till it came to four inches from the centre; then an elevation of 25 minutes was required to give it a fixed station. At 6 inches it required an angle of 35 minutes; at 8 of 45 minutes; at 10 a degree. At 12 inches from the axis the elevation was 1 degree 45 minutes, and so on at the several stations as they stand in the annexed table. This, after numerous trials, I take to be the most correct, though the others succeeded very nearly the same. It is to be observed, that when the globule or drop had arrived to near 17 inches on the planes from their axis, it would become of an oval form; and as it ascended higher, so would its figure become more and more oblong; and unless the drop was small on such an elevation of planes as was required at such a progress of the drop, it would be parted, some of it descending, and the rest of it running up to the top at once; but on a drop that separated these I found the remaining part of it, at 18 inches, would bear an angle of elevation equal to 22 inches, to balance its weight. Higher than that I could not observe. The planes were separated at their axis about $\frac{1}{10}$ of an inch. I found but little difference between small and larger drops of the oil in regard to the experiments. The angles were measured by a quadrant marked on paper, of near 20 inches radius, divided into degrees and quarters.

| Distance in Inches from the axis. | Angle of Elevation. | |
|---|---|---|
| 2 | 0° | 15′ |
| 4 | 0 | 25 |
| 6 | 0 | 35 |
| 8 | 0 | 45 |
| 10 | 1 | 0 |
| 12 | 1 | 45 |
| 14 | 2 | 45 |
| 15 | 4 | 0 |
| 16 | 6 | 0 |
| 17 | 10 | 0 |
| 18 | 22 | 0 |

In the year 1712,* Dr Brook Taylor communicated to the Royal Society the beautiful experiment (See CAPILLARY ATTRACTION, vol. v. p. 409, and Plate CCX. Fig. 6.) respecting the hyperbolic surface of water elevated between two glass planes, inclined at an angle of two and a half degrees. Mr Hawksbee (*Phil. Trans.* 1712, vol. xxvii. p. 539.) repeated the experiment with great care at two different inclinations, of 20′ and 40′, and obtained the following results:

| *Angle of* 20′ | | *Angle of* 40′ | |
|---|---|---|---|
| Distances from the touching ends of the Planes. | Heights of the Water at the preceding Distances. | Distances from the touching ends of the Planes. | Heights of the Water at the preceding Distances. |
| 13 inches | 1 | 9 inches | 1 |
| 9 | 2 | 6 | 2 |
| 7 | 3 | 4¾ | 3 |
| 6 | 3¾ | 3 | 4¾ |
| 5 | 5 | 2½ | 6 |
| 4 | 6¾ | 2 | 7½ |
| 3 | 9 | 1½ | 10 |
| 2½ | 12 | 1¼ | 12 |
| 2 | 15½ | 1 | 15 |
| 1¾ | 18 | ¾ | 19 |
| 1½ | 21½ | ½ | 28 |
| 1¼ | 27½ | ¼ | 50 |
| 1 | 35 | | |
| ¾ | 50 | | |
| ½ | 76 | | |

Mr Hawksbee afterwards found that the curve was an exact hyperbola in all directions of the planes, the asymptotes being the surface of the water, and a line drawn along the touching sides of the planes. Mr Hawksbee's next experiments were made on the heights to which spirit of wine ascended between two plates of glass separated successively to different distances. The following results were obtained:

| Distance of Plates. | Height of Ascent. |
|---|---|
| 0.0625 of an inch | 0.166 of an inch |
| 0.03125 | 0.333 |
| 0.015625 | 0.666 |
| 0.007802 | 1.333 |

As a drop of spirits of wine when placed between the two glass planes, did not move so nimbly as a drop of oil of oranges, Mr Hawksbee was enabled to observe the angles at which it remained suspended at different stations between the plates. The following tables contain the results for inclination of 10′ and 18′.

*Inclination of the Planes* 10′.

| Distance in Inches from the touching ends. | Angle of Elevation. | |
|---|---|---|
| 18½ | 1° | 30′ |
| 16½ | 1 | 50 |
| 14½ | 2 | 10 |
| 12½ | 2 | 40 |
| 10½ | 3 | 10 |
| 9½ | 3 | 30 |
| 8½ | 4 | 0 |
| 7½ | 5 | 5 |
| 6½ | 7 | 40 |
| 5½ | 10 | 50 |
| 4½ | 14 | 0 |
| 4 | 18 | 0 |

In this experiment Mr Hawksbee could not observe nearer than 4 inches from the touching ends.

*Inclination of the Planes* 18′

| Distance in Inches from the touching ends. | Angle of Elevation. | |

The preceding experiments of our author are not only the most numerous, but the most correct, that have been made on capillary attraction, and have been appealed to by La Place as a proof of the accuracy of his own theory. The opinions of Hawksbee respecting the cause of capillary attraction were equally correct. He ascribed the ascent of the fluid to the attraction of the whole surface of the tube; and he considered the attractive force of the glass as extending, like the refracting force, only to insensible distances.

In the year 1718, Dr James Jurin communicated to the Royal Society his *Inquiry into the Cause of the Ascent and Suspension of Water in Capillary Tubes.* This paper contains many new and ingenious experiments; but its author was unfortunate in the erroneous explanation which he gives of the phenomena. "Since in every capillary tube," says he, "the height to which the water will spontaneously ascend is reciprocally as the diameter of the tube, it follows that the surface, containing the suspended water in

* See Phil. Trans. 1712, vol. xxvii. p. 853.

every tube, is always a given quantity; but the column of water suspended is as the diameter of the tube; therefore, if the attraction of the containing surface be the cause of the water's suspension, it will follow that equal causes produce unequal effects, which is absurd." "Having shewn," continues he, "the insufficiency of this hypothesis, I come now to the real cause of the phenomenon, which is the attraction of the periphery or section of the surface of the tube to which the upper surface of the water is contiguous and coheres. For this is the only part of the tube from which the water must recede upon its subsiding, and consequently the only one which by the force of its cohesion or attraction opposes the descent of the water. This is also a cause proportional to the effect which it produces, since that periphery and the column suspended are both in the same proportion as the diameter of the tube." Dr Jurin afterwards accounts for the spontaneous ascent of the water. He supposes that the water which first enters a capillary tube, when its orifice is immersed in the fluid, has its gravity taken off by the attraction of the periphery with which its upper surface is in contact: Hence it must necessarily rise higher, partly by the pressure of the stagnant water, and partly by the attraction of the periphery immediately above that which is already contiguous to it. These opinions Dr Jurin endeavoured to support by the experiment represented at E, F, G in Fig. 5. of Plate CX. and described under Capillary Attraction. (See *Phil. Trans.* vol. xxx. p. 739.) In a subsequent paper he inquires into the cause of the suspension of water in tubes of glass, and seems to adopt the opinion, that the cohesion may depend on the pressure of a medium subtle enough to penetrate the receiver. "For though such a medium," says he, "will pervade the pores of the water as well as those of the glass, yet it will act with its entire pressure on all the solid particles, if I may so call them, of the surface of the water in the cistern; and whereas so many of the solid particles of the water in the tube, as happen to lie directly under the solid particles of the water above them, will thereby be secured from this pressure, and consequently there will be a less pressure of this medium on any surface of the water in the tube below the capillary, than in an equal surface of the water in the cistern; so that the column of water suspended in the tube may be sustained by the difference between these two pressures."

The subject of capillary attraction was treated at great length by George Bernhard Bullfinger, in a dissertation entitled *De Tubulis Capillarium, dissertatio experimentalis*, which appeared in the *Commentarii Acad. Petropolitanæ* for 1727. This paper contains an examination of the different hypotheses which had been employed to explain the phenomenon of capillary attraction, and several new experiments illustrative of his own opinion. He found that the relative ascent of spirit of wine, red wine, and water, were as 4, 7 and 12. He seems, upon the whole, to prefer the hypothesis of Dr Jurin, although he states a number of difficulties which attend it. Dr Jurin replied to this paper of Bullfinger's in the volume of the *Commentarii Acad. Petropolitanæ* for 1728; and his paper is published with the annotations of Bullfinger. After examining all the objections which had been stated, and apparently to the satisfaction of Bullfinger, Dr Jurin begs that he will no longer consider his explanation as a hypothesis, but as a true and established theory.*

When M. Bullfinger exhibited his experiments before the Academy of St Petersburgh, his colleague, the celebrated Daniel Bernoulli, who was at that time unacquainted with the speculations of his uncle on the same subject, proposed a new theory of capillary attraction. In order to get over the difficulty respecting the ascent of the water under the receiver of an air pump, he ascribed the phenomenon, not to the unequal pressure of the air, as his uncle had done, but to the unequal pressure of an ethereal fluid. He considered the base of the fluid as contiguous to the surface of the water; but he supposed that it was not so full at the sides of the pipe as in its axis; or, in other words, that the æther stood at a greater distance from the glass than water did, or was less dense in the neighbourhood of the glass. This effect he attributed to the particles of the æther being greater than those of water. This hypothesis, which differs in no respect from that of James Bernoulli, excepting in the substitution of æther for air, has the advantage of surmounting the difficulty already mentioned. But, in other respects, it is more inadmissible. Daniel Bernoulli attempted to shew that it explained many of the common experiments, and that the proportion between the magnitude of the particles of different fluids might be deduced from the height of their ascent in capillary tubes. He inferred, from a rude and erroneous experiment, that the particles of mercury were twice as small as those of water.

An excellent dissertation, entitled *Dissertatio Physica de Tubis Capillaribus Vitreis*, was published by M. Muschenbroek, which contains a great variety of interesting experiments upon this subject. He has committed a mistake, however, in maintaining that the height of ascent increases with the length of the tube. The constant quantity for water, as deduced by Dr Young, from his best experiments, is 0.392.

In the year 1736, Josiah Weitbrecht published a valuable paper in the *Commentarii Acad. Petropolitanæ*, entitled *Tentamen Theoriæ qua ascensus aquæ in tubis capillaribus explicatur*. He shews that water is more strongly attracted by glass than it is by its own particles; that the sphere of activity of the attraction of the glass is extremely small, that is, the action of the glass does not extend to the axis of the tube; that the water must be partly supported by the mutual attraction of its own particles; that the water in the capillary tube is drawn downwards, not only by its own gravity, but by the attraction of the water in the vessel; that the water in the tube is elevated by the attractive force of the whole internal surface of the tube successively applied; but that it is suspended solely by the action of the ring of glass immediately above the fluid column. M. Weitbrecht considers the force which suspends the water as represented by $Q-Q'$, $Q$ representing the force with which the water is attracted to the glass, and $Q'$ the force with which it is attracted downwards by the water in the vessel; and as $Q$ is greater than $Q'$ in water and most fluids, the quantity $Q-Q'$ is affirmative, and the water rises above its level. When the tube is taken out of the water, the force $Q'$ he considers as vanishing, and therefore the remaining force is allowed to act without opposition, and consequently the water rises to a greater height in the tube. In mercury $Q'$ is greater than $Q$, and therefore the expression is negative, and the fluid consequently sinks below its level. M. Weitbrecht made the following experiments on the ascent of water.

* "Si ista," says he, "quod speramus, Cl. Bullfinger satisfecerint, pollicemur nobis, pro candore et æquitate Viri humanissimi cum in osterum explicationem hanc phenomenon *non amplius pro hypothesi*, sive *futili ingenii commento, sed pro vera et indubita corundem theoria habitatura.*" Comment. Petrop. 1728, p. 291, 292.

In a subsequent memoir, entitled *Explicatio Difficilium experimentorum circà ascensum aquæ in tubis Capillaribus*, published in the *Comentarii Acad. Petropolitanæ*, for 1737, M. Weitbrecht resumes the subject. He shews that Muschenbroek was mistaken, in considering the height of ascent as affected by the length of the tube. He points out the effects produced by interposing bubbles of air between the different parts of the elevated column; he examines the phenomena exhibited by conical tubes, and tubes where the diameter of the bore changes rapidly; and he terminates his memoir with several interesting experiments on the effects of capillary syphons and bent capillary tubes.

Hitherto mercury was the only metallic fluid which had been employed in capillary experiments. M. Gellert, however, communicated a memoir to the Academy of Sciences at St. Petersburgh, entitled *De Phenomenis plumbi fusi in Tubis Capillaribus*. In making these experiments, he employed the thinnest glass tubes he could procure, and heated them gradually before he immersed them into the melted lead. In this way he found, that melted lead always stood below its level in a tube of glass, and that the altitudes in different tubes were nearly in the reciprocal ratio of their diameters. When the diameter of the tube was 10.21 of an English inch, the lead sunk 0.27 of an inch, whereas in a tube 0.07 it sunk 0.73 of an inch. These results give 567 and 510 for the constant quantity, the mean of which is 5385. In another paper, entitled, *De Tubis Capillaribus Prismaticis*, M. Gellert treats of the ascent of water in prismatic tubes of a triangular and quadrangular form, made of iron. He found, that they gave results perfectly analogous to those which were made of glass.

Before the time of Clairaut, no attempt had been made to analyse with accuracy the different forces which concur in the elevation of water in capillary tubes, and to subject the phenomena to a rigorous calculation. The merit of doing this belongs wholly to this eminent mathematician, who has published his investigations in the tenth chapter of his *Theorie de la Figure de la Terre tirée des Principes de l'Hydrostatique*, which was published at Paris in 1743, and of which a second edition appeared in 1808. In this chapter, which is entitled *De l'Elevation ou de l'Abaissement des Liqueurs dans les tuyaux Capillaires*, he begins by pointing out the mistake in the reasoning employed by Dr Jurin in the establishment of his hypothesis, and he then proceeds to the analysis of the forces by which the water is elevated and suspended. An account of this analysis has already been given in our article on Capillary Attraction. The resulting formula which he obtains for the altitude I $i$, (Plate CX. Fig. 9.) is I $i$ =

$$\frac{(2Q-Q')\cdot\int dx\,[b,x] + \int dx\,[b,x,Q,Q']}{p}, \text{ where}$$

Q = the intensity of the attraction of the glass.

Q′ = the intensity of the attraction of the water.

$b$ = the interior radius of the tube.

$p$ = the force of gravity.

The function of the distance which expresses the law of attraction both for glass and water is supposed given, and he employs $x$ to denote the distance of a particle from the plane MN, $[x]$ the force at which this particle is attracted by a body, of which this plane is the exterior surface, supposing the intensity of the attraction of this body to be unity. The function $[b\ x]$ expresses the force with which a particle Q, placed at the distance QO or $x$ from the surface CH is attracted by the tube or bulb cylinder CDABGHEF, and $[b, x, Q, Q']$ the force with which a corpuscle $p$ placed at the distance $x$ from VX is attracted by the small mass of water YVXZ.

"Without pushing the calculation farther," says M. Clairaut, "in order to find what will be the quantities $[b, x]$ and $[b, x, Q, Q']$ according to the different functions of the distances by which the law of attraction may be expressed, we may easily see that there will be an infinity of laws of attraction in which the preceding expression of I $i$ will give a sensible altitude, when the diameter $b$ of the tube is very small, and on the contrary, a height almost insensible when the tube is very wide." It follows from the value of I $i$, that if the attraction of the capillary tube is less than that of water, provided it is not twice as small, the water will still ascend; for it is obvious from the term $(2\ Q-Q')\int d\,x\,[b, x]$, that while Q′ is less than 2 Q, I $i$ will be positive.

In the Transactions of the Royal Society of Gottingen for 1751, M. Segner has referred all the phenomena of capillary attraction to the attraction of the superficial particles of fluids. Considering the resemblance at the surface of the drops of fluids and of fluids contained in capillary tubes to the surfaces, which geometers have named *lintearia* or elastic, he was led to consider fluids as enveloped in such surfaces, which, by their tension and elasticity, gave to fluids the form indicated by experiment. It appears, however, that Segner considered this only as a fiction which might represent the phenomena, but which ought only to be admitted in so far as it belonged to a law in which the attraction is insensible at sensible distances. Segner tried to establish this dependance; but in the opinion of La Place, "in following this reasoning it is easy to discover its inaccuracy, which is also proved by the incorrectness of the results to which he arrives. He finds, for example, that we ought to consider only the curvature of the vertical section of a drop, and not its horizontal curvature, which is not exact; and besides this, he did not perceive that the tension of the surface is the same, whatever be the magnitude of the drop."*

The subject of the adhesion of fluids to plates of solid bodies, which was first investigated by our countryman Dr Brook Taylor,† was now resumed with great success by M. Guyton Morveau, in 1773. The same subject was prosecuted by M. Achard of Berlin, and M. Dutour, the last of whom made a great number of experiments both on the adhesion of discs, and on the ascent of fluids. An account of the general results which they obtained, will be found in our article Adhesion.

In the year 1787, M. Monge published in the Memoirs of the Academy of Sciences, a paper entitled *Sur quelques effets d'attraction et de repulsion apparente entre les Molecules de Matiere*. These experiments relate principally to the apparent attraction and repulsion which are exhibited by floating bodies when they approach within a certain distance of each other; to the phenomena of drops; and to

* See *Comment. Gotting.* 1751, tom. i. p. 301.

† See *Phil. Trans.* 1721.

the ascent of water between two planes of glass. An account of his experiments will be found in the present chapter.

The subject of capillary attraction has been ably investigated by Dr Thomas Young, in his paper *On the Cohesion of Fluids*, which appeared in the *Philosophical Transactions* for 1805; and in which he has anticipated many of the views afterwards brought forward by La Place. This paper is divided into 8 sections. Sect. I. Contains the general principles; Sect. II. Treats of the form of the surface of fluids; Sect. III. Contains the analysis of the simplest form; Sect. IV. Contains the application of it to the elevation of particular fluids; Sect. V. Treats of apparent attractions and repulsions; Sect. VI. Treats of the physical foundation of the law of superficial cohesion; Sect. VII. Of the cohesive attraction of solids and fluids; and Sect. VIII. is entitled, additional extracts from La Place, with remarks. A general account of Dr Young's views, and some of his experimental results, will be found under our article on Capillary Attraction.

In December 1805, M. le Comte La Place laid before the National Institute of France a Dissertation on Capillary Attraction, which is marked with the high genius of its distinguished author. In 1806, it was published under the title of *Supplement au dixieme Livre du Traité de Mecanique Celeste, sur l'Action Capillaire.* In the theory advanced by Clairaut, it was supposed that the action of the capillary tube extended to a sensible distance, and even to the fluid particles in its axis; and, instead of attempting to discover the law of that action, he contented himself with observing that there were an infinity of laws of attraction, which, if substituted in his formulæ, would give results corresponding to those obtained from experiment. M. La Place, however, was anxious to ascertain the precise law of attraction which represented the phenomena; and, after long researches, he at last succeeded in discovering, that all the phenomena could be represented by the same law which represents the phenomena of refraction, namely, the law in which the attraction is only sensible at insensible distances; and upon this he has founded a rigorous theory of capillary attraction. The first Section of this work treats of the Theory of Capillary Attraction; and the second contains its application to some of the experiments of Hawksbee, and to others made at La Place's request by MM. Hauy and Tremery. In the year 1807, La Place published his *Supplement á la Theorie de l'Action Capillaire;* the object of which was to perfect the theory which he had given—to extend its application—to confirm it by new comparisons with experimental results—and, in presenting under a new point of view the effects of capillary action, to shew the identity of the attractive force upon which it depends with those which produce chemical affinities.

This Supplement treats, 1. Of the fundamental Equation of the Theory of Capillary Action. 2. Of a new manner of considering Capillary Attraction. 3. Of the Attraction and apparent Repulsion of small Bodies which move on the surface of Fluids. 4. On the Adhesion of Discs to the Surface of Fluids. 5. On the Figure of a large Drop of Mercury, and of the Depression of the Fluid in a Tube of Glass of a great Diameter. The theoretical results obtained from the formulæ investigated by M. La Place agree, in a very wonderful manner, with a series of experiments made, at his request, by M. Gay Lussac, as will be seen from the abstract of this theory with which the present chapter is concluded.

Having thus given a brief account of the progress of this branch of science, we shall now lay before our readers such additional information on the cohesion of fluids and on capillary attraction, as may appear to be necessary for completing the view of the subject which might be expected in a work of this kind.

### Sect. I. *On Capillary Attraction.*

#### 1. *On the Ascent of Fluids in Glass Tubes.*

The experiments which were made during the last century on the ascent of fluids in tubes of glass, differed so widely from each other in their results, that no confidence whatever could be placed in them. Some philosophers did not scruple to assign different heights for the same fluid and the same tube;* and even if the proper mode of cleaning the tube had enabled them to observe the highest point to which the water rose, they had no correct method of measuring the difference of level between the summit of the elevated column and the surface of the fluid. The rise of the water on the outside of the glass tube, rendered it particularly difficult to make such a measurement with the accuracy which such delicate observations required.

The first attempt to construct an accurate instrument, appears to have been about the same time by Dr Brewster and M. Gay Lussac, who, without any knowledge of each other's invention, have employed the very same principles for ascertaining, with the utmost accuracy, the altitude of the fluid above its natural level. We do not know which of these inventions are entitled to the merit of priority. Dr Brewster's instrument was invented some time in 1806. An account of it was submitted to the Royal Society of Edinburgh in February 1811, and a drawing and description of it was published in our article Capillary Attraction in 1812. Gay Lussac's instrument must have been invented in 1807, and probably much earlier, as the experiments contained in La Place's second supplement, which appeared in that year, seem to have been made with it; but so far as we know, no description of the instrument was published till 1816, when it appeared in M. Biot's *Traité de Physique.*

This instrument is represented in Plate CCCXVI. Fig. 3, where ABCD is a large cylindrical vessel of glass for containing the liquid. It is placed upon a base, which can be adjusted by the three *adjusting* screws V, V, V, so that its orifice AB may be perfectly horizontal, which can easily be ascertained by placing a level upon it. The capillary tube TSH with which the experiment is to be made, has a vertical motion in a groove CC, perpendicular to a plate *a b*, which is placed on the orifice AB of the glass vessel. By this means the tube is kept in a vertical position, and it is required only to measure the height of the column HS above the level NN of the fluid. For this purpose Gay Lussac employs a divided rule RR, which can be placed in a vertical position by means of two adjusting screws *v v*, and a plumb line FP. Along the divided scale, a small telescope GH of a short focal length, and with cross wires in the focus of the eye-glass, is made to move by the screw nut *s*, so that the horizontal wire may be made just to touch the lowest point of the surface of the fluid. In order to determine the point H which corresponds to the natural level of the fluid surface, the plate *a b*, along with the tube TT, is pushed aside till it is stopped by the side of the glass vessel, (for if it were taken out, the surface NN would descend,) and the bar *t t* resting upon the plate *a' b'* is placed on the side of the vessel from which the tube has been moved. The bar *t t* is made

* See our account of Carré's experiments, p. 808.

to descend by a screw cut upon it, till the lower point $t$ touches the water, which is known by the water rising instantaneously round it. When this contact is effected, a small portion of the water is removed by the small measure M, at the end of a crooked wire, so that the lower extremity $t$ is above the surface of the liquid by a very small quantity. The horizontal wire of the telescope is then made to come into apparent contact with the end $t$ of the bar, and the distance between this and the division corresponding to S, is a true measure of the altitude HS of the fluid.

It is obvious from the method now described, that the altitude thus found must always be too small, and that a correction depending upon the quantity of water removed by the measure M should be made. This correction must be very small, if the diameter of the glass vessel is great. This instrument is obviously liable to a source of error, from the interposition of the glass vessel between the telescope and the fluid column, as the least inequality or difference of parallelism in the parts of the glass opposite to S and H, would produce a sensible error in the result. This, however, may be easily obviated by cutting a piece out of the glass vessel, and cementing upon it a plate of parallel glass. We would also recommend, in making very accurate observations, that the sides of the glass tube next the telescope should be either ground flat about S, or have any inequality of refraction removed, by cementing upon it a plate of parallel glass.

The method of measuring the cohesion of fluids, which we have described for the first time under Capillary Attraction, will, we have no doubt be found the most correct. The apparatus will be greatly improved by using two solids of the same kind and form instead of one. By this means the termination of the elevated circle of fluid will be more easily ascertained.

With the instrument shewn in fig. 3, M. Gay Lussac has made several experiments on the ascent of water and alcohol in tubes of glass, of which the following are the results. In these experiments, the tubes were well wetted with the fluid.

Water.

| | Diameter of the Tubes in Millimetres. | Height of the Water in Millimetres above the lowest point of its Concavity. | Temperature in Degrees of the Centigrade Thermometer. |
|---|---|---|---|
| Exp. 1. | 1.29441 | 23.3164 | 8°.5 |
| Exp. 2. | 1.90381 | 15 5861 | |

The first of these experiments gives a constant quantity of 0.04641 in English inches, and the second a constant quantity of 0.04604. We have inserted these in the following table of constant quantities, for the purpose of giving a general view of the different results which have been obtained.

| Constant quantity in inches. | Observers. |
|---|---|
| 0.020 | Newton. See *Optics*, p. 366, 3d edit. |
| 0.021 | MM. Hauy and Tremery. |
| 0.026 | M. Hallstrom.* |
| 0.033 | Dr. Brewster, with a tube 0.0561 of an inch in diameter. |
| 0.0392 | Muschenbroek. This is given by Dr T. Young as the result of Muschenbroek's best experiment. |
| 0.040 | Average assumed by Dr T. Young. |
| 0.042407 | Average of Weitbrecht's seven experiments. |
| 0.04641 | Gay Lussac, with a tube 1.90 millimetres in diameter, and for the lower surface of the meniscus. |
| 0.04604 | Do. with a tube 1.29 millimetres in diameter. |
| 0.048 | Benjamin Martin |
| 0.053 | Mr Atwood. |
| 0.0645 | James Bernoulli. |

Our readers will no doubt be much surprised at the great discrepancy among the results in the preceding table, and particularly between those obtained by Dr Brewster and M. Gay Lussac, which were made with instruments founded on the same principle. M. La Place has ascribed these differences to the greater or less degrees of humidity on the sides of the tubes; and he informs us, that, in Gay Lussac's experiments the tubes were very much wetted. Now, it appears to us, that though by this method the water will always stand nearly at the same height in the same tube, yet it does not afford us an accurate measure of the height of ascent. Let us suppose that a tube $\frac{1}{100}$ of an inch in diameter is so perfectly cleared of all grease and extraneous matter, that the attractive force of the glass is allowed to exert itself without any diminution, and that the water stands at the height of 3.3 inches. Let us now suppose that by some means or other a film of water of the thickness of $\frac{1}{300}$ of an inch is introduced at the upper end of the tube, and equably diffused over its interior surface, it is obvious that the water will rise above its former level, and consequently to a height greater than that which is due to the force exerted by the tube and the mutual action of the fluid. We conceive, therefore, that M. Gay Lussac's measures err in excess; and that the error increases inversely as the diameter of the tube.

The discrepancies in the table appear to us also to be partly owing to the different kinds of glass employed. The flint glass of which tubes are composed, varies very much in its density; and there is every reason to believe, both from analogy and from some direct experiments which we have made, that the substance of the tube has a very perceptible influence on the height to which the fluid ascends.

The following were the results which M. Gay Lussac obtained for alcohol.

Alcohol.

| Exp. | Diameter of the Tube in Millimetres. | Height of the Alcohol in Millimetres above the lowest part of its Concavity. | Density of the Alcohol. | Temperature in degrees of the Centigrade Scale. |
|---|---|---|---|---|
| 1. | 1.29441 | 9.18235 | 0.81961 | 8°.5 |
| 2. | 1.90381 | 6.08397 | 0.81961 | 8°.5 |
| 3. | 1 29441 | 9.30079 | 0 8595 | |
| 4. | 1.29441 | 9 99727 | 0.94153 | |
| †5. | 10.508 | 0.3835 | 0.813467 | |

The results of experiments 1 and 2, when reduced to English inches, give .01798 and .01840 for the value of the constant quantity. The constant quantity for alcohol found by Dr Brewster is almost the same as this, namely .0178. Benjamin Martin makes the constant quantity 18, and Muschenbroek 10.

M. Gay Lussac obtained the following result for oil of turpentine.

* M. Hallstrom found that water rose 11.7 Swedish lines in a tube 0.7 of a line in diameter.

† This is a mean of five experiments.

OIL OF TURPENTINE.

| Diameter of Tube in Millimetres. | Altitude. | Density. |
|---|---|---|
| 1.29441 | 9.95159 | 0.869458 |

The following are the experiments which were made at the desire of La Place, by Messrs. Hauy and Tremery:

| Diameter of Tube in Millimetres. | Height of the Water in Millimetres. | Constant Quantity or Height for a Tube 1 millimetre in Diameter. |
|---|---|---|
| | WITH WATER | |
| 2 0000 | 6 75 | 13.500 |
| 1.3333 | 10 00 | 13.333 |
| 0.7500 | 18.00 | 31.875 |
| | | Mean 13.5693 |
| | WITH OIL OF ORANGES. | |
| 2.0000 | 3.400 | 6 8 |
| 1.3333 | 5.000 | 6.6667 |
| 0.7500 | 9.00 | 6.75 |

The following experiments were made by Dr Robison with a tube of a very slender bore.

| | |
|---|---|
| Oil of turpentine | 1.35 inches. |
| Spirits of wine | 2 5 |
| Water | 5.5 |
| Caustic volatile alkali | 6.25 |
| Solution of sal ammoniac | 8.07 |

2. *On the Ascent of Fluids between two Plates of Glass.*

It appears from the experiments mentioned by Newton in his *Optics*, (p. 366. edit. 3d, 1721,) that water rose one inch between two plates of glass, whose distance was $\frac{1}{100}$ of an inch, and that water rose to the same height in a capillary tube, the semi-diameter of whose bore was equal to the distance of the plates, which gives .010 as the constant quantity for the glass plates, and .020 as the constant quantity for capillary tubes.

The following experiments were made by M. Monge, on the rise of water between two plates of glass. The plates of glass were first cleaned with caustic alkali, and carefully washed, and, when separated to different distances, by the interposition of silver wires of different thicknesses, they were plunged in the water of the Seine, which had been previously filtered. The diameters of the silver wires, from which the distance of the plates was inferred, were obtained by rolling a wire round a tube of glass, and finding the number of thicknesses which occupied an exact number of lines. By dividing the number of lines by the number of revolutions, he obtained the exact diameter of the wire, and consequently the distance of the plates. The following are the results which he obtained.

| Distance between the plates of glass in parts of a line. | Height of the water above its level, in lines. | Constant quantity. |
|---|---|---|
| $\frac{4}{33}$ or 0.1212 inch | 15.5 lines. | 18 786 |
| $\frac{4}{39}$ 0.0802 | 33.5 | 26.80 |
| $\frac{1}{38}$ 0.03571 | 74 | 26.427. |

Messrs Hauy and Tremery likewise observed the height to which water ascended between two parallel plates of glass placed vertically, at the distance of 1 millimetre, and obtained the following result:

| Distance between the Plates, Millimetre. | Height of ascent in Millimetres. | Constant quantity in Millimetres. |
|---|---|---|
| 1 | 6.5 | 6.5 |

M. Gay Lussac measured with great care the rise of water between two plates of glass ground perfectly flat, and placed exactly parallel to each other. In order to do this with accuracy, he kept the plates separate by four very fine iron wires cut consecutively from the same piece, so as to have their diameters as equal as possible; and in order to find the thickness of the wire, he placed a great number of them together, and measured the sum of their diameters. The following was the result of his observations.

| Distance of the Plates of Glass in Millimetres. | Height of the Water to the lowest point of the Concavity in Millimetres. | Temperature in the Centigrade Scale. |
|---|---|---|
| 1.069 | 13.574 | 16° |

The constant quantity is here 14.51, or 0.02251, when reduced to English inches, for a distance of $\frac{1}{100}$th of an inch.

It is obvious from these experiments, that water ascends to twice the distance in capillary tubes that it does between two plates, whose distance is equal to the diameter of the tube.

We have already seen, under CAPILLARY ATTRACTION, that if the two plates of glass are inclined to each other at a small angle, the water will rise between them in such a manner that its surface is a hyperbola. Thus, in Plate CCCXVI. Fig. 4. let ABEF, CDEF be the two plates of glass, and DE the surface of the water, then E $n$ $p$ D, E $m$ o B will be the surface of the fluid, which Mr Hawksbee found to be hyperbolic, by measuring the ordinates of abscissæ of the curves.

The hyperbolic form of the surface may be deduced from the observed fact, that the altitudes of the fluids in capillary tubes, or between parallel glass plates, are inversely as the diameters of the tubes, or the distance of the plates. The distance of the plates at $m$ is obviously $m\ n$, or $s\ t$, and their distance at $o$ is $o\ p$ or $q\ r$. But $m\ s$ and $o\ q$, being the altitudes of the fluid at $m$ and $o$, we have $m\ s : o\ q = o\ p : m\ n$, but $F\ t : F\ r = s\ t$ or $m\ n : q\ r$, or $o\ p$. Hence $F\ t : F\ r = m\ n : o\ p$. But in the Apollonian hyperbola, the ordinates are inversely proportioned to their respective abscissæ, and therefore E $m$ $o$ B is the Apollonian hyperbola. Mr Hawksbee's experiments have already been given in p. 809.

3. *On the Depression of Mercury and Melted Lead in Capillary Tubes.*

If a capillary tube of glass is immersed in mercury, or any of the metals in a fluid state, the metallic fluid, instead of being elevated like water, stands considerably lower in the tube than in its natural surface. The most correct experiments on the depression of mercury were made by Lord Charles Cavendish. The following are the results which he obtained:

| Inside Diameter of the Tube in Inches. | Grains of Quicksilver in one Inch of the Tube. | Depression of the Surface of the Mercury in Inches. |
|---|---|---|
| 0.6 | 972 | 0.005 |
| 0.5 | 675 | 0.007 |
| 0.4 | 432 | 0.015 |
| 0.35 | 331 | 0.025 |
| 0.30 | 243 | 0 036 |
| 0.25 | 169 | 0.050 |
| 0.20 | 108 | 0.067 |
| 0.15 | 61 | 0.092 |
| 0.10 | 27 | 0.140 |

Messrs Hauy and Tremery found the following depression of mercury:

| Diameter of the tube. | Depression of the mercury. |
|---|---|
| 2 millimetres. | 3.666 millimetres. |
| 1.333 | 5.5 |

The ultimate product or constant quantity inferred by Dr T. Young from Lord C. Cavendish's experiments is 0.015, whereas Hauy's experiments make it 0.01137.

The results of the experiments of Gellert have already been given in p. 811.

Water suffers also a depression like mercury in tubes of glass that have been coated with grease. This was first observed by Carré, and was afterwards verified by the experiments of Cigna and Dutour.

M. Dutour took two tubes, each of which was about two lines in diameter, and having lined one of them with a thin film of wax, and the other with grease, he plunged them about four lines deep in water. The water was depressed in both the tubes, but less in the first than in the second.

### 4. *On the Adhesion of Discs to the Surface of Fluids.*

In our article Adhesion, we have already given an account of the experiments of Taylor, Morveau, Achard, and Dutour.

The following results were obtained by M. Gay Lussac for a circular plate of white glass, with water, alcohol, and oil of turpentine.

| Fluids. | Diameter of the circular plate. Millimetres. | Weight necessary to raise it. Grammes. | Specific Gravity. |
|---|---|---|---|
| Water | 118.366 | 59.40 | |
| Alcohol | 118 366 | 31.08 | 0.81961 |
| Alcohol | 118.366 | 32.87 | 0.8594 |
| Alcohol | 118.366 | 37.152 | 0.94153 |
| Oil of turpentine | 118.366 | | |

The following result was obtained for a disc of copper:

| | Diameter of disc of copper. | Weight necessary to raise it. | Temperature centigrade. |
|---|---|---|---|
| Water | 116.604 | 57.945 | 18°.5 |

M. Gay Lussac made many experiments on the adhesion of a disc of glass to mercury, but the results which he obtained differed widely from one another. In making his experiments on the adhesion of discs of glass, the disc was suspended at one scale of a balance, and raised vertically by placing, successively and slowly, small weights in the other scale. The sum of these weights at the moment when the disc detached itself, indicated the force of adhesion. In making these experiments on mercury, however, he observed, that the sum of the weights was more or less great according to the slowness with which they were successively added; and in adding them at very great intervals, the sum varied from 158 grammes to 296 grammes for a disc 118.366 millimetres in diameter.

Besile found, that the adhesion of 25 square lines of mercury was 82 French grains, while that of the same surface of water was $8\frac{1}{4}$ grains. In some cases, he found that the apparent adhesion was diminished under the exhausted receiver of an air pump.

### 5. *On the Magnitude and Form of Drops of Fluids.*

The effect of the cohesion of fluids is very finely exemplified in the formation of drops. It is obvious, that drops of fluids that have the least force of cohesion, will have the least magnitude, provided their specific gravities are the same; for the effect of the force of cohesion must be diminished by the weight of the drop which will be sooner detached, and therefore of a less magnitude, than if the fluid had less weight. Dr Young infers, from the law of the superficial cohesion of fluids, "that the linear dimensions of similar drops depending from a horizontal surface, must vary precisely in the same ratio as the heights of ascent of the respective fluids against a vertical surface, or as the square roots of the heights of ascent in a given tube. Hence the magnitudes of similar drops of different fluids must vary as the cubes of the square roots of the heights of ascent in a tube." In water, for example, Dr Young found the weight of a drop to be 1.8 grains, and the weight of a drop of diluted alcohol 0.85 of a grain; whereas the height of the same alcohol was to the height of water in the same tube as 100 to 64. The weight of the drop should have been .82, as inferred from the consideration of the heights of ascent combined with that of the specific gravities. This result is widely different from that which was obtained by Dr Brewster (See p. 742.) with his capillary hydrometer. The magnitude of a drop of water was to the magnitude of a drop of spirit nearly proof as 2.93 to 1; and, therefore, taking the specific gravity of spirit at 0.920, the weights of the drops were to one another as 3.255 to 1, or as 100 to 31 nearly.

The magnitude of drops of fluids depends also upon the form of the surface from which they fall. If the fluid is collected at the extremity of a very minute fibre of glass, the drop will fall when its weight balances the attractive force exerted by the glass, and therefore, in the present case, the drop will be very small; but if the fluid is collected on a hemispherical surface, the surface of glass which is in contact with the fluid is greater; and, therefore, the drop must contain a much greater quantity of water before its weight balances the attractive force of the hemispherical surface.

The form of a drop of fluid, abstracting the consideration of its weight, would always be that of a perfect sphere; and we accordingly find that the drops of rain by which the rainbow is formed, and very small drops of fluids lying upon a surface which does not attract them, have a shape almost perfectly spherical. In other cases the form of a drop is modified by its weight. Dr Young has given the following as the equation of the surface of a drop of water:

$$a a x \ddot{x} + a a \dot{y} y = x y \dot{y} \ddot{z} \text{ when } \ddot{z} = 0, \text{ or}$$

$$a^4 x^2 \ddot{x}^2 + 2 a^4 x \dot{y}^2 \ddot{x} + (a^4 - x^2 y^2) \dot{y}^4 - x^2 y^2 \dot{x}^2 \dot{y}^2 = 0.$$

In order to shew that two drops of water do not attract each other when at a distance, M. Monge put some spirit of wine into a cup, and having taken a capillary tube containing some of the same fluid, he allowed it to fall from a height of a few lines, drop by drop, into the cup; the drops did not immediately mix with the rest of the fluid, but preserved their form, which was nearly spherical; rolled over the surface with great freedom, like balls over a billiard table, impinged against each other; changed their form by the force of impact; and, after being reflected from each other, continued to move upon the surface till they were again mixed with the general mass. This experiment does not succeed so well when the spirit of wine is warm. M. Monge explains this phenomenon by supposing that a thin film of air adheres to the drop; and, by diminishing its specific gravity, causes it to float upon the fluid surface; and hence he concludes, that the experiment will succeed best with those liquids which are most evaporable, or which have the greatest affinity for the surrounding air. A similar phenomenon, as M. Monge observes, is seen in the drops of water which fall from the oars during the rowing of a boat, and in the drops produced by the condensation of the steam of any warm fluid, such as coffee, &c. These drops are real spheres of fluid, and not spherical vesicles like those formed on the surface of water with heavy rains. These results are hostile to the idea of M. Saussure, who, in his Essays on Hygrometry, has stated that drops of the same liquid cannot be pushed against one another, nor remain simply in contact without instantly uniting; and that only hollow vesicular globules are capable of floating upon the surface of the same fluid with themselves.

In repeating the experiments of Monge, Dr Brewster found that the appearances were most beautiful when the capillary tube dischared the drops upon the inclined plane of fluid, which is elevated by the attraction of the edge of the cup. They ran down the inclined plane with great velocity, and sometimes even ascended the similar plane on the opposite side of the vessel. When the drop was discharged at the distance of one or two-tenths of an inch from the surface of the water, they had always the same magnitude when the tube was held in the same position; but when the point of the tube was brought within a tenth of an inch of the surface of the spirit of wine, this surface, instead of attracting the drop to it instantly, as Saussure would have predicted, actually resisted the gravity or weight of drop, and allowed it to attain a diameter nearly twice as great as it would have had, if it had been discharged in the ordinary manner. This swoln globule floated upon the surface in the same manner as the smaller drops, surrounded with a depression of the fluid surface similar to what is produced by a glass globule floating on mercury, or by the feet of particular insects, that have the power of running upon the surface of water. (See Fig. 5.) The floating globules are often produced even when they are discharged from a height of three or four inches; and by letting them fall upon the inclined plane of fluid formerly mentioned, they will often rebound from the surface, and fall over the sides of the cup.

When a drop of mercury is laid upon glass, it assumes a flat spheroidal form, in consequence of its weight. The section of its surface, as M. La Place observed, by a vertical plane drawn through its centre, is very much curved at its summit. The curvature increases on receding from that point, till the tangent to the curve is vertical. At this point, the curvature and the width of the section will be a maximum. Below that point it will approach its axis, and will at last coincide with the plane of the glass, and form with it an acute angle. M. Gay Lussac observed at the temperature of 12°.8 of the centigrade thermometer, the thickness of a large drop of mercury, circular, and a decimeter in diameter, resting upon a plane surface of white glass perfectly horizontal. By a very accurate micrometer, he found its thickness to be 3.378 millimetres. M. Segner had long before obtained nearly the same result, viz. 3.40674 millimetres.

The cohesion of fluids is beautifully shewn in a phenomenon, which is the very reverse of the formation of a drop, and which was first observed by Dr Brewster. If we take a phial, with a wide mouth, half filled with Canada balsam, and allow the balsam to flow to the mouth of the phial and fill it up, then when the phial is placed on its bottom, a fine transparent film of balsam will be seen extending over the mouth of the phial. If we now take a piece of slender wire, and touch the film near the middle, so as to tear away a little part of it, the remaining part of the film which has been elevated by this force will descend to its level position, and the ragged aperture from which the balsam has been torn will be seen to assume a form perfectly circular, having its edge in a slight degree thickened, like a circle with a raised margin turned out of a piece of wood. This fine circular aperture grows wider and wider, and continues to preserve its circular form till the mouth of the phial is again opened.

The following curious experiment, which was performed by Dr Brewster, is intimately connected with the subject of capillary attraction. Above a vessel MNOP, Fig. 6. nearly filled with water, a convex lens LL was placed at the distance of the 10th of an inch, and rays R, R, R, were incident upon its upper surface. The focus of these rays was at F, a little beyond the bottom of the vessel, so that a circular image of the luminous object was seen on the bottom of the vessel, having AB for its diameter. If the lens is now made to descend gradually towards the surface of the water, and the eye kept steadily upon the luminous image AB, a dark spot will be seen at $\varphi$ in the centre of AB, a little while before the lens attracts and elevates the water MN. Sometimes this spot may be seen playing back and forwards by the slight motion of the hand, so that the lens can even be withdrawn from the fluid surface without having actually touched it. In general, however, the sudden rise of the water to the lens follows the appearance of the black spot. When the water is in contact with the glass, the focus of the rays R, R is now transferred to $f$, and the circular image on the bottom is now $a\,b$, and the intensity of the light in this circle is to that in the circle AB, as $AB^2 : a\,b^2$. Now it is obvious, that the darkish spot at $\varphi$ is just the commencement of the transference of the focus from F to $f$; or when the dark spot is produced, the progress of the rays is the same as if the focus were transferred to $f$. This remarkable effect may arise from two causes. 1. The approach of the lens to the surface MN, may occasion a depression $m\,o\,n$ in the surface of the fluid of the same curvature as L $l$ L, which would have the effect of transferring the focus from F to $f$. This depression may be produced by a film of air adhering to the lens, in the same manner as the depression is produced on the surface of alcohol, by a drop of alcohol rolling over it, as shewn in Fig. 5, or by some other repulsive force with which we are unacquainted. 2. The transference of the focus from F to $f$, may be occasioned by the optical contact of the glass and water taking place at a greater distance from the lens than the distance at which the capillary attraction commences. For if the surfaces $l\,l$, $m\,n$, at a certain distance, act upon the rays of light as if they were one surface, then it is manifest that a dark spot ought to appear at $\varphi$, if this distance is less than that at which capillary attraction begins.

### 6. *Account of La Place's Theory of Capillary Attraction.*

In the first supplement published by M. le Comte La Place, his method of considering the phenomena was founded on the form of the surface of the fluid in capillary spaces, and on the conditions of equilibrium of this fluid in an infinitely narrow canal, resting by one of its extremities upon this surface, and by the other on the horizontal surfaces of an indefinite fluid, in which the capillary tube was immersed. In his second supplement, he has examined the subject in a much more popular point of view, by considering directly the forces which elevate and depress the fluid in this space. By this means he is conducted easily to several general results, which it would have been difficult to obtain directly by his former method. Of this method we shall endeavour to give as clear a view as possible.

Let AB, Fig. 7. be a vertical tube whose sides are perpendicular to its base, and which is immersed in a fluid that rises in the interior of the tube above its natural level. A thin film of fluid is first raised by the action of the sides of the tube; this film raises a second film, and this second film a third film, till the weight of the volume of fluid raised exactly balances all the forces by which it is actuated. Hence it is obvious, that the elevation of the column is produced by the attraction of the tube upon the fluid, and the attraction of the fluid for itself. Let us suppose that the inner surface of the tube AB is prolonged to E, and after bending itself horizontally in the direction ED, that it assumes a vertical direction DC; and let us suppose the sides of this tube to be so extremely thin, or to be formed of a film of ice, so as to have no action on the fluid which it contains, and not to prevent the reciprocal action which takes place between the particles of the first tube AB and the particles of the fluid. Now, since the fluid in the tubes AE, CD is in equilibrium, it is obvious, that the excess of pressure of the fluid in AE is destroyed by the vertical attraction of the tube and of the fluid upon the fluid contained in AB. In analyzing these different attractions, M. La Place considers first those which take place under the tube AB. The fluid column BE is attracted, 1. by itself; 2. by the fluid surrounding the tube BE. But these two attractions are destroyed by the similar attractions experienced by the fluid contained in the branch DC, so that they may be entirely neglected. The fluid in BE is also attracted vertically by the fluid in AB; but this attraction is destroyed by the attraction which it exercises in the opposite direction upon the fluid in BE, so that these balanced attractions may likewise be neglected. The fluid in BE is likewise attracted vertically upwards by the tube AB, with a force which we shall call Q, and which contributes to destroy the excess of pressure exerted upon it by the column BF raised in the tube above its natural level.

Now, the fluid in the lower part of the round tube AB is attracted, 1. By itself; but as the reciprocal attractions of a body do not communicate to it any motion if it is solid, we may, without disturbing the equilibrium, conceive the fluid in AB frozen. 2. The fluid in the lower part of AB is attracted by the interior fluid of the tube BE, but as the latter is attracted upwards by the same force, these two actions may be neglected as balancing each other. 3. The fluid in the lower part of BE, is attracted by the fluid which surrounds the ideal tube BE, and the result of this attraction is a vertical force acting downwards, which we may call $-Q'$, the contrary sign being applied, as the force is here opposite to the other force Q. As it is highly probable that the attractive forces exercised by the glass and the water vary according to the same function of the distance, so as to differ only in their intensities, we may employ the constant co-efficients $\varrho$, $\varrho'$ as measures of their intensity, so that the forces Q and $-Q'$ will be proportional to $\varrho$ $\varrho'$; for the interior surface of the fluid which surrounds the tube BE, is the same as the interior surface of the tube AB. Consequently, the two masses, viz. the glass in AB, and the fluid round BE, differ only in their thickness; but as the attraction of both these masses is insensible at sensible distances, the difference of their thicknesses, provided their thicknesses are sensible, will produce no difference in the attractions. 4. The fluid in the tube AB is also acted upon by another force, namely, by the sides of the tube AB in which it is inclosed. If we conceive the column FB divided into an infinite number of elementary vertical columns, and if at the upper extremity of one of these columns we draw a horizontal plane, the portion of the tube comprehended between the plane and the level surface BC of the fluid, will not produce any vertical force upon the column; consequently, the only native vertical force is that which is produced by the ring of the tube immediately above the horizontal plane. Now, the vertical attraction of this part of the tube upon BE, will be equal to that of the entire tube upon the column BE, which is equal in diameter, and similarly placed. This new force will therefore be represented by $+Q$. In combining these different forces, it is manifest that the fluid column BF is attracted upwards by the two forces $+Q$, $+Q$, and downwards by the force $-Q'$; consequently, the force with which it is raised upwards will be $2Q-Q'$. If we represent by V the volume of the column BE, D its density, and $g$ the force of gravity, then $gDV$ will represent the weight of the elevated column; but as this weight is in equilibrio with the forces by which it is elevated, we have the following equation:

$$g\,DV = 2Q - Q'.$$

If the force 2Q is less than $Q'$, then V will be negative, and the fluid will sink in the tube; but as long as 2Q is greater than $Q'$, V will be positive, and the fluid will rise above its natural level; as was long before shewn by M. Clairaut.

Since the attractive forces, both of the glass and the fluid, are insensible at sensible distances, the surface of the tube AB will act sensibly only on the column of fluid immediately in contact with it. We may therefore neglect the consideration of the curvature, and consider the inner surface as developed upon a plane. The force Q will therefore be proportional to the width of this plane, or, what is the same thing, to the interior circumference of the tube. Calling $c$, therefore, the circumference of the tube, we shall have $Q = \varrho c$; $\varrho$ being a constant quantity, representing the intensity of the attraction of the tube AB upon the fluid, in the case where the attractions of different bodies are expressed by the same function of the distance. In every case, however, $\varrho$ expresses a quantity dependent on the attraction of the matter of the tube, and independent of its figure and magnitude. In like manner we shall have $Q' = \varrho' c$; $\varrho'$ expressing the same thing with regard to the attraction of the fluid for itself, that $\varrho$ expressed with regard to the attraction of the tube for the fluid. By substituting these values of Q, $Q'$, in the preceding equation, we have $g\,DV = c\,(2\varrho - \varrho')$.

If we now substitute, in this general formula, the value of $c$ in terms of the radius if it is a capillary tube, or in terms of the sides if the section is a rectangle, and the value of V in terms of the radius and altitude of the fluid column, we shall obtain an equation by which the heights of ascent may be calculated for tubes of all diameters, after the height, belonging to any given diameter, has been ascertained by direct experiment.

In the case of the cylindrical tube, let $\pi$ represent the ratio of the circumference to the diameter, $h$ the height of the fluid column reckoned from the lower point of the meniscus, $q$ the mean height to which the fluid rises, or the height at which the fluid would stand if the meniscus were to fall down and assume a level surface, then we have $\pi r^3$ for the solid contents of a cylinder of the same height and radius as the meniscus; and as the meniscus, added to the solid contents of the hemisphere of the same radius, must be equal to $\pi r^2$, we have $\pi r^3 - \frac{2\pi r^3}{3}$, or $\frac{\pi r^3}{3}$, for the solid contents of the meniscus. But since $\frac{\pi r^3}{3}=\pi r^2 \times \frac{r}{3}$, it follows that the meniscus $\frac{\pi r^3}{3}$ is equal to a cylinder whose base is $\pi r^2$, and altitude $\frac{r}{3}$. Hence, we have $q=h+\frac{r}{3}$;

or, what is the same thing, the mean altitude $q$ in a cylinder is always equal to the altitude $h$ of the lower point of the concavity of the meniscus increased by one third of the radius, or one sixth of the diameter of the capillary tube. Now, since the contour $c$ of the tube $=2\pi \varrho$, and since the volume V of water raised is equal to $q \times \pi r^2$, we have, by substituting these values in the general formula,

$$g\, D\, q \pi r^2 = 2\pi r\,(2\varrho - \varrho'), \quad \text{(No. 1.)}$$

and dividing by $\pi r$ and $g$ D, we have,

$$r q = 2\,\frac{2\varrho - \varrho'}{g\, D} \text{ and } q = 2\frac{2\varrho - \varrho'}{g\, D} \times \frac{1}{r}. \quad \text{(No. 2.)}$$

In applying this formula to Gay Lussac's experiments, we have the constant quantity $2\,\frac{2\varrho - \varrho}{g\, D} = r q = 647205 \times \overline{23{,}1634 + 0{,}215735} = 15{,}1311$ for Gay Lussac's 1st experiment. In order to find the height of the fluid in his 2d tube by means of this constant quantity, we have $r=\frac{1.90381}{2}=0.951905$, and $2\,\frac{2\varrho - \varrho'}{g\, D} \times \frac{1}{3} = q = \frac{15{,}1311}{0.951905} = 15.8956$, from which, if we subtract one sixth of the diameter, or 0.3173, we have 15.5783 for the altitude $h$ of the lower point of the concavity of the meniscus, which differs only 0.0078 from 15.861, the observed altitude.

If we apply the same formula to Gay Lussac's experiments on alcohol, we shall find the constant quantity $2\frac{2\varrho - \varrho'}{g\, D} = 6.0825$ as deduced from the 1st experiment, and $h = 6.0725$, which differs only 0.0100 from 6.08397, the altitude observed.

From these comparisons it is obvious, that the mean altitudes, or the values of $q$, are very nearly reciprocally proportional to the diameters of the tubes; for, in the experiments on water, the value of $q$ deduced from this ratio is 15.895, which differs little from 15.9034, the value found from experiment; and that in accurate experiments, the correction made by the addition of the sixth part of the diameter of the tube is indispensably requisite.

If the section of the pipe in which the fluid ascends is a rectangle, whose greater side is $a$, and its lesser side $d$, then the base of the elevated column will be $= a\, d$, and its perimeter $c = 2\,a + 2\,d$. Hence, the value of the meniscus will be $\frac{a\, d^2}{2} - \frac{a\, \pi\, d^2}{8} = \frac{a\, d^2}{2}\left(1 - \frac{\pi}{4}\right)$, that is, $q = h + \frac{d}{2}\left(1 - \frac{\pi}{4}\right)$. Hence, if in the general equation No. 1. we substitute for $c$ its equal $2\,a + 2\,d$, and for V its equal $a\, d\, q$, we have

$$g\, D\, q\, a\, d = \overline{2\varrho - \varrho'} \times \overline{2\,a + 2\,d},$$

and dividing by $a$ and by $g$ D, we have

$$d\, q = 2\,\frac{2\varrho - \varrho'}{g\, D} \times \overline{1 + \frac{d}{a}}, \text{ and}$$

$$q = \frac{2\frac{2\varrho - \varrho'}{g\, D} \times \overline{1 + \frac{d}{a}}}{d}$$

In applying this formula to the elevation of water between two glass plates, the side $a$ is very great compared with $d$, and therefore the quantity $\frac{d}{a}$ being almost insensible, may be safely neglected. Hence the formula becomes

$$q = 2\frac{2\varrho - \varrho'}{g\, D} \times \frac{1}{d}.$$

By comparing this formula with the formula No. 2. it is obvious, that water will rise to the same height between plates of glass as in a tube, provided the distance $d$ between the two plates of glass is equal to $r$, or half the diameter of the tube. This result was obtained by Newton, and has been confirmed by the experiments of succeeding writers.

As the constant quantity $2\,\frac{2\varrho - \varrho'}{g\, D}$ is the same as already found for capillary tubes, we may take its value, viz. 15,1311, and substitute it in the preceding equation, we then have

$$q = \frac{15.1311}{1.060} t = 14.1544; \text{ and since}$$

$$h = q - \frac{d}{2}\left(1 - \frac{\pi}{4}\right), \text{ subtracting}$$

$$\frac{d}{2}\left(1 - \frac{\pi}{4}\right) = 0.1147, \text{ we have}$$

$h = 14.0397$, which differs very little from 13.574, the observed altitude.

It will be seen from the formula No. 2. that of all tubes that have a prismatic form, the hollow cylinder is the one in which the volume of fluid raised is the least possible, as it has the smallest perimeter. It appears also, that if the section of the tube is a regular polygon, the altitudes of the fluid will be reciprocally proportional to the homologous lines of the similar base, a result which, as we have seen, M. Gellert obtained from direct experiment. Hence in all prismatic tubes, whose sections are polygons inscribed in the same circle, the fluid will rise to the same mean height. If one of the two bases is, for example, a square, and the other an equilateral triangle, the altitudes will be as $2 : 3\frac{3}{4}$, or very nearly as $7 : 8$.

M. La Place has remarked, that there may be several states of equilibrium in the same tube, provided its width is not uniform. If we suppose two capillary tubes communicating with one another, so that the smallest is placed above the greatest, we may then conceive their diameters and lengths to be such, that the fluid is at first in equilibrium above its level in the widest tube, and that in pouring in some of the same fluid, so as to reach the smaller tube, and fill part of it, the fluid will still maintain itself in equilibrium. When the diameter of a capillary tube diminishes by insensible gradations, the different states of equilibrium are alternately stable and instable. At first the fluid tends to raise itself in the tube, and this tendency diminishing, becomes nothing in a state of equilibrium. Beyond this it becomes negative, and consequently the fluid tends to descend. Thus the first equilibrium is stable, since the fluid, being a little removed from this state, tends to return to it. In continuing to raise the fluid, its tendency to descend diminishes, and becomes nothing in the second state of equilibrium. Beyond this it becomes positive, and the fluid tends to rise, and consequently to remove from this state, which is not stable. In a similar manner it will be seen, that the third state is stable, the fourth instable, and so on.

Although the preceding method of considering the phenomena of capillary attraction is extremely simple and accurate, yet it does not indicate the connection which subsists between the elevation and depression of the fluid, and the concavity or convexity of the surface which every fluid assumes in capillary spaces. The object of M. La Place's first method, contained in his first supplement, is to determine this connection.

By means of the methods for calculating the attraction of spheroids, he determines the action of a mass of fluid terminated by a spherical surface, concave or convex, upon a column of fluid contained in an infinitely narrow canal, directed towards the centre of this surface. By this action La Place means the pressure which the fluid contained in the canal would exercise, in virtue of the attraction of its entire mass upon a plane base situated in the interior of the canal, and perpendicular to its sides, at any sensible distance from the surface, this base being taken for unity. He then shews that this action is smaller when the surface is concave than when it is plane, and greater when the surface is convex. The analytical expression of this action is composed of two terms: the first of these terms, which is much greater than the second, expresses the action of the mass terminated by a plane surface,* and the second term expresses the part of the action due to the sphericity of the surface, or, in other words, the action of the meniscus comprehended between this surface and the plane which touches it. This action is either additive to the preceding, or subtractive from it, acording as the surface is convex or concave. It is reciprocally proportional to the radius of the spherical surface; for the smaller that this radius is, the meniscus is the nearer to the point of contact.

From these results relative to bodies terminated by sensible segments of a spherical surface, La Place deduces this general theorem. "In all the laws which render the attraction insensible at sensible distances, the action of a body terminated by a curve surface upon an interior canal infinitely narrow, perpendicular to this surface in any point, is equal to the half sum of the actions upon the same canal of two spheres, which have for their radii the greatest and the smallest of the radii of the osculating circle of the surface at this point."

By means of this theorem, and the laws of hydrostatics, La Place has determined the figure which a mass of fluid ought to take when acted upon by gravity, or contained in a vessel of a given figure. The nature of the surface is expressed by an equation of partial differences of the second order, which cannot be integrated by any known method. If the figure of the surface is one of revolution, the equation is reduced to one of ordinary differences, and is capable of being integrated by approximation, when the surface is very small. La Place next shews, that a very narrow tube approaches the more to that of a spherical segment as the diameter of the tube becomes smaller. If these segments are similar in different tubes of the same substance, the radii of their surfaces will be inversely as the diameter of the tubes. This similarity of the spherical segments will appear evident, if we consider that the distance at which the action of the tube ceases to be sensible, is imperceptible; so that if, by means of a very powerful microscope, this distance should be found equal to a millimetre, it is probable that the same magnifying power would give to the diameter of the tube an apparent diameter of several metres. The surface of the tube may therefore be considered as very nearly plane, in a radius equal to that of the sphere of sensible activity; the fluid in this interval will therefore descend, or rise from this surface, very nearly as if it were plane. Beyond this the fluid being subjected only to the action of gravity, and the mutual action of its own particles, the surface will be very nearly that of a spherical segment, of which the extreme planes being those of the fluid surface, at the limits of the sphere of the sensible activity of the tube, will be very nearly in different tubes equally inclined to their sides. Hence it follows that all the segments will be similar.

The approximation of these results gives the true cause of the ascent or descent of fluids in capillary tubes in the inverse ratio of their diameter. If in the axis of a glass tube we conceive a canal infinitely narrow, which bends round like the tube ABEDC in Fig. 7. the action of the water in the tube of this narrow canal, will be less on account of the concavity of its surface, than the action of water in the vessel on the same canal. The fluid will therefore rise in the tube to compensate for this difference of action; and as the concavity is inversely proportional to the diameter of the tube, the height of the fluid will be also inversely proportional to that diameter. If the surface of the interior fluid is convex, which is the case with mercury in a glass tube, the action of this fluid on the canal will be greater than that of the fluid in the vessel, and therefore the fluid will descend in the tube in the ratio of their difference, and consequently in the inverse ratio of the diameter of the tube.

In this manner of viewing the subject, the attraction of capillary tubes has no influence upon the ascent or depression of the fluids which they contain, but in determining the inclination of the first planes of the surface of the interior fluid extremely near the sides of the tube, and upon this inclination depends the concavity or convexity of the surface, and the length of its radius. The friction of the fluid against the sides of the tube may augment or diminish a little the curvature of its surface, of which we see frequent examples in the barometer. In this case the capillary effects will increase or diminish in the same ratio.

The differential equation of the surfaces of fluids inclosed in capillary spaces of revolution, conducts La Place to the following general result; that if into a cylindrical tube we introduce a cylinder which has the same axis as that of the tube, and which is such that the space comprehended between its surface and the interior surface of the tube has very little width, the fluid will rise in this space to the same height as in a tube whose radius is equal to this width. If we suppose the radii of the tube and of the cylinder infinite, we have the case of a tube included between two parallel and vertical planes, very near each other. This result has been confirmed, as we have already seen, by the experiments of Newton, Hauy, and Gay Lussac. La Place then applies his theory to the phenomena presented by a drop of fluid, either in motion or suspended in equilibrium, either in a conical capillary tube, or between two plates, and inclined to each other, as discovered by Mr Hawksbee;—to the mutual approximation of two parallel and vertical discs immersed in a fluid;—to the phenomena which take place when two plates of glass are inclined to each other at a small angle;—and to the determination of the figure of a large drop of mercury laid upon a horizontal plate of glass.

In the application of his theory to the experimental results obtained by Hawksbee respecting the angles required for suspending a drop of oil of oranges at different stations between two inclined planes of glass, La Place obtained the results contained in the following table.

Column 1st contains the number of the first column of

* M. La Place is of opinion, that the suspension of mercury in a barometer tube, at a height two or three times greater than that which is due to the pressure of the atmosphere, depends on this term. He conceives too, that the refracting force of transparent bodies, cohesion, and in general chemical affinity, depend also upon it.

Hawksbee's table, subtracted from 20 inches; and column 2d contains Hawksbee's 2d column, diminished by 5′ 22″.

| Distance in inches from the middle of the drop to the intersection of the plane. | Angles of Elevation observed. | Angles of Elevation calculated by La Place's formula. | Differences in aliquot parts of the calculated angles. |

## Sect. II. *On the Approximation and Recession of Bodies floating near each other in a fluid.*

It was long ago observed by philosophers, that when bodies floating on the surface of a fluid approached either one another or the sides of the vessel, they moved rapidly into contact, as if they had been two floating magnets. This phenomenon, which was in general ascribed to the mutual attraction of the floating bodies, was tolerably well explained by M. Marriotte in his *Traité du Mouvement des Eaux.* It was reserved, however, for M. Monge to describe and explain these phenomena with accuracy, which he has done in his *Memoire sur quelques effets d'attraction ou de repulsion apparente entre les Molecules de Matiere.*

The following are the principal experiments upon this subject:

1. If two light bodies, capable of being wetted with water, are placed one inch distant on the surface of water perfectly at rest, they will float at rest, and experience no motion but what is derived from the agitation of the air; but if the distance at which they are placed is only a few lines, they will approach each other with an accelerated motion. If the vessel which contains the water is capable of being wetted by it, such as glass, and if the floating body is placed within a few lines of the edge of the vessel, it will move towards the edge with an accelerated motion.

2. If the two floating bodies are not susceptible of being wetted with fluid, such as two balls of iron in a vessel of quicksilver, and if they are placed at the distance of a few lines, they will move towards each other with an accelerated motion; and if the vessel is made of glass, in which the surface of the mercury is always convex, the bodies will move towards the sides when they are placed within a few lines of it.

3. If one of the bodies is susceptible of being wetted with water, and the other not, such as two globules of cork, one of which has been carbonised by the flame of a taper, then if we attempt, by means of a wire or any other substance, to make the bodies approach, they will fly from each other as if they were mutually repelled. If the vessel is of glass, and if the carbonised piece of cork is placed in it, it will be found impossible to bring the cork in contact with the sides of the vessel.

In these experiments it is obvious, that the approximation and the recession of the floating bodies are not produced by any attraction or repulsion between the two; for if the bodies, instead of floating on the fluid, are suspended by long and slender threads, it will be found that they have not the slightest tendency either to approach or recede when they are brought extremely near each other. From these experiments the following laws are deducible:

1. If two bodies, floating on the surface of a fluid, and capable of being wetted by the fluid, are placed near each other, they will approach as if they were mutually attracted.

2. If the two bodies are not susceptible of being wetted by the fluid, they will still approach each other when brought nearly into contact, as if they were mutually attracted.

3. If one of the two bodies is susceptible of being wetted and the other not, they will recede from each other as if they were mutually repelled.

*Explanation of the first law.*—If two plates of glass AB, CD, Fig. 8. are brought so near each other that the point H, where the two curves of elevated fluid meet, is on a level with the rest of the water, they will remain in perfect equilibrium. If they are brought nearer each other, however, as in Fig. 9. the water will rise between them to the height G. The mass of water which is thus raised, attracts the sides of the glass plates, and causes them to approximate in a horizontal direction, the mass of water having always the same effect as a curved chain hung to the two plates. The same thing is true of two floating bodies, when they come within such a distance that the fluid is elevated between them. This case is shewn in Fig. 10, where the bodies A, B, placed at a capillary distance, have the water raised between them, and are therefore brought together by the attraction of the fluid upon the sides of the globules.

*Explanation of the second law.*—If the two floating bodies A, B, Fig. 11, are not capable of being wetted by the liquid, the liquid will be depressed between them at H, below its natural level, when they are placed at a capillary distance. The two bodies, therefore, are more pressed inwards by the fluid which surrounds them, than they are pressed outwards by the fluid between, and in virtue of the difference of these pressures they mutually approach each other.

*Explanation of the third law.*—If one of the floating bodies A, Fig. 12. is capable of being wetted, while the other B is not, the fluid will rise round A, and be depressed round B: Hence the depression round B will not be symmetrical; and therefore the body B, being placed as it were on an inclined plane, its equilibrium is destroyed, and it will move towards the right hand, where the pressure is the least.

The results of M. Monge's experiments have been completely confirmed by the theory of capillary attraction given by La Place. From this theory it follows, that whatever be the nature of the substances of which the floating planes are made, the tendency of each of them to one another is equal to the weight of a prism of fluid whose height is the elevation of the fluid between the planes, measured to the extreme points of contact of the interior fluid with the plane, *minus* the elevation of the fluid on the exterior sides of the tube, whose depth is half the sum of these elevations, and whose width is the horizontal distance between the planes. The elevation must be reckoned negative when it changes into a depression as in mercury. If the product of the three preceding dimensions is negative, the tendency of the planes becomes repulsive. La Place also concludes, that when the planes are very near each other, the elevation of the fluid between them is in the inverse ratio of their mutual distance, and is equal to half the sum of the elevation which would have taken place, if we suppose the first plane of the same matter as the second, and the second of the same matter as the first.

It follows from these theorems, that the repulsive force of floating planes is much more feeble than the attractive force which is developed when the planes are very near each other, and which occasions them to approach each other with an accelerated motion. In this case the elevation of the fluid between the planes is very great, relative to its elevation on the outside of the same plane. In neglecting, therefore, the square of this last elevation in relation to the square of the first, the fluid prism, whose weight expresses the mutual tendency of the planes, in virtue of the first of the two preceding theorems, will be equal to the product of the square of the elevation of the interior fluid, by half the horizontal distance of the planes. This elevation being, by the second theorem, reciprocally proportional to the mutual distance of the planes, the prism will be proportional to their horizontal distance divided by the square of that distance. The tendency of the two planes to each other will consequently be in the inverse ratio of the square of their distance; and therefore, like the forces of electricity and magnetism, it will follow the law of universal attraction.

When the two planes are of such a nature that the one is capable of being wetted with the fluid, while the other is not capable of being wetted, then, in consequence of these two opposite actions, the surface of the intermediate fluid will have a point of inflection; and it follows from the theory, that they will repel each other at every distance. But if they are brought near each other by force, the point of inflexion will approach more and more to one of the planes, and will at last coincide with it. If the planes are then brought still nearer each other, the fluid will begin either to ascend, or be depressed between them. From this arises another force, which pushes the planes towards each other, and which, when it comes to surpass the pressure of the exterior fluid, causes the planes to approach each other with an accelerated motion. This change of repulsion into attraction appeared to M. La Place so singular, that he requested M. Hauy to examine the subject experimentally. In order to do this, he employed planes of ivory and talc, the first of which is capable of being wetted with water, while the other possesses that kind of unctuosity which prevents the water from adhering to it.

M. Hauy suspended, by a very fine thread, a small square plate of talc, so that the lower part of it was immersed in the water. Into the same vessel, at the distance of some centimetres, he immersed the lower part of a parallelopiped of ivory, so that one of its faces was parallel to the plate of talc. The ivory was made to advance towards the talc in this state of parallelism, and was stopped at short intervals, in order to shew that the effect of the motion communicated to the fluid was insensible in the experiment. When the parallelopiped of ivory, moving with great slowness, approached very nearly to the talc, the latter moved suddenly into contact with the ivory. In separating the two bodies, the ivory was wetted to a certain height above the level; and in repeating the experiment before wiping the ivory, the attraction commenced sooner, and sometimes exhibited itself at the very first, without being preceded by any sensible repulsion. This experiment was repeated several times with the same result.

Another series of phenomena, which indicate apparent attraction and repulsion, are seen in the motion of small lighted wicks when swimming in a basin of oil, and in the motion of camphor upon the surface of water. Although these phenomena are not produced by capillary attraction, yet we shall give a short account of them at present, on account of their general similarity.

The phenomena of lighted wicks were carefully observed, and minutely described, by Professor Wilson of Glasgow, in the Transactions of the Royal Society of Edinburgh. His *Hydrostatical Lamp*, as he calls it, consists of a small circular disc of common writing paper, about $\frac{3}{8}$ of an inch in diameter, having about a quarter of an inch of soft cotton thread rising up through a puncture in the middle of the disc, to answer the purpose of a wick. If this wick is lighted, and the disc placed in a shallow glass vessel, filled with pure salad oil, it will immediately sail briskly forward in one direction till it meets the side of the vessel, and will afterwards take a circular course, always bearing up to the sides, and will thus perform many revolutions. The circulation is sometimes from right to left, and sometimes from left to right. When the wick is placed out of the centre of the disc, it will sail to that part of the disc which is farthest from the wick, and if the disc is made of an oval form, and the wick placed in one of its foci, the disc will sail in the direction of the nearest extremity of the transverse axis. Dr Wilson observed a very active repulsion between the stem of the disc and the oil of the surface contiguous to it. When fine charcoal dust was scattered around the disc, it left behind it a diverging wake clear of all dust. Other fluids, such as oil of turpentine, ether, alcohol, or any of the inflammable fluids possessing much tenuity, also double rum, melted tallow, bees wax, and rosin, exhibit the same effects when the discs float upon their surface.

Dr Wilson accounts for these phenomena in the following manner: When the oil has an uniform temperature, all its parts are in equilibrio; but when the lamp is lighted, the oil below the disc being most heated, will expand itself, and will be raised above the general level, from the diminution of its specific gravity, and the unbalanced upward pressure of the fluid. The weight of the disc will therefore press down the oil, or even the weight of the oil itself will cause it to rise as it were from below the wick in a thin superficial stream. Hence Dr Wilson conceives, that this constant stream will flow most readily and copiously towards that side of the base of the lamp where the resistance is least, or where it has the shortest way to press forwards, that is, from under the wick or flame, or the edge of the disc which is the nearest. The re-action of the stream of rarefied oil rising most rapidly and most copiously from one side of the disc, will therefore impel the lamp in the contrary direction. When the discs are soaked with oil, or when they are made of a thin plate of talc, they always sink to the bottom as soon as the flame is extinguished. If a wafer much heated is thrown upon any of the fluids above mentioned, it will immediately glide away, and continue in motion till it cools.*

The singular motions of pieces of camphor floating upon the surface of water have been long observed; but they were never completely described and explained, till M. Venturi published, in the Memoirs presented to the Institute of France, his ingenious memoir, entitled *Precis de quelques experiences sur la section que des cylindres de camphre eprouvent a la surface de l'eau et reflexions sur les mouvemens qui accompagnent cette section.*

Having cut some pieces of camphor into the shape of small cylinders, a line in diameter, and an inch high, he fixed each of them to a base of lead, and placed them vertically in plates. He then poured water into the plates, till it reached about half way up each cylinder. After two or

* See the *Edinburgh Transactions*, vol. iv. p. 144, &c.

three hours the cylinders began to diminish at the place where they were cut by the surface of the water, and after about twenty-four hours they were entirely cut through into two parts, none of which had suffered any sensible diminution.

He next took three pieces of camphor, each of which weighed twenty-four grains, and he placed one of them in dry air, another in water, and the third on the surface of water. After four days the piece on the surface of the water was entirely dissipated, while each of the other two had lost only four or five grains.

M. Venturi next placed some of his camphor cylinders on the surface of water, in vessels of different sizes, and he always found that the cylinder was cut through soonest in those vessels that presented the greatest surface. This singular fact arises from the camphor being dissolved by the water, and extending itself over all the fluid surface, when it is the more readily evaporated by its coming into contact with a greater quantity of air. The dissolution of the camphor may be seen detaching itself from the cylinder in the form of a very transparent liquid oil, and spreading itself over the whole surface of the water. When in the contour of the cylinder, there is some place which furnishes this oil more abundantly, if small light substances are thrown upon the surface, they are repelled from this place with great briskness, and then turning round, they come back to the same place, and again enter the current, where they continue to circulate in this manner. If a small piece of camphor previously wetted at its extremity approaches the margin of the vessel, and then touches the vessel itself, it deposits a fluid visible to the eye. This fluid is oily; and on attaching itself to the vessel, it destroys its capillary attraction for the water, and the water retires from it and becomes convex at this place. When the piece of camphor is taken away, the water does not return to its place till the oily liquor is evaporated. When the cylinders of camphor are half immersed in water, the oily liquor which issues from it destroys the cohesion between the water and the cylinder, and a small depression takes place round the cylinder. The dissolution stops for a moment till the oily liquor expanded over the water has evaporated. The water then returns to its elevated state round the cylinder; the camphor is dissolved and diffused; and the same operations are repeated.

The motions of small pieces of camphor observed by M. Romieu are produced by the mechanical re-action of the jet of dissolution against the camphor; and if the centre of percussion of all the jets do not coincide with the centre of gravity, a rotatory and progressive motion will be produced. As the jets are generated only on the circumference of the section of the piece of camphor, it ought to revolve round an axis perpendicular to the horizon; and the smallest pieces will obviously turn round with more velocity than larger ones.

MM. Lichtenburg and Volta ascribed this rotation to an emanation from the camphor, and also from the benzoic and succinic acids, which have the same property. Brugnatelli discovered, that the bark of aromatic plants, when thrown upon water, moved round like camphor; and Venturi remarked a similar motion in the saw-dust of different woods, that had imbibed either a fixed or a volatile oil. Romieu ascribed these motions to electricity. He found that the camphor sometimes refused to turn, and at other times its movements were suddenly stopped, by touching the water with particular bodies. The cause of these irregularities, which long perplexed philosophers, was discovered by Venturi. He found, that whenever the water was touched by any body which was fat or oily, or which diffused a small portion of fixed oil, or a great portion of volatile oil over the surface, the dissolution and the motion of the camphor were immediately stopped. In order to prove that this effect was not produced by electricity, as Romieu and several Italian philosophers believed, Venturi touched the surface of the water both with conductors and non-conductors of electricity, which were well cleared of all oily or greasy matter, and the motions of the camphor were never in the slightest degree affected. When the same substance was afterwards greased with a small drop of oil of olives, and again brought into contact with the water, an oily film immediately advanced over the whole surface of the water, repelled the small bits of camphor, and, as if by a magic stroke, deprived them of their apparent vitality. Venturi repeated this experiment in a basin of water 20 feet in diameter. The camphor turned round in one end of the basin; and when an ounce of oil was poured in at the other extremity, the motions of the camphor were speedily stopped.

If the surface of the water on which the camphor swims, is not sufficiently extensive to allow the liquor from the camphor to evaporate, the dissolution of the camphor is either retarded or stops altogether, or the undissipated liquor forms itself into a thin film upon the surface of the water. In like manner, the particles of the saw-dust of wood soaked in oils, moves quickly when they touch the water: but their motions do not continue, because the film of oil which they spread over the water is not dissipated.

If the water is very pure, and is exposed to a heat even so high as that of boiling water, the dissolution and the motions of the camphor are not prevented. On the contrary, they are often promoted by the application of this heat.

M. Venturi applies the preceding principles to the explanation of the motion of the tremellæ observed by Adanson and by Corti. This aquatic plant rises to the surface of the water during the day, and descends to the bottom at night. If the plant is shut up in a box, whose sides are opaque, and if a pencil of light is admitted through an opening in one of its sides, the tremelli changes its situation in a few hours, and advances to the hole at which the light penetrates. M. Venturi observed with a microscope, that its branches have a small motion belonging to each of them, in virtue of which they sometimes oscillate from one side to another, and sometimes advance to free themselves from the pencil when they are interlaced. These appearances are explained by Venturi on the supposition that the water which it absorbs is decomposed by the assistance of light, and that the plant gives out the oxygen in a direction always opposite to the light. Hence it will follow that the plant must always move towards the quarter from which the light is admitted.

## CHAP. VI.

### Description of Instruments, and Experiments for illustrating the doctrines of Hydrostatics.

#### 1. *Description of the Mechanic or Hydrostatic Paradox.*

It appears from Cor. 2. of Prop. iv. p. 770, that the pressure exerted upon the bottoms of vessels filled with fluid, does not depend upon the quantity of fluid which they contain, but solely upon its altitude. This proposition has been called the mechanic or hydrostatic paradox, and the instrument for illustrating it has received the same name.

This instrument is shewn in Fig. 1. where AB is a box, which contains about a pound of water, and *a b c d e* a glass tube, fixed to the end C of the beam of a balance, and the other end to a moveable bottom, by which the water in the box is supported, the bottom and wire being equal in weight to an empty scale suspended at the other extremity of the balance. If a pound weight is put into the empty scale, it will cause the bottom to rise a little, and the water will appear at the lower end of the tube *a*. The water will therefore press with a force of one pound upon the bottom. If another pound is put into the scale, the water will ascend to *b*, twice as high as the point *a*, above the bottom of the vessel. If a third, a fourth, and a fifth pound be put successively into the scale, the water will rise at each time to *c*, *d*, and *e*, the distances *a b*, *b c*, *c d*, *d e*, being equal to one another. This result will be obtained, however small be the bore of the glass tube ; and since when the water is at *b*, *c*, *d*, *e*, the pressures upon the bottom are successively twice, thrice, four times and five times as great as when the water was contained within the box, it follows, that the pressure upon the bottom of the vessel depends wholly on the height of the water in the glass tube, and not upon the quantity which it contains. If a long narrow tube, therefore, be fixed in the top of a cask, and if both the cask and the tube be filled with water, then, though the tube be so small as not to hold a pound of the fluid, the pressure of the water in the tube will be in danger of bursting the cask in pieces ; for the pressure is the same as if the cask was continued up in its full size to the height of the tube, and filled with water : (See Chap. I. Sect. 1. Prop. IV. Cor. 2.) It follows, therefore, from this principle, that any quantity of water, however small, may be made to exert a force of any assignable magnitude, by increasing the height of the column, and diminishing the base on which it presses. This, however, has its limits ; for when the tube becomes capillary, the attraction of the glass will support a great quantity of the included water, and will therefore diminish the pressure upon its base. The preceding machine should be so constructed, that the moveable bottom may have no friction against the inside of the box, and that no water may get between it and the box. The method of effecting this will be manifest from Fig. 2. where ABCD is a section of the box, and *a b c d* its lid, which is made very tight. The moveable bottom E, with a groove round its edges, is put into a bladder *f g*, which is tied close round it in the groove by a strong waxed thread. The upper part of the bladder is put over the top of the box, at *a* and *d*, all around, and is kept firm by the lid *a b c d*, so that if water be poured into the box through the aperture *l l* in its lid, it will be contained in the space *f* E *g h*, and the bottom may be raised by pulling the wire *i* fixed to it at the point E of the moveable bottom. See Ferguson's *Lectures*, vol. ii. p. 100. Edit. Edin. 1806.

#### 2. *Description of the Hydrostatic Press.*

This ingenious and powerful machine, which has been recently brought into notice by the late Mr. Bramah, is founded on the doctrine contained in the corollary to the fundamental principle of the equilibrium of fluids, (see p. 759,) namely, that if any number of pistons are applied to apertures of different sizes in the sides of a vessel full of water, the forces with which the pistons are applied will be in equilibrio, if they are proportional to the apertures to which they are applied. Thus, if a piston G, (Fig. 1.) is applied to an aperture at G, having an area of two square inches, it will be in equilibrio with another piston applied to the whole aperture AB of 2000 square inches, if the force with which the piston G is applied, is to the force with which AB is applied as 2 to 2000, or as 1 to 1000. Hence it follows, that a force of one pound applied at G will raise 1000 pounds placed upon the piston AB. The same result will be obtained if the vessel has the form shewn in Fig. 11. the one piston being applied at *a b*, and the other at AB.

The hydrostatic press founded on this principle was first proposed as a new machine by Pascal, in his *Traitez de l'Equilibre des Liqueurs, et de la Pesanteur, de la Masse de l'Air*, Chap. II. Edit. 2d. Paris, 1664. He describes it as a new sort of machine for multiplying forces, (*Nouvelle sorte de machine pour multiplier les forces*,) and he considers it as a new mechanical power equal in value to the lever or the screw. Although Pascal speaks so highly of his new machine, it is not a little singular, that no attempt appears to have been made for more than a century and a half to apply it to the useful purposes of life. Mr Bramah had the very great merit, not only of re-inventing the machine, (for we believe he was not aware of its having been proposed by any other person,) but of pointing out its application to a great variety of useful purposes, such as working cranes, pulling up the roots of trees, packing goods of all kinds, &c. In our article Crane, we have given a full description of the hydrostatic press, as applied to a crane ; and by studying that part of the article, our readers will have no difficulty in understanding the construction of the instrument.

The hydrostatic press is represented by the parts

GHEFFL of Fig. 1. Pl. CCXV. In the Figure, FF represents the wooden frame which supports the iron cylinder L. This cylinder communicates with a small copper pipe *g g h*, terminating in a common forcing-pump at *h*, which stands in an iron cistern H, containing the water. The power is applied to the handle G of the pump, and the piston, pressing on the surface of the water in the pipe at *h*, communicates its force, through the intervention of the water, to the piston of the cylinder L, to the top of which the work to be performed is applied. See also our article Jack.

3. *Hydrostatic Bellows improved by Ferguson.*

The common hydrostatic bellows consisted of a tube of glass or any other substance, about three feet high, communicating with a cylindrical vessel, whose sides were made of leather like a pair of bellows, while its upper and lower surfaces were formed of circular or oval boards about 15 inches in diameter. When water is poured into the tube, it flows into the bellows, and separates the boards a little. Heavy weights to the amount of 300 pounds, are then placed upon the upper board, and by pouring water into the tube till it reaches the top, the moveable board with all its load will be raised, and kept in equilibrio by the column of fluid, although the fluid itself does not weigh more than a quarter of a pound. In order to shew the experiment with more effect, a man may place himself upon the upper board instead of the weights, and raise himself merely by pouring water into the small pipe.

The following very ingenious machine has been proposed by Mr Ferguson as a substitute for the common hydrostatical bellows: ABCD, Fig. 3. is an oblong square box, into one of whose sides is fixed the upright glass tube *a* I, which is bent into a right angle at the lower end, at *i*. Fig. 4. To this bent extremity is tied the neck of a large bladder K, which lies in the bottom of the box ABCD. Over this bladder is placed the moveable board L, Figs. 3. and 5. in which the upright wire M is fixed. Leaden weights N, N, with holes through their centre, to the amount of 16 pounds, are put upon this wire, and press upon the board L. The cross bar *p* is then put on, in order to keep the glass tube in an upright position; and afterwards the bent piece EFG, for keeping the weights N, N, horizontal, and the wire M vertical. Four upright pins, about an inch long, are placed on the corners of the box, for the purpose of supporting the board L, and preventing it from pressing the sides of the bladder together. When the machine is thus fitted up, pour water into the tube I, till the bladder is filled up to the board L. Continue pouring in more water, and the upward pressure which it will excite in the bladder will raise the board, with all its weights, even though the tube should be so small as to contain no more than an ounce of water. See Ferguson's *Lectures*, vol. ii. p. 104.

4. *Experiments for illustrating the quaquaversus pressure of Fluids, and the Effects produced at different Depths.*

*Exp.* 1. If we take a common wine glass AB, and, holding it in a vertical direction, bring its mouth in contact with the surface of water in the vessel M, it will be seen, that a small quantity of water has entered the wine glass, and that the remainder of the glass is filled with air. By depressing the glass, or sinking it in the fluid, a greater quantity of water will enter it; the included air being condensed into a smaller space as the pressure of the superincumbent column of water is increased. By continuing to depress the glass, it will be seen that the pressure of the water increases with the depth, and by holding the mouth of the glass in different directions, as shewn at CD and EF, Fig. 6. it will appear, that the water presses equally in every direction.

*Exp.* 2. If we insert into an empty vessel a number of tubes of glass bent into various angles, or if we hold them in the hand, and introduce into their lower orifices a quantity of mercury, so that the surface of the mercury may come to the very orifice of the shorter legs; then, if water is poured into the vessel, it will be seen, during the time of its filling, that the mercury is pressed gradually from its lower orifices towards the higher orifices, which are supposed to rise to a greater height than the surface of the water. Now, as the lower orifices of the glass tubes may be made to point in every possible direction, it follows, that the pressure of the superincumbent fluid is also propagated in every direction. When it is required that the lower orifice should point exactly downwards, in order to show the upward pressure of fluids, a straight tube should be used, and the mercury introduced into it must be kept in by the application of the extremity of the finger, till the height of the water above the orifice is equal to 14 times the length of the column of mercury introduced. Upon removing the finger, and continuing to pour in water, the mercury will ascend in the tube. If the finger were removed before it had risen to a height 14 times greater than the length of the mercurial column, the mercury would have fallen out of the tube, as it is 14 times heavier than water, and therefore requires a column 14 times as long to keep it in equilibrio.

*Exp.* 3. The pressure of fluids at different depths may be very simply illustrated, by attaching a bag made of leather, and filled with mercury to the extremity of a glass tube, so that the mercury may just enter the tube when the bag is held in air. By immersing the bag in water, the pressure of the fluid upon the bag will force up the mercury, and the height to which it rises will show the magnitude of the pressure at different depths.

*Exp.* 4. The propagation of pressure through fluids is also illustrated by the amusing experiment of the *Cartesian Devil*, as it has been called, after Descartes, by whom it was discovered. The figure of a man made of glass or enamel, is so constructed that it has the same specific gravity as water, and is therefore suspended in a mass of fluid. A bubble of air, (similar to the air in the glass of Exp. 1) communicating with the water, is placed in some part of the figure, sometimes in a small globe, as shewn at *m*. At the bottom B (Fig. 7.) of the vessel is a diaphragm of bladder, which can be pressed upwards by applying the finger to the extremity *e* of a lever *e o* moving round *o* as its centre of motion. The pressure applied to *a* is communicated through the water to the bubble of air, which is thus compressed: The specific gravity of the figure is therefore increased, and it sinks to the bottom. By removing this pressure, the figure again rises, so that it may be made to oscillate or dance in the vessel without any visible cause. Fishes made of glass are sometimes substituted in place of the human figure, and when a common jar is used for the experiment, the pressure is applied to the upper surface of it at A. The construction of the apparatus shewn in Fig. 6. is obviously the best, as the spectator does not observe the means which are employed to alter the specific gravity of the figure.

*Exp* 5. The pressure of fluids at very great depths is finely illustrated by an experiment which has often been made at sea, of making an empty bottle well corked descend to a great depth. The pressure of the water drives in the cork, and the bottle when brought up is always filled with water. Mr Campbell, the respectable author of

*Travels in the South of Africa*, tried this experiment on his voyage home from the Cape of Good Hope. He drove very tight into an empty bottle a cork, which was so large that half of it remained above the neck. A cord was then tied round the cork, and fastened to the neck of the bottle, and a coating of pitch was put over the whole. When it was let down to about the depth of 50 fathoms, the captain felt, by the additional weight, that it had instantaneously filled; and, upon drawing it up, the cork was found in the inside of the bottle, which was of course filled with water.

Another bottle was prepared in a similar manner; but in order to secure the cork, a sail needle was passed through the cork, so as to rest on the mouth of the bottle, and the whole was covered over with pitch. When the bottle had descended 50 fathoms, the captain again felt that it had filled with water; but, upon bringing it up, the cork and needle were found in the same position, and no part of the pitch appeared to be broken, although the bottle was completely filled with water. The water had in this case obviously insinuated itself through the pores of the pitch and the cork, and not, as Mr Campbell imagines, through the pores of glass. The experiment of forcing mercury through wood by the common pressure of the atmosphere, takes away the apparent improbability of this explanation. See Campbell's *Travels*, p. 507. Note. Lond. 1815.

5. *Experiment for illustrating the equality of the pressure of fluids in every direction.*

If a soft or frangible substance is exposed to any force in one direction more than another, it will either lose its shape, or be broken to pieces; but if the force with which the body is pressed is applied to every part of the body, it will preserve its form if it is soft, and will not be broken if it is frangible. Hence it follows, that if any body is exposed to a pressure sufficiently powerful to change its shape or crush it to pieces, and if it preserve its form and its integrity under this pressure, we are entitled to infer that the pressure is equal in every direction.

Let a piece of very soft wax, of an irregular shape, and an egg, be placed in a bladder filled with water. Let the bladder be then laid in a brass box, and a cover of brass put upon the bladder, so as to be entirely supported by it. If a hundred or a hundred and fifty pounds weight be laid upon this cover, so as to press upon the bladder, this enormous force, though propagated through the fluid, and acting upon the soft wax and egg, will produce no effect. The egg will not be broken, nor will the wax change its figure.

6. *Apparatus for illustrating the Doctrine of Specific Gravities.*

In order to shew that when a solid body is immersed in a fluid, the loss of weight which it sustains is equal to the weight of the water which it displaces, or of a quantity of water of the same bulk with the body, the following very simple apparatus has been employed.

A cylindrical or cubical body of any kind, either entirely solid, or made hollow and loaded within, so as to sink in the fluid, is exactly fitted to a hollow cylinder or cubical vessel, so that the solid contents of the hollow cylinder or cubical vessel is exactly equal to the solid contents of the cylindrical or cubical solid. Plate CCCXVII. Fig. 8. The cylindrical or cubical vessel is then suspended to the hook of a hydrostatic balance, or any other balance, and the solid cylinder or cube is suspended to a hook in the bottom of the cylindrical or cubical vessel. Weights are now put into the opposite scale of the balance till an equilibrium is produced in air. Every thing remaining in this situation, the solid cylinder or cube is completely immersed under water, and consequently the equilibrium is destroyed; that is, the scale of the balance to which the apparatus is suspended will require to have added to it a weight equal to the loss of weight sustained by the solid, in order to restore this equilibrium. By filling with water, therefore, the cylindrical or cubical vessel, it will be found that the equilibrium is exactly restored. Hence it is obvious to the eye, that the loss of weight sustained by the solid is exactly equal to the weight of water displaced.

7. *To make a Body lighter than Water lie at the bottom of a Vessel filled with Water.*

We have seen in Prop. IV. p. 772, that when a body has a less specific gravity than a fluid, it will float upon the surface of the fluid, as it is pressed upwards with a force greater than its own weight. If by any means, however, we can prevent the upward pressure from acting upon the lighter body, it is manifest that it must remain at the bottom of the vessel in the same manner as it would rest upon any other body in the open air, for the body is not only pressed down by its own weight but by the weight of the superincumbent fluid.

In order to show how to prevent the upward pressure from acting upon the solid, let us take two pieces of wood planed perfectly flat and smooth, so that no water can get in between them when their smooth surfaces are put together. If one of the pieces of wood is cemented to the bottom of a glass vessel, so as to have its smooth side uppermost, and if the other piece is placed above it, and held in that situation till the vessel is filled with water, it will be found to lie as quietly and firmly as if it were a plate of lead or stone. If the edge of the upper plate, however, is raised in the slightest degree, so as to allow the water to insinuate itself between the plates, the wood will instantly spring to the surface.

This experiment is sometimes made in a different manner. A flat and smooth brass plate is fixed at the bottom of the vessel, and a large mass of cork has a thin smooth brass plate fixed to its bottom, so that the specific gravity of the cork and its brass base may be much less than that of water. The brass plate on which the cork rests is then placed on the fixed brass plate; and when water is poured into the vessel, the cork will remain at the bottom. The two brass plates should be oiled a little on their touching surfaces, and should be ground upon one another, but not very accurately, for in this case the force of cohesion would prevent their separation, independent of the weight of the superincumbent pressure of the fluid, as it is well known that one brass plate can lift another in the open air, even when it is two or three pounds weight. The experiment as made with the brass plates is therefore not so satisfactory as the one with pieces of wood, for the reason which we have now assigned; and though we are satisfied that the cork and the brass plate are together lighter than water, yet the result appears less striking, as we are always in the habit of seeing brass sink to the bottom.

A similar result may also be obtained by fixing a glass plate at the bottom of a glass vessel, using a plate of ivory instead of wood, and pouring mercury into the vessel in place of water.

8. *Experiment for illustrating the parabolic form of a fluid surface influenced by a centrifugal force.*

In order to show that a horizontal surface of water assumes a parabolic form when it is acted upon by a centrifugal force, along with the force of gravity, we have only to take a bucket containing water, whose surface *c d* is of course horizontal when the bucket is at rest. If by means of a rope R, (Plate CCCXIII. Fig. 3.) however, fastened to the handle AB, we give the bucket a rotatory motion round a vertical line, the surface will lose its horizontal form, and the water becoming concave in the centre, will rise round the sides of the vessel, and have its surface of the form of a parabolic conoid, whose section *m n o* is a parabola. See Chap. I. Prop. I. cor. p. 769.

9. *Description of Dr Hooke's Semicylindrical Counterpoise.*

The principal object of this ingenious contrivance was to keep a vessel always full of water, or any other fluid; but as it is not only of use in hydrostatical experiments, but also illustrative of the principles of the equilibrium of fluids, we have thought it necessary to give a drawing and description of it in this place. In Plate CCCXVII. Fig. 9. ABG is a vessel of any form. Upon a horizontal axis C, a semicylinder or a hemisphere, whose section is DEF, is made to revolve, and the weight of the semicylinder is so adjusted that it is exactly equal to the weight of a portion of the fluid of half its magnitude. When the vessel is filled with water, the semicylinder is half immersed, and since it has half the specific gravity of the fluid, the semicylinder is in the same circumstance as if it were floating, and therefore exerts no pressure on the horizontal axis C. As the vessel is emptied either by evaporation, or by discharge from an orifice, the quantity of the semicylinder immersed will be diminished, and the equilibrium of consequence destroyed; and it will therefore move round the axis C till half of it is again immersed, and the equilibrium restored. In this way the semicylinder will always descend as the water runs out, and consequently the fluid must necessarily stand at the same height AB in the vessel.

10. *Experiments illustrative of the Pressure of the Superior Strata of Fluids upon the Inferior Strata.*

*Exp.* 1. If we pour coloured water into a glass vessel, and put a tube of glass, with a bore exceeding $\frac{2}{10}$ of an inch, the coloured water will stand in the tube at the same height as it does in the vessel. Let oil of turpentine be now poured above the water, and its pressure upon the surface of the water will cause the coloured fluid to ascend in the tube, but always to a height less than that of the surface of the oil of turpentine; the column of the coloured fluid raised, being to the thickness of the mass of oil in the inverse ratio of their specific gravities. The same experiment may be made by substituting quicksilver in place of the coloured water, and water in place of the oil of turpentine.

*Exp.* 2 If a vessel contains any fluid, a heavier fluid may be introduced below the lighter one, without any admixture taking place, and their separating surface will be horizontal. If a vessel for example contains water, let a quantity of milk be drawn up into a glass tube by suction, and if the open end of the tube is placed at the bottom of the vessel, and the milk allowed to discharge itself gradually, it will occupy the lower part of the vessel.

11. *Description of the Hydreoles invented by M. Mannoury Dectot.*

In Prop. I. of Chap. I. Sect. II. it has been demonstrated, that when two fluids are placed in the opposite branches of a bent glass tube or syphon, the altitudes above the point of junction will be in the inverse ratio of their specific gravities; that is, a fluid lighter than water will rise to a greater height in one of the branches than the water in the other.

M. Mannoury Dectot has employed this principle very ingeniously in raising water above its natural level, by mixing air with the water, so as to diminish its specific gravity, and thus cause it to rise to a considerable height in one of the branches of the syphon. In order to make an intimate mixture of water and air, he introduces the air in the form of minute bubbles, which lodge among the molecules of the water, and being kept separate from each other, they are retained by adhesion in such a manner that they are only disengaged slowly, and do not unite with each other and escape until the water which contains them has been raised to the proper height.

M. Mannoury Dectot has given two forms to this machine, one of which he calls the hydreole by suction, and the other the hydreole by pressure. In the hydreole by suction, the water passes through a mass of air, absorbs part of it, and becomes in some measure gaseous, and therefore it will rise to a greater height than the reservoir from which it flows.

In the hydreole by pressure, the air is driven by force through a number of small holes, so as to mix itself with the water in a number of minute bubbles. In order to form a proper idea of this machine, let us suppose that ABCD, Plate CCCXIII. Fig. 11. is a reservoir filled with water, and that the bent tube *a b c d* is joined to it at D. The water will obviously rise to the same level *a b*, A B in both vessels. Let us suppose, that a pair of bellows M is applied to an opening N in the tube, closed with a plate of iron, perforated with a great number of small holes, the air discharged from the bellows will enter the water in the form of very minute bubbles, which will be kept separate from each other by the mutual adhesion of the particles of water. The water above N will thus be rendered specifically lighter, and will therefore rise in the tube *a b c d*. Instead of using a pair of bellows, M. Mannoury Dectot obtains a current of air in the following manner. Between the opening N and the reservoir ABCD, he places a close vessel, communicating by one pipe with the reservoir, and by another with the opening at N. A column of water from the reservoir runs into the close chamber, compresses the included air, and this compressed air rushing through the other tube, enters through the holes in the aperture at N, and mixes itself with the water to be raised.

We have not been able to obtain any account of the preceding machine, but the very general one contained in the report of MM. Prony, Perier, and Carnot, which was approved of by the Institute of France, on the 28th December 1812. An account of M. Mannoury Dectot's new hydraulic machines will be found in Part III. of this article, on Hydraulic Machinery.

12. *Description of the Common Syphon.*

The syphon is a tube of glass or metal, bent in such a manner that one of its legs or branches is longer than the other. It is represented in Fig. 10. by ABCD. The shorter leg AB is immersed in the fluid in the vessel MNOP, and by applying the mouth to the orifice D, and sucking out the air in the syphon, the water ascends, and will continue to be discharged at D till the vessel is completely emptied.

Let us suppose that the syphon had legs of equal length, such as AB, BC, and that the water was drawn up by suction till it reached the extremity C; then it is obvious, that as the pressure of the air on the surface of water is equal to the pressure of the air at the extremity C, and as the columns AB, BC of the fluid are equal, there is no force which could enable the water to discharge itself at C. When the leg BC, however, is lengthened, so as to be equal to BD, then the water is discharged at D by the pressure of the additional column CD, and the velocity with which it is discharged will be in proportion to the difference between the legs of the syphon.

13. *Description of an Improved Syphon.*

The improved syphon is shewn in Fig. 11. where D is a stop-cock fixed at the extremity of its longer branch AB. A small bent tube ED lying along the outside of the branch, communicates with the cavity of the branch AB, above the stop-cock. When the aperture C is placed in the fluid to be drawn off, the mouth of the stop-cock D is closed, and the air is drawn out of the longer branch by suction at E. Instead of a stop-cock at B, the finger may be applied till the air is sucked out at E.

14. *Description of a Syphon acting by Capillary Attraction.*

If a bunch of cotton or worsted threads, or any absorbing fibres, is placed with one extremity in a vessel of water, and with the other hanging over the edge of it, the fluid will rise among the threads by the force of capillary attraction, and the water will be discharged from the longer branch in successive drops. Mr Leslie has very ingeniously employed this syphon for keeping moist the bulb of his hygrometer.

15. *Explanation of intermitting or reciprocating Springs upon the principle of the Syphon.*

A reciprocating spring, is a spring which alternately flows and ceases to flow. The name is also given to those springs which have a periodical swell, or which discharge a great quantity of water at one time, and a small quantity at another, after regular intervals. The first of these kinds of springs is easily accounted for, by supposing that the channel which carries off the water from a cavern has the form of a syphon. In this case, the water will only flow when it rises in the cavern to a height equal to that of the syphon, and the flow will stop till the cavern is again filled to the same height. The following explanation of the second kind of intermitting springs was suggested about a century ago to Dr Atwell of Oxford, by the phenomena of Laywell Spring at Brixam, near Torbay, in Devonshire. Let AA, Plate CCCXVII. Fig. 12. be a large cavern near the top of a hill, which derives its supply of water from rains or melted snow percolating through the chinks of the mountain, and let CC be the small channel which conveys the waters of the cavern to the opening G in the hill, where they are discharged in the form of a small spring. From the cavern AA let there be a small channel D, which carries water into another B, and let the water of the second cavern be carried off by a bent channel E*e*F wider than D, and joining the first channel CC at *f*, before it issues from the mountain, the point of junction *f* being below the level of the bottom of both the caverns. As the cavern B fills with water, the fluid will ascend to the same height in the channel E*e*F, but it will not be discharged by this channel till the surface in B is on a level with *e*, the highest part of the channel. The water will then be carried off by the natural syphon E*e*FG, till the whole is discharged, and consequently there will be a great swell in the spring at G. This swell will now cease, as the channel D does not convey the water into B so fast as the syphon E*e*F carries it off; and it will again commence as soon as the water in B rises to a level with the summit *e*. Mr Ferguson has illustrated this operation by a simple machine, a description of which will be found in his *Lectures*, vol. ii. p. 106, 107.

16. *To construct a Vessel, from which the Water will escape when it reaches a certain height.*

This vessel, which is called Tantalus's cup, consists of a metallic vessel, ABCD, divided into two compartments by the partition EF. A glass tube H *h*, open at both ends, is inserted in the opening H, in the partition EF, the lower end being allowed to reach a little below EF. The tube H *h* must then be covered by a small glass receiver *a b c*, or a wide tube hermetically sealed above, a small aperture being left at the bottom of this tube to admit the water. This mechanism is generally covered by the figure of a man representing Tantalus, as shewn in the drawing. If water is now poured into the vessel, it will get admittance into the receiver or wide tube, and will always stand at the same height in this tube that it does in the vessel. The water will therefore be retained in the vessel as long as it does not enter the tube H *h*, but as soon as the water rises in the vessel to the same level as the point *h*, it will flow down the tube H *h*; which acting like a syphon will discharge the whole fluid in the vessel. If water is poured slowly in with the intention of making it rise to the lips of Tantalus, it will never reach them, provided the syphon carries off the water faster than it is poured in. In the lower compartment of the vessel, there ought to be a small air-hole near the top, to allow the air to escape when the water takes its place.

17. *To construct a vessel which retains water when it is upright, but discharges it when it is inclined.*

Let ABCD be the vessel divided as formerly into two compartments by the partition EF. Into this partition insert the longer branch *b c* of a syphon *a b c*, whose shorter branch *b a* reaches nearly to the bottom of the vessel. If water is now poured into the vessel till it stands a little below the lower side of the bent part of the syphon, it is obvious that no water will descend through the syphon, as it has not risen high enough through the shorter branch to enable it to pass through the bent portion. If the vessel, however, is inclined to one side, as it is in the act of drinking, the water will rise higher in the short branch *a b*, pass over the bent part of the syphon, descend in the longer branch, and carry off all the water into the lower compartment of the vessel. Fig. 14. In order that this experiment may succeed, the sides of the vessel ought not to be symmetrical round the point *a* at the summit of the syphon; for in this case no inclination of the vessel, however great, will cause the water to flow over the point *a*. The syphon should therefore be placed towards one side of the vessel, and the vessel inclined to the same side.

A similar effect may be produced much more elegantly by using the double cup shewn in Fig. 15. where *a b c* represents the syphon. The person who tries to drink, must apply his lips to the side *b* of the syphon, otherwise the experiment will not succeed.

18 *To construct a machine in which all the water projected into a basin from a jet d'eau appears to be drank by a bird.*

This ingenious and elegant machine is shewn in Fig. 16. where ABCD is a vessel divided into three compartments by the partitions EF and GH. In the partition EF insert two tubes, one of which LM, forms a communication between the bottom of the compartment BG and the bottom of EC; while the other tube IK forms a communication between the upper part of EC and the upper part of HF. A third tube NO is fixed in the cover AB, extending from near the bottom of HF, and rising with a tapering bore to the point O, through the middle of the vessel SR, intended to receive the water which falls from the pipe NO. The figure of a bird with its bill immersed in the water in the basin SR, is placed on one side, and through its body passes a bent syphon QP, the lower branch of which goes into the compartment BG.

When the two upper compartments are nearly filled up to a little below K with water, through two apertures for that purpose, and when these apertures are shut, it is obvious that when the cock of the pipe LM is opened, the water will descend through LM, and occupying the compartment EC, will drive the air up through the pipe IK, and compress the air contained in the cavity HF. This condensed air pressing on the surface HK of the water, will raise it in the tube NO, and cause it to be projected upwards in a jet d'eau. The water from the jet, after being carried to a height due to the pressure which it experiences, will fall down into the vessel SR. But as the water escapes from the compartment BG, the air in that compartment will be rarefied, and will therefore not be sufficient to balance the pressure, if the exterior air upon the surface of the water is SR. This unbalanced pressure will therefore force the water up the syphon QP, through which all the water in the vessel SR will be conveyed into the cavity BG, as if it had been drank by the bird.

For farther information respecting the subjects treated of under this chapter, the reader is referred to the following works: Pascal's *Traitez de l'Equilibre des Liqueurs*, &c. &c. Paris, 1664; S. Gravesende's *Physices Elementa Mathematica*, lib. iii. Leid. 1742; *Phil. Trans.* 1732, vol. xxxvii. p. 301; Desagulier's *Course of Experimental Philosophy*, vol. ii. lect. 7 and 8, Lond. 1763; Ferguson's *Lectures on Select Subjects in Mechanics, Hydrostatics, Hydraulics*, &c. vol. ii. Edin. 1806; Dr Thomas Young's *Course of Lectures on Natural Philosophy*. vol. i. See also Part III. of this article on Hydraulic Machinery.

## Part II. ON HYDRAULICS.

HYDRAULICS, from ὑδωρ *water*, and αυλος, which sometimes signifies a *torrent*, is that branch of the science of hydrodynamics which treats of fluids considered as in motion. It therefore embraces the phenomena exhibited by water issuing from orifices in reservoirs, projected obliquely or perpendicularly in jet d'eaux, moving in pipes, canals, and rivers, oscillating in waves, or opposing a resistance to the progress of solid bodies.

### CHAP. I.

### On the Motion of Fluids issuing from Reservoirs by Vertical or Horizontal Orifices.

*General Principles.*

When a vessel is filled with a homogeneous fluid, and is in equilibrium, all the particles of fluid which it contains are equally pressed in every direction. But if a small aperture is made in the bottom of the vessel, the particles which rested upon the part of the bottom which is removed being no longer supported, will descend by their own gravity. The particles immediately above them will also descend, and all the fluid in the vessel will descend in lines nearly vertical; and when they arrive within three or four inches of the orifice, they will gradually turn into a direction more or less oblique, and make directly for the orifice. The same thing happens when the orifice is made on the side of the vessel. The preceding results were obtained experimentally by M. Bossut, who employed a glass vessel kept constantly, and rendered the motion of the fluid particles visible, by throwing into the water minute substances specifically heavier than it; such as filings, and small fragments of pounded slate.

When the vessel was allowed to empty itself by an orifice in the bottom of the vessel, the surface of the fluid preserved its horizontality during its descent, and when it came to within six lines, or half an inch of the orifice, a funnel-shaped hollow or cavity appeared in the surface of the fluid. When the water issued from an orifice in the side of the vessel, the water also preserved its horizontality; and when the surface reached the upper edge of the orifice, the water inclined a little from the orifice, forming an approximation to a hollow.

As the various particles of fluid which rush towards the orifice move in directions which converge to a point without the orifice, it is obvious that the column of fluid which issues from the vessel ought to have a smaller diameter than the orifice itself. This diminution in the diameter of the column was first observed by Sir Isaac Newton, and was called by him the *vena contracta*, or the contraction of the fluid vein. The distance from the orifice at which the greatest contraction takes place, is equal to the semidiameter of the orifice, and the area of the section of the vein at this place was to the area of the orifice as 10 to 14.14 according to Newton, or as 10 to 16 according to Bossut. When the orifice, instead of being a mere aperture in a thin plate, is a short cylindrical tube, Bossut found that the area of the section of the vena contracta was to that of the orifice as 10 to 12.3.

In proceeding to give a very short view of the theory of fluids issuing from orifices, we must warn the reader not to expect that strict coincidence between theory and practice which is to be found in many other branches of science. In optics and astronomy, and even in those parts of hydrostatics which we have already considered, the theoretical results scarcely differ at all from those which are obtained from accurate experiments; but in every branch of hydraulics the deductions of theory are so uncertain, that they are of no use whatever in any of the important purposes to which this science is applicable. It is only the general laws deduced from experiment that can be safely employed in the various operations of hydraulic architecture.

We shall therefore pass over very rapidly the theoretical part of the subject, and endeavour to lay before our readers a full account of the practical parts of hydraulics, availing ourselves of the invaluable labours of the Abbé Bossut.

*Definitions.*

1. A *vertical orifice* is an orifice placed in a vertical direction, so as to allow the water to issue in a horizontal stream.

2. A *horizontal orifice* is an orifice placed in a horizontal direction, so as to allow the fluid to escape in a vertical direction.

3. An *ajutage* is a name given to any orifice, or cylinder, or cone, from which water issues.

4. An *additional tube* is a tube of any form, inserted in a simple orifice made in the sides or bottom of a vessel.

5. A *head of water* is a term used to denote the height of the fluid above the orifice, or in general the height of a spring or source of water above the lowest point where it can be employed to exert a mechanical force, either by its impulse or by its weight.

6. If water issues with a velocity V, equal to that which a heavy body would acquire by falling through a height H, the velocity is said to be the velocity *due to the height H*, and the height is said to be *due to the velocity V*.

Prop. I.

If a fluid moves in an open canal, or through a tube, kept constantly full, whose diameter gradually varies, and if the fluid has the same velocity in every point of the same section, the velocities in different sections will be in the inverse ratio of the areas of the sections.

Since the canal and tube are always full, the same quantity of fluid must pass through every section in the same time. But as the quantity of fluid which passes through any section, whose area is A, is proportional to that area, and also to the velocity V with which it flows, it must be proportional to A and V jointly, or $A \times V$. In like manner the quantity of fluid which runs through the area $a$ of any other section in which $v$ is the velocity, will be proportional to $a \times v$. Hence $V : v = a : A$.

Scholium.

The case stated in the proposition is one which is purely theoretical, and can never occur in practice. In every canal the velocity of the surface is always greatest, and in every tube the particles in its axis always move most rapidly.

Prop. II.

If a fluid is discharged from a vertical or horizontal orifice infinitely small, in a vessel where the fluid is kept constantly at the same height, the velocity with which the fluid issues, is equal to that which a heavy body would acquire by falling through a height equal to the height of the fluid above the orifice.

Let ABDC, Fig. 1. be a vessel in which the surface of the water always stands at AB, and let $m\,n$ be the very small orifice through which the fluid is discharged. Let us suppose the fluid divided by horizontal planes into an infinite number of laminæ, then since the area of the orifice $m\,n$ is infinitely small compared with the area of the laminæ, it will follow, from Prop. I. that the velocity with which the laminæ descend must be infinitely small. Now it is obvious that the lowest film of fluid $m\,n$ is pressed out by the weight of the column $m\,n\,p\,o$. (See Chap. I. Sect. I. Prop. IV.) Let M be the mass of the column of fluid $m\,n\,h\,g$, which is discharged at every instant by the pressure of $m\,n\,p\,o$, or by the force $m\,n \times m\,o$, and let $m$ be the mass of a lesser column of fluid $m\,e\,f\,n$, which would have been discharged in the same time, solely by its own gravity, which may be represented by the line E $m$. Then if V be the velocity of the column $m\,g\,h\,n$, and $u$ the velocity of the column $m\,e\,f\,n$, the quantity of motion of the column $m\,g\,h\,n$ will be $V \times M$, and the quantity of motion of the column $m\,e\,f\,n$ will be $u \times m$. But the moving forces are $m\,n \times m\,o$, and $m\,n \times E\,m$; and as they must be proportional to the quantities of motion which they produce, (see Dynamics,) we have

$$m\,n \times m\,o : m\,n \times E\,m = V \times M : u \times m \text{ or}$$
$$V \times M : u \times m = m\,o : E\,m.$$

But the masses M, $m$ discharged in the same time are as the area of the orifice multiplied by the velocity; that is, $M : m = m\,n \times V : m\,n \times u$, or $M : m = V : u$, and as magnitudes have the same ratio as their equimultiples have, (Euclid, V. 15,) we have

$M\,V : M\,u = V^2 : u^2$; but it has already been shewn that $M\,V : M\,u = m\,o : E\,m$, hence
$V^2 : U^2 = m\,o : E\,m$.

Now if $v$ is the velocity which a heavy body would acquire by falling through the height $m\,o$, we have, by Dynamics, Case 4,

$$v^2 : u^2 = m\,o : m\,E, \text{ consequently}$$
$$V^2 : u^2 = v^2 : u^2,$$

and $V^2 = v^2$ and $V = v$, that is, the velocity V, with which the fluid issues from the orifice $m\,n$, under the pressure of the column $m\,n\,p\,o$, is equal to the velocity $v$, which a heavy body would acquire by falling through the height $m\,n$.

It is obvious, that the preceding reasoning is applicable to a vertical orifice, or to an orifice in any position, provided its depth is equal to $m\,n$, for the pressure of the fluid is the same in all directions.

*Cor.* 1. If the vessel ABDC, instead of being kept constantly full, is allowed to empty itself by the orifice $m\,n$, the velocity will always diminish; and when the surface has assumed a lower level GH, the velocity will be that which is due to $h\,m$.

*Cor.* 2. As the velocities of heavy bodies, descending by the force of gravity, are as the square roots of the spaces or heights through which they fall, (see Dynamics, Case 4,) the velocity of the issuing fluid will be as the square roots of the altitude of the surface of the fluid above the orifice. That is, if the water stands successively at the heights $o\,m$, $h\,m$, the velocities will be as $\sqrt{mo} : \sqrt{mh}$.

*Cor.* 3. As the quantities of fluid discharged are proportional to the velocities when the orifices remain the same, they will also be proportional by *Cor.* 2. to the square roots of the height of the fluid in the vessel.

*Cor.* 4. If the orifice is horizontal, but opening upwards, so as to discharge the fluid in a vertical direction, the water will rise in a jet to the same height as the surface of the fluid in the reservoir. As all heavy bodies acquire in falling a velocity which would carry them upward to the same height from which they fell, the same must be true of fluids. In practice, however, the resistance of the air, and the friction of the fluid upon the sides of the orifice, prevent this from being true.

*Cor.* 5. If the fluid, when it issues from the orifice, should continue to move uniformly with the velocity with which it issues, it would describe a space equal to 2 $mo$, in the same time that a heavy body would fall through the height $om$.

In studying the preceding proposition, the reader must consider it as giving the velocity, not at the orifice itself, but at the *vena contracta*, where the velocity is greatest. Sir Isaac Newton having found that the velocity at the *vena contracta* was that which was due to the whole height of the fluid, and that the velocity at the *vena contracta* was to the velocity of the orifice as $\sqrt{2} : 1$, or as 1.414 : 1, necessarily concluded that the velocity at the orifice is only that which is due to *half* the altitude of the fluid.

### Prop. III.

If a cylindrical or prismatic vessel, of which the horizontal section is every where the same, is filled with fluid, and empties itself by an orifice, the velocity with which the surface descends, and also the velocity with which the water issues, is uniformly retarded.

Since the velocity of the surface of the fluid is to the velocity at the orifice, as the area of the orifice is to the area of the horizontal section of the vessel, or the area of the surface, the velocity of the surface must vary as the velocity at the orifice. But the velocity at the orifice varies as the square root of the height of the fluid in the vessel, by Prop. II. Cor. 2.; consequently the velocity of the surface must also vary according to the height of the fluid, that is, with the space through which it descends. But as the velocity of heavy bodies projected upwards varies in this manner, the velocity of the fluid surface must be uniformly retarded in the same manner as heavy bodies.

### Prop. IV.

If a fluid issues from a cylindrical or prismatic vessel, whose horizontal section is every where the same, and in which the fluid is always kept at the same height, the orifice will discharge twice the quantity contained in the vessel, in the same time that the vessel would have emptied itself.

As the surface of the fluid is uniformly retarded, and as its velocity becomes nothing at the bottom, the space which the descending surface would describe, with the first velocity, continued uniform during the time that the vessel takes to empty itself, is twice the space that the surface really describes in the time in which the vessel empties itself. In this time, therefore, the quantity of fluid discharged in the former case is twice that which is discharged in the latter case, as the quantity discharged when the vessel is kept constantly full may be measured by what would be the descent of the surface, if it could descend with the velocity with which its descent commences.

The preceding demonstration is given by Mr Vince. M. Bossut deduces the proposition as a corollary from formulæ which express the quantity of water discharged under the circumstances stated in the proposition.

### Prop. V.

To determine the quantity of water discharged by a small vertical or horizontal orifice, the time of discharge, and the height of the fluid in the vessel, when any two of these quantities are known.

Let A represent the area of the small orifice $mn$; W the quantity of water discharged; T the time of discharge, H the height of $mo$ fluid in the vessel, and $g = 16.087$ feet, the space described by gravity in a second. Then since, by dynamics, the times are as the square roots of the spaces, we have $\sqrt{g} : \sqrt{H} = 1 \text{ second} : \sqrt{\frac{H}{g}}$, the time in which a heavy body would fall through the height H. But since the velocity is uniform, the space described will be double in the time that a heavy body would describe the height H, and therefore a column of fluid $= A \times 2H$ will be discharged in the time $\sqrt{\frac{H}{g}}$. Now, as the quantities of fluid discharged in different times are proportional to the times, we have $2AH : W = \sqrt{\frac{H}{g}} : t$. Hence,

$$W = \frac{2AHt}{\sqrt{\frac{H}{g}}} = \frac{2AHt \times \sqrt{g}}{\sqrt{H}}, \text{ and since } \frac{H}{\sqrt{H}} = \sqrt{H},$$

we have $W = 2At\sqrt{gH}$

$$A = \frac{W}{2t\sqrt{gH}}$$

$$t = \frac{W}{2A\sqrt{gH}}$$

$$H = \frac{W^2}{4gt^2A^2}.$$

*Cor.* By means of these formulæ, we may determine the quantity of water $W'$ which is discharged in the same time T, from any other vessel in which $A'$ is the area of the orifice, and H the altitude of the fluid; for since $t$ and $g$ are constant, we shall have

$$W : W' = A\sqrt{H} : A'\sqrt{H'}.$$

### Prop. VI.

To determine the time in which the surface of water in a vessel will descend through a given height, where the fluid is discharged through a small orifice in the bottom.

Let ABCD, (Plate CCCXVII. Fig. 2.) be the vessel, and let it be required to determine the time in which the surface of the fluid descends from AB to RS. Draw MN, $\mu\nu$ parallel and infinitely near to each other, then since $P\pi$ is infinitely small, we may consider the height $\pi o$ as constant during the time that the lamina of fluid $MN\mu\nu$ flows through the orifice; and consequently its velocity is uniform. The time $t$, therefore, in which the height $P\pi$ is described, will, by Prop. IV. be $t = \frac{MN \times P\pi}{2A\sqrt{g}\sqrt{Pm}}$; for in the present case $W = MN \times P\pi$, and $H = Pm$. In a similar manner we may obtain the times $t'$, $t''$ for all the other elementary laminæ into which the sum ABNM may be supposed to be divided, and therefore the sum of all these elementary terms, which may be obtained either by fluxions or by a geometrical construction, will be the time required in the proposition.

In order to find the time geometrically, draw EF equal and parallel to BC, and construct upon EF as an axis a parabola FTG, with a given parameter $p$. Prolong the lines AB, MN, $\mu\nu$, and RS, till they meet the parabola in G, $c$, $d$, and T. Construct a second curve XZY, so that each of the ordinates H $a$, K $b$, L Z, may be equal to the corresponding sections MN, $\mu\nu$, RS, divided by their corresponding ordinates in the parabola H $c$, K $d$, LT. Now, since

$H a = \frac{MN}{H c}$, and $MN = H a \times H c$, and since by the property of the parabola, (See Conic Sections, Prop. XIII. $H c^2 = HF \times p$, and $\sqrt{HF} = \sqrt{Pm} = \frac{H c}{\sqrt{p}}$, we have, by substituting, in the above value of $t$, the preceding values of MN, and $\sqrt{P m}$, $t = \frac{H a \times H c \times HK \times \sqrt{p}}{2 A \times \sqrt{g} \times H c}$, and dividing by $\sqrt{p}$ and H $c$

$$t = \frac{\sqrt{p}}{2 A \sqrt{g}} \times HK \times H a$$

which consists of the constant factor $\frac{\sqrt{p}}{2 A \sqrt{g}}$ multiplied into the variable curvilineal area H $a$ $b$ K. But as the same may be shewn for every other element of the time, it follows, that the time of descent from AB to RS will be equal to $\frac{\sqrt{p}}{2 A \sqrt{g}} \times$ ELZX.

*Cor.* It follows from this proposition, that the times in which the surface AB will descend through the heights $o$ P, $o$ $s$, will be proportional to the corresponding areas EH $a$ X, ELZX, and that the time of descent through any of these heights is to the time in which the vessel is completely emptied, as the corresponding area EH $a$ X or ELZX, is to the whole area EFYX.

### Prop. VII.

To determine the time in which the surface of water in a prismatic or cylindrical vessel will descend through a given height, viz. from AB to RS in Fig. 3.

This problem, as Bossut has remarked, may be very easily resolved by the method of fluxions; but we shall follow this excellent mathematician in the elementary demonstration which he has given of it. Let us suppose, that a body, not heavy, ascends through the height $m$ $o$, Fig. 3. and describes that space in the very same way as a heavy body would descend through the height $o$ $m$. Then it is obvious that the different velocities of the ascending and descending body may be expressed by the ordinates of a parabola GTF. When the ascending body has arrived in $\pi$, it will describe the small space $\pi$ P or KH, with a velocity represented by the ordinate H $c$; but the time of describing $m$ $o$ is $\sqrt{\frac{m o}{g}}$; and if the final velocity of the ascending body were continued uniform, the body would describe a space $= 2$ $m$ $o$ in the time $\sqrt{\frac{m o}{g}}$. But in uniform motions, the spaces divided by the velocities are as the times of description. Hence $\frac{2 m o}{EG} : \frac{HK}{H c} = \sqrt{\frac{m o}{g}}$ : Time HK, (or the time of describing GV.) Consequently

$$\text{Time HK} = \frac{HK \times EG}{2 H c \sqrt{g} \times \sqrt{m o}},$$

and substituting for $\sqrt{m o}$ its value $\frac{EG}{\sqrt{p}}$, $p$ being the parameter of the parabola, we have

$$\text{Time HK} = \sqrt{\frac{p}{g}} \times \frac{HK}{2 H c};$$

but by Prop. VI. the time in which the water descends through the same space P $\pi$, or HK, is

$$\frac{\sqrt{p}}{2 A \sqrt{g}} \times H a \times HK = \frac{\sqrt{p}}{2 A \sqrt{g}} \times \frac{MN}{H c}.$$

If we now substitute in place of H $a$ its equal $\frac{MN}{H c}$; and multiply the first of these expressions by MN, and the second by A, the products will be equal, or

$$\frac{MN}{2} \frac{\sqrt{p} . HK}{\sqrt{g} H c} = \frac{MN . A \sqrt{p} . HK}{2 A \sqrt{g} . H c}.$$

Hence, by Euclid, (VI. 16) the time of the body's ascending through $m$ $o$, is to the time in which the surface descends through P $\pi$, as the area A of the orifice is to the area MN of the base of the cylindrical or prismatic vessel; and as the same is true of all the other elementary times which the ascending body and the descending surface employ in describing small equal spaces, it follows, that the whole time in which the ascending body will describe the height $m$ $o$, is to the time in which the vessel will be completely emptied, as the area A of the orifice is to the area of the base of the vessel. The time, therefore in which the vessel will empty itself will be $\sqrt{\frac{m o}{g}} \times \frac{B}{A}$, being the area of the base.

If RDSC is the vessel, then the time in which it will be entirely emptied will be $\sqrt{\frac{m s}{g}} \times \frac{B}{A}$, consequently the differences of these times, or the time in which the surface A B will descend into the position RS, will be

$$\text{Time } m s = B \frac{(\sqrt{m o} - \sqrt{m s})}{A \sqrt{g}}.$$

### Prop. VIII.

To construct a clepsydra, or water clock, of a cylindrical form.

The equation in the preceding proposition enables us to do this in a very simple manner. Let us suppose that it is required to measure 12 hours, and that the height AD is divided into 144 equal parts; then the height of the surface of the water at the commencement of the time will be 144 parts. At the end of one hour the height will be 121; at the end of the second hour it will be 100, as in the following Table:

| | | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Hours to run . . . . . . . . . . . . | 12 | 11 | 10 | 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 0 |
| Hours from commencement . . . . . | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 |
| Height of the surface from the bottom | 144 | 121 | 100 | 81 | 64 | 49 | 36 | 25 | 16 | 9 | 4 | 1 | 0 |
| Length of each hour in parts . . . . . | 23 | 21 | 19 | 17 | 15 | 13 | 11 | 9 | 7 | 5 | 3 | 1 | |

Since the velocity with which the surface AD descends is as the square roots of the altitudes, then, as the velocities are proportional to the times, the times in which these altitudes are described will also be as the square roots of the altitudes. Hence, since 12, 11, 10, &c. are the times in which the different heights are to be described, the heights should be as $12^2$, $11^2$, $10^2$, or as 144, 121, 100, 81.

The exact time of describing each part of the altitude A is easily deduced from the formula. If the time is to be one hour, then we must proportion the area B of the base, and the height $h$ of the vessel, to the area A of the orifice; so that 1 hour $= B\frac{(\sqrt{h}-\sqrt{\frac{121}{144}})}{A\sqrt{g}}$, or 1 hour $= \frac{B\sqrt{h}}{12\,A\sqrt{g}}$; from which any of the three quantities B, $h$, and A may be found, when two of them are given.

Scholium.

In practice, the 11 first divisions should only be employed, on account of the effect of the funnel-shaped cavity upon the regularity of the discharge. See p. 828.

Prop. IX.

If a prismatic or cylindrical vessel ABCD is kept constantly full, it will discharge twice as much water as it contains in the time that it takes to empty itself completely.

It follows from Prop. VII. that the time in which it empties itself is $\frac{B\sqrt{h}}{A\sqrt{g}}$, $h$ being equal to the height $m\,o$; and from Prop. V. that the quantity of fluid discharged in the same time, when the vessel is kept constantly full is $\frac{B\sqrt{h}}{A\sqrt{g}} \times 2\,A\sqrt{g\,h} = 2\,B \times h$; but this quantity is double of the prism ABCD, which is equal to $B \times h$.

Scholium.

In practice, the effect of the funnel-shaped cavity must be considered. See Chap. III. Sect. V.

Prop. X.

If water is discharged from two prismatic or cylindrical vessels, the times in which their surfaces descend through similar heights, will be in the compound ratio of the areas of the bases, and the difference between the square roots of the height of each surface at the beginning and end of its motion directly, and inversely as the areas of the orifices.

Let the corresponding quantities in the two vessels be distinguished by accents, then, by Prop. VI. time $o\,s$ : time $o'\,s' = B\frac{(\sqrt{o\,m}-\sqrt{s\,m})}{A\sqrt{g}} : B'\frac{(\sqrt{o'\,m'}-\sqrt{s'\,m'})}{A'\sqrt{g}}$ or dividing by $\sqrt{g}$, as $B\frac{(\sqrt{o\,m}-\sqrt{s\,m})}{A} : B'\frac{(\sqrt{o'\,m'}-\sqrt{s'\,m'})}{A'}$.

Scholium.

In practice, the effects of the contraction of the fluid vein must be considered, as in Chap. III. Sect. V. p. 656.

Prop. XI.

To determine the quantity of water which is discharged in a given time from a large rectangular orifice in the side of a vessel.

Hitherto we have supposed, that the orifice from which the water was discharged, when it issued from the side of a vessel, was so small, compared with the diameter of the vessel, that every part of the orifice might be considered as at the same depth below the surface. As this supposition, however, is inadmissible in the case of large orifices, we must now suppose a large orifice divided into an infinite number of small rectangles, (if the orifice is rectangular,) and regarding each of these as an orifice, all the points of which are equidistant from the fluid surface, we must determine the quantity of water discharged by means of the preceding propositions. The sum of all these elementary quantities will then be the total quantity of fluid discharged during the given time.

In order to shew the mode of doing this, by a geometrical construction, we shall take the case of a rectangular orifice as given by Bossut. Let LNOM be the given orifice in the vessel ABCD, Fig. 4. kept constantly full of water. Draw XZ, $x\,z$, infinitely near each other, and parallel to LM, so as to form the elementary rectangle XZ$z\,x$. Then if RI is the height, which may be considered as the distance of all the points of the small orifice from the surface AD, the quantity of water discharged in the time $t$ will be $2\,XZ \times I\,i \times t\sqrt{g} \times \sqrt{RI}$. In order to find the sum of all these elementary quantities, construct upon the axis RV the parabola RT, whose parameter is $p$, and produce KM, IZ, $i\,z$, VO to Y, S, $s$, and T. The small parabolic area IS, $s\,i$ may be considered as a rectangle $= IS \times I\,i$. But $IS = \sqrt{RI} \times \sqrt{p}$; hence $IS \times I\,i = I\,i \times \sqrt{RI} \times \sqrt{p}$. Calling $e$ this parabolic area, and $q$ the elementary quantity of water which flows through the elementary orifice XZ $z\,x$, we shall have $e : q = I\,i \times \sqrt{RI} \times \sqrt{p} : 2\,XZ \times t\sqrt{g} \times I\,i \times \sqrt{RI}$, which gives us

$$q = e \times \frac{2\,XZ \times t\sqrt{a}}{\sqrt{p}}.$$

If we can determine, therefore, the sums of all the $e$'s or the parabolic surface KVTY, we shall easily determine the sum of the $q$'s or the total quantity Q, which is discharged in the time $t$ from the aperture LNOM.

Complete the rectangle RVTH, and draw SG $s\,g$ parallel to VR. Now the area RHT is composed of the elements SG, $s\,g$, which are proportional to the squares of the distances RG, R $g$: (see Conic Sections, Sect. IV. Prop. XII. Cor.) Hence these elements increase as the sections of a pyramid, whose summit is R, and whose height is RH. Consequently the form of all the GS's which make up the area RHT, are equal to $\frac{1}{3}\,RH \times HT$; therefore the area $RVT = \frac{2}{3}\,VR \times VT$. The space KVTY, or the sum of the $e$'s, is therefore $= \frac{2}{3}(RV \times VT - RK \times KY)$; but

$$q = e \times \frac{2\,XZ \times t\sqrt{g}}{\sqrt{p}}.$$

Hence we have

$$Q = \tfrac{2}{3}\,(RV \times VT - RK \times KY) \times \frac{2\,XZ \times t\sqrt{g}}{\sqrt{p}}.$$

If we substitute in this expression $\sqrt{VR} \times \sqrt{p}$ instead of VT; $\sqrt{RK} \times \sqrt{p}$ instead of KY; and if we call $VR = H$, and $RK = h$, and $XZ = b$, we have

$$Q = \frac{4\,b\,t\sqrt{g}\,(H\sqrt{H} - h\sqrt{h})}{3}.$$

In this expression, $g$ is always $= 16.087$.

Prop. XII.

To determine the horizontal distance to which water will be projected from orifices in the side of a vessel, and the nature of the curve which it will describe.

Let ABCD, Fig. 5. be a vessel of water, which is discharged at O through the bent tube GEO, in the direction OP. If the water were influenced by no other force but that with which it is projected, it would move uniformly in the direction $m\,o$ P, with a velocity equal to that which a heavy body would acquire in falling through the height QO. But as it is acted upon by gravity, as soon as it escapes from the orifice O it will obviously describe some curve line O $n\,p$. Make the elementary space O$m$ = $m\,o$, and O P = 2 OQ. Draw PM parallel to ON, and join QM. Let fall from the points $m$, $o$, P, the vertical lines $m\,n$, $o\,p$, PV, which will be parallel to OM, and complete the parallelograms O $m\,n$ R, O $o\,p$ S, OPVT. Let us now suppose, that in the time in which the water would have described the space O $m$, the force of gravity would have caused it to fall through the height OR; and that in the time in which it would have described the space O $o$, it would have descended through OS by the force of gravity alone. Now, since the fluid at O is solicited by two forces, one of which, viz. the force of projection, would carry it through the space O $m$ in a certain time, while the other, viz. the force of gravity, would carry it through the space OR in the same time, the fluid will at the end of the given time be found at $n$. In like manner it may be shewn, that at the end of the time in which the water would have described O $o$ uniformly, it will be found in the point $p$. But since O $m$, O $o$ represent the times in which the water reaches the points $m$, $p$ of its path, and since in these times the force of gravity has caused the water to fall through the spaces $m\,n$, $o\,p$, then, as the spaces are proportional to the squares of the times, we have $mn,\ op = \mathrm{O}m^2 : \mathrm{O}o^2$, that is, on account of O $m\,n$ R, O $o\,p$ S, being parallelograms $\mathrm{OR} : \mathrm{OS} = \mathrm{R}n^2 : \mathrm{S}p^2$, which is the relation between the abscissæ and the ordinates of the Apollonian hyperbola. (See Conic Sections, Sect. IV. Prop. XII. Cor.)

It would be unnecessary to proceed any farther in explaining and demonstrating the geometrical construction which is usually given for finding the amplitude either of oblique or horizontal jets, as the construction and the demonstration of it are exactly the same as that which we have given in our article Gunnery, for the parabolic path of projectiles. The two classes of phenomena, and the mathematical laws by which they are regulated, are exactly the same.

### Prop. XIII.

To determine the pressure exerted on the interior of conduit pipes by the water which they convey.

Let the fluid column, Plate CCCXVIII. Fig. 5. No. 2. be divided into an infinite number of equal and vertical laminæ GF $gf$. Then, if we abstract friction, it is obvious that all the points of the same lamina have the same velocity, and that this velocity is the same in all the laminæ. If $q\,r$ represent the section of the contracted vein at the orifice $p\,n$, the velocity of the laminæ is to the velocity in $q\,r$, as the area of the orifice $q\,r$ is to the area of the section GF; for at every instant there passes out of $q\,r$ a small prism of water equal to GF $g\,f$, and therefore these prisms have velocities reciprocally proportional to their bases. (See Prop. I. p. 488.) If we therefore call $h$ the constant height of water in the reservoir, D the diameter of the tube, $d$ that of the orifice $q\,r$, and if we consider that the velocity in $q\,r$ is that due to the height $h$, and may be expressed by $\sqrt{h}$, then $\mathrm{D}^2 : d^2 = \sqrt{h} : \frac{d^2\sqrt{h}}{\mathrm{D}^2}$, the velocity of the water in the pipe. But as the velocity $\sqrt{h}$ is due to the height $h$, the velocity $\frac{d^2\sqrt{h}}{\mathrm{D}^2}$ will be due to the altitude $\frac{d^4 h}{\mathrm{D}^4}$. But since each particle of fluid that reaches the extremity PN of the pipe tends to move with the velocity $\sqrt{h}$, while it moves only with the velocity $\frac{d^2\sqrt{h}}{\mathrm{D}^2}$, every point of P$p$ or N$n$ upon which it rests must be pressed with a force equal to the difference of the pressure due to the velocities $\sqrt{h}$, and $\frac{d^2\sqrt{h}}{\mathrm{D}^2}$, that is, every part of the pipe will be pressed with a force equal to $h - \frac{d^2 h}{\mathrm{D}^4}$.

*Cor.* 1. If an aperture very small in relation to each of the orifices PN, $p\,n$ is made in the side of the pipe, the water will issue with a velocity due to the height $h - \frac{d^4 h}{\mathrm{D}^4}$. This height will vanish when $d = \mathrm{D}$, or when the whole aperture PN is opened.

See Bossut's *Traité d'Hydrodynamique*, Tom. II. chap. xi. p. 197, &c. from which the preceding proposition is taken.

### Scholium.

In page 854, 855, of the present article, will be found a set of valuable experiments by Bossut, in which he has measured the quantity of water discharged by apertures in the side of the pipe. The agreement between the formula and the observed results is very striking.*

* In a series of very recent and interesting experiments on the discharge of liquids through small orifices, made by M. Hachette, of which some account will be found in the following chapter, he has discovered that the quantity of fluid discharged by orifices varies, by placing an obstacle at some distance from the orifice. Daniel Bernoulli made an experiment on this subject, and concluded from it, that an obstacle does not alter the quantity of fluid discharged. In his experiment, however, the time of the flow was too short for obtaining correct results.

M. Hachette employed a circular orifice, 20 millimetres in diameter, which discharged water from a large vessel into a vessel placed at a great distance from the orifice. The surface of the water in the vessel sank about six decimetres in 10′ 21″. The plane face of an obstacle was presented at different distances from the orifice, and the jet fell perpendicularly on this plane. The following were the results:

| Distance of the Obstacle in Millimetres. | | | | |
|---|---|---|---|---|
| 128 | 80 | 50 | 24 | 4 |
| Corresponding Times in which the Surface of the Water sunk Six Decimetres. | | | | |
| 10′ 21″ | 10′ 25″ | 10′26″ | 11′ 13″ | 15′54″ |

Hence it follows, that at the distance of 128 millimetres (5.039 inches), the obstacle produces no effect; but that, at the distance of four millimetres 0.157 of an inch, the time is increased rather more than one-half.

## CHAP. II.

### On the Lateral Communication of Motion in Fluids.

This branch of hydrodynamics has been cultivated almost solely by M. Venturi, professor of natural philosophy at Modena, who published an account of his ingenious investigations in 1798. Sir Isaac Newton was acquainted with the fact that such a lateral communication took place, and has deduced from it the propagation of rotatory motion from the interior to the exterior strata of a whirlpool; but M. Venturi has the sole merit of explaining the different phenomena which it produces, and of applying it to the explanation of many curious phenomena. The following propositions contain a brief and general view of the subject.

### Prop. I.

The motion of a fluid is communicated to the lateral parts which are at rest.

In order to establish this proposition by direct experiment, Venturi introduced the horizontal cylindrical pipe A *c* (Plate CCCXVIII. Fig. 5. No. 3.) into a vessel DEFB, filled with water as high as DB. Opposite the aperture C, and at a little distance from it, is placed a small rectangular canal of tinned iron SMBR, open at the top SR, and having its inclined bottom MB resting on the edge B of the vessel. The breadth of this canal is 24 lines, the diameter of the tube AC is 14.5 lines, and the extremity A is inserted in a reservoir, of which the water is kept at a constant height. When the water of the reservoir is permitted to flow through AC, the current rises along the canal MB, and of course rushes out of the vessel in the current BV. In this way a current is created in the fluid in the vessel DEFB. This fluid is carried into the canal SR, and issues at B along with the water in the reservoir. In a few seconds, therefore, the water DD falls to MH. A similar effect will be obtained if we bring any light bodies near a stream of water issuing from a reservoir. These bodies will be carried along by the air which descends with the stream.

From these experiments it follows, that the lateral parts of a fluid are carried along with any stream that flows through the fluid, and consequently that the motion of the fluid is communicated to the lateral parts which are at rest.

### Scholium.

Venturi has applied the principle in the proposition to explain the theory of the water-blowing machine. He has also shewn that the eddies of the water in rivers are produced by motion communicated from the more rapid parts of the stream to the lateral parts which are more at rest; and has pointed out a method, which he has actually tried with success, of draining, by means of a fall of water without the help of machines, a piece of ground, even though the ground should lie on a lower level than the established current below the fall. See Prop. VI.

### Prop. II.

In descending cylindrical tubes, the upper extremities of which have the form of the contracted vein, the velocity of the effluent water is that which corresponds with the height of the fluid above the inferior extremity of the tube.

M. Venturi has established this proposition upon the principle of virtual ascension, combined with the pressure of the atmosphere, in the following manner. Let BLKO, Plate CCCXVIII. Fig. 6, be a conical tube, having the form of the vena contracta, and let the cylindrical tube LCQK have the same diameter as the contracted part LK. Now, the fluid stratum LK continuing to descend through the height LC, will tend to have its motion accelerated in the same manner as all other bodies falling by the force of gravity. Hence, when it passes from LK to LM, it tends to detach itself from the stratum which lies immediately above it; or, which is the same thing, it tends to produce a vacuum between LK and MN, and the same effect is produced through the whole length LC of the tube. The pressure of the atmosphere becomes active, as far as is necessary, to prevent the vacuum, and its action is the same, both at A, the surface of the fluid, and at C, the inferior extremity of the tube. The atmospherical pressure at A increases the velocity of the fluid which issues at CQ, while the atmospherical pressure at C destroys the sum of the accelerations which would be produced along L C, so that the fluid remains continuous in the tube.

Let T be taken to represent the time in which the continuous column of fluid LCQK passes through the tube LC, whatever be the velocity at L, and the successive acceleration from L to C. Then, if we suppose this column to return upwards from D to E, it will pass through the space DE, which is equal to LC in the same time T, and during this time it will lose all the acceleration which it acquired in its descent from L to C. The pressure of the column ED, continued during the time T, is therefore the force necessary to destroy the successive acceleration from L to C, and to prevent the fluid from losing its continuity in the tube LC. Hence it follows, that the part of the pressure of the atmosphere which is exerted at CQ to destroy the sum of the accelerations along LC, is equal to the pressure of a column ED of a fluid of the same nature as that of the reservoir from which the water flows. And since the same pressure must also be exerted upon the surface A of the reservoir, if we take $FA = LC$, the fluid at LK will issue with a velocity due to the height $FL = AC$, abstracting the retardation produced by the external inequalities of the tube LCQK.

### Scholium.

The theory of Venturi has been recently controverted by M. Hachette, who supposes, that the principal cause of the increased expenditure by tubes is the adhesion of the fluid to the sides of the tubes arising from capillary attraction. The following account of Hachette's experiments, taken from M. Poisson's Report, will enable the reader to determine which of the two theories is the most plausible. We conceive, that new experiments are necessary to decide the question.

Exp. I. The fluid in motion was mercury, and the pipe was made of iron. When the mercury was perfectly pure, it had no affinity for the iron, and flowed out as it would have done from a small orifice equal to the diameter of the pipe. But when the mercury was covered with a pellicle, formed of an alloy of tin and other metals, this alloy covered the inside of the pipe, and the mercury then flowed with a full stream.

Exp. II. The fluid next used was water, and the pipe was coated within with wax. The water flowed as if through a small orifice, without filling the tube. But whenever the water was made to moisten the wax, the pipe was instantly filled, owing to the wax being replaced by the first coat of water which covers it. Hence the reason why a disc of glass at last adheres to water with the same force whether it is covered or not with a coating of wax; for as soon as the wax is wetted, it is merely the action of water on water which determines the phenomena, as M. La Place has explained in his *Theory of Capillary Action.*

Another important fact determined by M. Hachette is, that in a vacuum, or in air rarefied to a certain degree, the phenomena of pipes cease to take place. Thus, if water is made to run in a full stream through a tube under the receiver of an air pump, then, upon rarifying the air in the receiver, the fluid vein was observed to detach itself from the sides of the pipe, when the internal pressure was reduced from 0.76 of a metre to 23 centimetres of mercury. By thus diminishing the internal pressure the effect of the external pressure is increased, which is transmitted to the pipe by means of the fluid contained in the vessel, and to which is added the pressure of the fluid. But there is a point at which these two pressures are sufficiently powerful to detach the fluid vein from the sides of the pipe, in the same manner as a disc of glass or metal may be detached from the surface of a fluid to which it adheres by the application of a sufficient force. The phenomena, therefore, exhibited in a vacuum, or in rarefied air, agree perfectly with the explanation of M. Hachette, and does not prove, as might be supposed, that the phenomena of pipes are produced by the pressure of the air in which the fluid is discharged; an opinion which is inconsistent with the two preceding experiments, for in these experiments the action of the air was the same, and yet the phenomena were different, according to the nature of the fluid, and the matter of which the pipe was composed.

When the fluid vein has been detached by rarefying the air, M. Hachette observed, that the water does not again begin to flow in a full stream when the air is re-admitted. This contraction of the vein, which took place in the rarefied air, continues to subsist though the pressure of the atmosphere is restored. Hence he concludes, that the adhesion of the water to the sides of the pipe takes place only at the commencement of the motion, before the fluid has acquired a sensible velocity in a direction which separates it from the sides. In order to verify this conjecture, M. Hachette made the following experiment:—The water flowed in a full stream through a pipe without the receiver of an air-pump. A small hole was made in this pipe very near the orifice. The external air then entered into the pipe, as ought to have happened according to the theory of D. Bernoulli. It interposed itself between the water and the sides of the pipe. The contraction of the vein takes place in the inside of the tube, and the water ceases to flow in a full stream. This being the case, the small hole was exactly shut. The adhesion of the water to the pipe was not again produced, and the flowing of the water continued as if the pipe had not existed, so that it might have been removed or replaced without any change in the flow of the water. This experiment succeeded equally well whatever was the direction of the jet; but care must be taken not to agitate the apparatus, for a very small lateral motion of the fluid causes it to adhere again to the moist sides of the pipe. It was probably from having neglected this precaution, that M. Venturi obtained a result apparently different from the preceding. See Thomson's *Annals of Philosophy*, July 1817, vol. x. p. 34.

PROP. III.

If water is discharged from a short tube of a conical form, the pressure of the atmosphere will increase the expenditure in the ratio of the exterior section of the tube to the section of the contracted vein, whatever be the position of the tube, provided that its internal figure be adapted throughout to the lateral communication of motion.

Having already shewn that the atmospherical pressure increases the expenditure through additional tubes, whatever be their position, Venturi next proceeds to examine the mode of action by which the atmosphere produces this augmentation, and he begins with the case best adapted to favour the action of the atmosphere, which is that of conical diverging tubes.

Let AB, Plate CCCXVIII. Fig. 14, the extremity of the tube ABEPF, be applied to an orifice in a thin plate, and let the part ABCD have the form nearly of the contracted vein, which is found by experiment to make no perceptible alteration upon the expenditure by the simple orifice AB. The water which issues through CD is disposed to continue its course in a cylindrical form CGHD; but if the lateral parts CFGDFH continue, the cylindrical stream CGHD will communicate its motion to the lateral parts successively from part to part, as shewn in Prop. I. Hence, if the divergence of the sides CE, DF be such as is best adapted to the speedy and complete lateral communication of motion, all the water contained in the truncated conical tube CDEF will at last acquire the same velocity as that of the stream which continues to issue through CD. Upon this supposition, while the fluid stratum CDQR, preserving its velocity and thickness, would pass into RQTS, a vacuum would be formed in the solid zone R $m\,r$ SQ $n\,o$ T. Or if it should be supposed that the stratum CDQR, preserving its progressive velocity, should enlarge in RQTS; this cannot happen without its becoming thinner and detaching itself from the stratum which succeeds it, and by that means leaving a vacuum equal to the zone R $m\,r$ SQ $n\,o$ T. A similar effect would obviously take place throughout the whole of the tube CE, and if the quantity C $m$ is supposed invariable, the sum of all these empty spaces will be equal to the solid zone VE $x$ G $z$ YFH.

From this reasoning it follows, that the lateral communication of motion produces the same effect in a conical tube, whether horizontal or vertical, as is produced by the action of gravity in a descending cylindrical tube, as described in Prop. II. In this case, also, a part of the pressure of the atmosphere is active on the reservoir, and at the outer extremity EF. If the action of the atmosphere upon the surface of water in the reservoir increases the velocity at the section CD, this velocity will likewise communicate itself to the whole fluid CDFE, and the tendency to a vacuum will take place as before; but since the atmospherical action is as powerful at EF, it will take away at EF all the velocity which it added at CD; so that being deducted from the same mass, and in the same time at EF, the fluid will not cease to be continuous in the pipe. It is found by computation, that this will happen when the velocity of CD is increased in the ratio of CD to $EF^2$.

By applying the general laws of motion to the lateral fluid filaments of the stream which issues through AB. it is found that they tend to describe a curve which commences within the reservoir, for example at A, and continues towards CSE. In order to determine the nature of this curve, it is necessary to know and to combine together, by calculation, the mutual convergency of the fluid filaments in AB, the law of the lateral communication of motion between the filaments themselves, and their divergent progression from C to E. These combinations and calculations are considered by Venturi as beyond the efforts of analysis. When the tube ABFE has a figure different from this natural curve, the experimental results will always differ more or less from those deduced from theory.

PROP. IV.

The quantity of fluid discharged through cylindrical tubes is less than through conical tubes which diverge from the commencement of the contracted vein, and have the same external diameter.

The general theory is the same for tubes both of a cylindrical and a conical form, but the loss of living force is greater in the cylinder, and the effect of the communication of motion in these tubes cannot approach its maximum as in the cone. Let the compound tube ACNM, Plate CCCXVIII. Fig. 11. have the part ACFD of the form of the *vena contracta*, and let the cylindrical part GINM have its diameter MN greater than DF. Hence it follows, from the reasoning in the preceding proposition, that the lateral communication of motion tends to produce a vacuum in the solid zone ROYSXQTZ. If the communication of motion in the tube were completely made, it would follow that the pressure of the atmosphere would increase the velocity of the contracted vein in the ratio of $DF^2$ to $MN^2$. The form, however, of the cylindrical tube always destroys a considerable part of the effect; for the fluid filaments AD, in describing the curve DR, strike the sides of the tube GM at R with considerable force, and thus lose a part of their motion. Eddies or circular whirls are produced in the space DGR, as in a basin which receives water by a channel. These eddies are to a certain extent a failure in the effect, and retard the efflux of the water. A much less increase of the expenditure takes place in the cylindrical tube than corresponds to the ratio of $DF^2$ to $MN^2$.

The reader will be able to form a general notion of the effects of these internal shocks and eddies upon the efflux of a cylindrical tube, by attending to the experiments in Table XII. p. 844, of this article.

M. Venturi next considers, whether, in the internal part of the simple cylindric tube KLV, Fig. 12. there is the same augmentation of velocity, and the same contraction of the stream, as in the compound tube of Fig. 11. By reasoning according to the principles which he has established, he concludes, 1. That in the section KL of Fig. 12. there is the same increase of velocity as takes place in the section AC of Fig. 11. (See Prop. II.) The fluid particles which pass through these sections have in both cases the same direction; for this direction can depend only on the impulse received within the reservoir, which is the same in both cases. In Fig. 12. the fluid particles, after having passed through the section KL, immediately begin to experience the effect of the lateral communication of motion, and therefore they must deviate laterally through the curve L $x$ $z$, before they arrive at the place of contraction, which they assume at DF, Fig. 11. and which they likewise assume when the orifice is made in a thin plate. If we suppose a tube of glass $y$ K, Fig. 12. to have one of its extremities applied at K, and the other opening into the reservoir, it will be seen that the pressure of the atmosphere which is exerted upon the coloured fluid T, (see p. 844. Table XII. exp. 7.) must act likewise upon the surface of the reservoir, and aid the pressure of the fluid in the reservoir in forcing the water into the tube $y$ K, as it presses the coloured liquor into TS. In like manner, the pressure of the atmosphere must increase the impulse of all the fluid particles which arrive at KL, and consequently must increase the expenditure. As a part of the active force of the fluid must always be destroyed by the eddies in an additional cylindric tube, it follows that the effluent column can never have the velocity which is due to the real head, and which is observed nearly entire in orifices in a thin plate; and the diminution of velocity corresponds with the increase of the time beyond that indicated by the theory.

SCHOLIUM.

The theory of the lateral communication of motion in fluids must apply in a similar manner to ascending and descending tubes, whenever the form admits of this lateral communication. In descending tubes, the increase of expenditure, occasioned by this cause, must be added to that which is produced by the acceleration of gravity, and which has been estimated in Prop. II. But in ascending tubes, we must subtract this effect from that which is produced by gravity.

PROP. V.

By means of proper adjutages applied to a given cylindrical tube, it is possible to increase the expenditure of water through that tube in the proportion of 24 to 10, the head or the altitude of water in the reservoir remaining the same.

The truth contained in this proposition is deduced from the experiments which we have given in Table XII. p. 844 and 845 of this article, and the form of the adjutages is explained in p. 845, and represented in Plate CCCXVIII. Fig. 16.*

SCHOLIUM.

"At Rome," says Venturi, "the inhabitants purchased the right of conveying water from the public reservoirs into their houses." The law prohibits them from making the pipe of conveyance larger than the aperture granted them at the reservoir, as far as the distance of 50 feet. The legislature was therefore aware, that an additional pipe of greater diameter than the orifice would increase the expenditure; but it was not perceived that the law might be equally evaded by applying the conical frustum CD beyond the 50 feet. From the structure of this compound pipe, we learn, that it is not proper to make the flues of chimnies too large in the apartments; but that it will be sufficient if they be enlarged at their upper terminations, according to the form CD, Fig. 16. This divergency of the upper part will carry off the smoke very well, even when it is not practicable to afford chimnies of sufficient length to the upper apartments. The same observation is applicable to chemical furnaces for strong fire.

PROP. VI.

The eddies of the water in currents and rivers are produced by motion, communicated from the more rapid parts of the stream to the lateral parts, which are more at rest.

"The water which moves in the channel MNH, Fig. 5. No. 4. meets the obstacle BA, which impedes its course,

* Mr Clement, in some very recent experiments on the discharge of water through cylindrical and conical tubes, has succeeded in increasing the expenditure of water in a much greater ratio by changing the form of the compound tube used by Venturi. See Poisson's Report on M Hachette's Memoir, Part III.

and causes it to rise and discharge itself in the direction AC, with an increased velocity. Suppose the water in BDCA to be dormant, the current AC communicates its motion to the lateral particles E, (Prop. 1.) and conveys them forward; the surface of the dormant water becomes depressed at E, and the most remote particles towards D are urged, according to the laws of the equilibrium of fluids, to fill the depression. The current AC continues to carry them off, and the space BDCA continues to be exhausted. The water of the current AC, by virtue of the same laws, is acted upon by a constant force which urges it towards the cavity E, while its natural course or projection carries it towards AC. Under the agency of these two forces, the water AC acquires a curve-lined motion in CD, and descends as it were through an inclined plane, becoming retrograde in DE, whence it would proceed to strike the obstacle BA, and the current AC, after which it would undergo several oscillations previous to acquiring a state of equilibrium and repose. But the current AC continues its lateral action; a second time it draws away the water through CD into E, and forces it to renew its motion through the curve CDE; in which manner the eddy continues without ceasing.

If the river should pass through a contraction of its bed at N, it will produce eddies at both sides, at P and at Q, similar to those we have considered at DC.

Suppose the stream of water, after having struck the bank GH, to be reflected into a new direction HS, the lateral communication of motion will excite eddies in the angle of reflection R.

When two currents of unequal velocity meet obliquely in the middle of the river, the most rapid current will produce eddies in that which is the least rapid.

Suppose a stream of water to flow over a bed of unequal depth. If the longitudinal section of the inequalities of the bottom exhibit a gentle slope, as at ABC, Fig. 5. No. 5. the superior water will impress its motion by lateral communication upon the inferior water which is near the bottom, beneath the line AC, and a current will take place through the whole depth of the section MB. The current, which is formed near the bottom at B, is turned out of its course by the slope BC, and proceeds to rise above the surface at Q, sometimes in the form of a curling wave, or vertical whirlpool. If the extremities of the hollow place form an abrupt angle, as DEFG, eddies will be produced even at the bottom, in the vertical direction at D, and sometimes also at G. These phenomena may be observed in an artificial channel with glass sides.

*Every eddy destroys a part of the moving force of the current of the river.* For the water which descends by a retrograde motion in the inclined plane CDE, Fig. 5. No. 4. cannot be restored in the direction of the current of the river but by a new impulse. It is as it were a ball, which is forced to rise on an inclined plane, whence it continually falls back again to receive new impulsions.

Hence we deduce, as a primary consequence, *that in a river, of which the course is permanent, and the sections of its bed unequal, the water continues more elevated than it would have done, if the whole river had been equally contracted to the dimensions of its smallest section.* The cause of this phenomenon is the same as that which retards the expenditure through the tube with enlarged parts. (Prop. 7. No. 4.) The water which descends from the elevation above the contracted part N into the basin PQ, Fig. 5. No. 4. loses nearly the whole of the velocity it acquired by descending from it; because the narrow part has a curved slope towards the lower part of the river, which directs the velocity of the stream in an horizontal direction. Guglielmini has well remarked, that a fall does not influence the velocity of the lower stream, because the eddies of the water in the basin PQ destroy the velocity produced by the fall. This velocity increases the depth, and enlarges the width of the channel at PQ. Eddies are formed on each side, at the bottom, and at the surface, both in the horizontal and vertical directions. It would be to no purpose to attempt to prevent this hollowing out and enlargement of the channel by such a fall, by adopting the means of close walls, for the basin would then obtain its enlargement where these constructions might end.

If the channel have a number of successive contractions and dilatations MN, without cascade or dam, there will still be formed, at each dilatation, eddies which will diminish the velocity more than if the channel had an uniform section equal to that in M or N. It will therefore follow, that the surface of the water, after each dilatation, must rise, in order to recover the velocity it lost by the eddies. If we call the height to which the water must rise, above the elevation necessary to have overcome the retardations of a bed of uniform section, $= a$, and the number of equal and successive alternate dilatations and contractions be $= m$, the height of the rise in the stream thus alternately dilated beyond that of the same river uniformly contracted, will be $= am$. We here suppose the bottom of the river to be uniform. If this bottom be of such a nature to be attacked by the current, the contracted parts will be hollowed out, and the matter will be deposited in the enlarged parts.

The second consequence which we draw from the principle here established, respecting the loss of force caused by the eddies, is of considerable importance in the theory of rivers, and appears to have been neglected by those who have treated on this subject. The friction of the water along the wet banks, and over the bottom of rivers, is very far from being the only cause of the retardation of their course, which consequently requires a continued descent to maintain its velocity. One of the principal and most frequent causes of retardation in a river is also produced by the eddies, which are incessantly formed in the dilatations of the bed, the cavities of the bottom, the inequalities of the banks, the flexures or windings of its course, the currents which cross each other, and the streams which strike each other with different velocities. A considerable part of the force of the current is thus employed to restore an equilibrium of motion, which that current itself does continually derange."

## CHAP. III.

### Account of Experiments on the Discharge of Water from Vessels through simple Orifices and additional Tubes.

#### Sect. I. *On the Vena Contracta.*

In the first chapter of Hydraulics we have explained the cause of the contraction of the fluid vein, or *vena contracta*, and have stated in general the effect which this contraction produces upon the quantity of water discharged from vessels. The following are the measures of the contraction according to different authors; A being the area of the orifice, and $a$ the area of the section of the contracted vein:

| | A. | $a$. |
|---|---|---|
| Sir Isaac Newton, . . . . . | 141 | 100 |
| Poleni, . . . . . . . | 140 | 100 |
| Highest found by Bossut, . . . | 150 | 100 |
| Mean of six experiments by Bossut, | 150.6 | 100 |

| | A. | a. |
|---|---|---|
| Lowest found by Bossut, . . | 151.5 | 100 |
| Bernoulli, . . . . . . | 156 | 100 |
| Michelotti, . . . . . . | 156 | 100 |
| Du Buat, . . . . . . | 150 | 100 |
| Venturi, . . . . . . | 158.5 | 100 |
| Eytelwein, . . . . . . | 156.2 | 100 |

The measures given by Bossut were taken by a pair of spherical compasses, with which he measured directly the diameter of the contracted vein, which he found to preserve the same diameter for some lines. The altitude of the water in the reservoir which Bossut used was 11 feet 8 inches. He measured the *vena contracta* also, when the water issued by vertical orifices placed 4 feet below the surface of the fluid, and he obtained the very same results.

The ratio of A to $a$ is however by no means constant. It undergoes perceptible variations, by varying the form and position of the orifice; the thickness of the plate in which the orifice is made; the form of the vessel; and the velocity of the issuing fluid.

Sect. II. *On the quantity of Water discharged by orifices of different forms, from vessels kept constantly full.*

In order to determine the quantity of water discharged by orifices of different forms, M. Bossut employed very clear water, which was excellent for drinking. The experiments were made at Mezieres, in the beginning of September, in very fine weather, which is the only information from which we can conjecture the temperature of the water. The orifices were perforated in plates of copper half a line thick; the time was ascertained sometimes by a seconds watch, and at other times by a simple seconds pendulum; and the most exact measures were used in ascertaining the quantity of water discharged. The fundamental measure which he employed was a hollow cube of copper, having one of its sides exactly six inches within. It contained the eighth part of a cubic foot when it was entirely full, and on its four interior faces were traced four vertical scales for ascertaining the quantity of water which it contained when it was full. M. Bossut also used other two measures, one of which was a small barrel containing exactly a cubic foot, or eight times the contents of the cubical vessel; and the second was a barrel containing eight cubic feet. Each of these barrels had two small tubes rising from their upper end, through one of which the water was poured, and upon which was the mark to shew when it contained exactly the number of cubic feet. The second tube allowed the included air to escape as the water was poured in.

Table I. *Shewing the quantity of Water discharged in one Minute by Orifices differing in form and position.*

| Constant Height of the Fluid above the centre of the Orifice. | Form and position of the Orifice. | Diameter of the Orifice. | No. of Cub. In. discharged in a Minute. |
|---|---|---|---|
| Ft. In. Lin. | | Lines. | |
| 11 8 10 | Circular and Horizontal, | 6 | 2311 |
| | Circular and Horizontal, | 12 | 9281 |
| | Circular and Horizontal, | 24 | 37203 |
| | Rectangular and Horizontal, . . . . . | 12 by 3 | 2933 |
| | Horizontal and Square, | 12 side | 11817 |
| | Horizontal and Square, | 24 side | 47361 |
| 9 0 0 | Vertical and Circular, | 6 | 2018 |
| | Vertical and Circular, | 12 | 8135 |
| 4 0 0 | Vertical and Circular, | 6 | 1353 |
| | Vertical and Circular, | 12 | 5436 |
| 5 0 7 | Vertical and Circular, | 12 | 628 |

From these results we may conclude,

1. That the quantities of water discharged in equal times by the same orifice from the same head of water, are very nearly as the areas of the orifices; and,

2. That the quantities of water discharged in equal times by the same orifices under different heads of water, are nearly as the square roots of the corresponding heights of the water in the reservoir above the centres of the orifices.

If we call Q, $q$ the quantities of water discharged in the same time from the two orifices A,A′ under the same height of water in the reservoir; $q$ and Q′ the quantities of water discharged during the same time by the same aperture A, under the different heads of water $h$, $h'$, we have by the first of the above results, $Q : q = A : A'$; and by the second, $q : Q' = \sqrt{h} : \sqrt{h'}$; from which we obtain $q = \frac{A' \times Q}{A}$, and $q = \frac{Q' \sqrt{h}}{\sqrt{h'}}$ then since $\frac{A' \times Q}{A} = \frac{Q' \sqrt{h}}{\sqrt{h'}}$, we have by Euclid, B. V. $Q : Q' = A \sqrt{h} : A' \sqrt{h'}$, that is, in general.

3. The quantities of water discharged during the same time by different apertures under different heights of water in the reservoir, are to one another in the compound ratio of the areas of the apertures, and of the square roots of the heights in the reservoirs.

This general rule may be considered as sufficiently correct for ordinary purposes; but, in order to obtain a great degree of accuracy, Bossut recommends an attention to the three following rules.

1. Friction is the cause, that, of several similar orifices, the smallest discharges less water in proportion than those which are greater, under the same altitudes of water in the reservoir.

2. Of several orifices of equal surface, that which has the smallest perimeter ought, on account of the friction, to give more water than the rest, under the same altitude of water in the reservoir.

3. That, in consequence of a slight augmentation which the contraction of the fluid vein undergoes, in proportion as the height of fluid in the reservoir increases, the expence ought to be a little diminished.

In the following Table, given by the Abbé Bossut, he has compared the theoretical with the real discharges from an orifice one inch in diameter, and the different altitudes of the fluid in the reservoir. The real discharges in column 3d were not determined by direct experiment, but were ascertained with the precaution indicated in the three preceding rules, and may be considered to be as accurate as if they had been obtained from direct experiment. The fourth column was computed by M. Prony.*

TABLE II. *Comparison of the Theoretic with the Real discharges from an Orifice one inch in diameter.*

| Constant height of the Water in the Reservoir above the centre of the Orifice. | Theoretical discharges through a circular Orifice one inch in diameter. | Real discharges in the same time through the same Orifice. | Ratio of the theoretical to the real discharges. |

| 12 | 15180 | 9384 | 1 to 0.61819 |
| 13 | 15797 | 9764 | 1 to 0.61810 |
| 14 | 16393 | 10130 | 1 to 0.61795 |
| 15 | 16968 | 10472 | 1 to 0.61716 |
| 1 | 2 | 3 | 4 |

It appears from this Table, that the real as well as the theoretical discharges are nearly proportional to the square roots of the heights of the fluid in the reservoir. Thus for the heights 1 and 4, whose square roots are as 1 to 2 feet, the real discharges are 2722 and 5436, which are to one another as 1 to 1.997, very nearly as 1 to 2.

By means of the formula in the preceding page, we may easily apply the above Table to the determination of the quantities discharged under different altitudes of water in the reservoir, and from orifices of different sizes. Let it be required, for instance, to determine the quantity of water discharged from an orifice of 3 inches in diameter, under an altitude of 30 feet. Then, since the real quantities discharged are in the compound ratio of the orifices, and the square roots of the altitudes of the water, and since the theoretical discharge by an orifice 1 inch in diameter, under an altitude of 15 feet, is 16968 cubical inches in a minute, we have $1\sqrt{15} : 9\sqrt{30} = 16968 : 215961$, the theoretical discharge. But since the theoretical is to the real discharge as 1 to .62, the above value being diminished in that ratio, gives 133309 cubic inches for the real quantity of water discharged by the orifice.

The following formulæ have been given by M. Prony, as deduced from the preceding experiments of Bossut,†

$$Q=0.61938\ AT\sqrt{2g}\ H,$$

A being the area of the orifice in square feet, H the altitude of the fluid in feet, T the time, $g$ the force of gravity at the end of a second, and Q the quantity of water in cubic feet. As $\sqrt{2g}$ is a constant quantity, and is equal to 7.77125, we have

$$Q=4.818\ AT\sqrt{H}\ \text{for orifices of any form.}$$

If the orifices are circular, and if $d$ represents their diameter, then

$$Q=3.7842\ d^2\ T\sqrt{H}.$$

From the second of these equations we obtain

$$A=\frac{Q}{4.818\ T\sqrt{H}}$$

$$T=\frac{Q}{4.818\ A\sqrt{H}}$$

$$H=\frac{Q}{(4.818\ AT)^2}$$

These formulæ will be found to give very accurate results; but if we wish to obtain a still higher degree of accuracy, we must not use the mean co-efficient 0.6194, but the one in the Table which comes nearest to the circumstances of the case. Thus, if the head of water happens to be small, such as 1 foot, then we must take the co-efficient 0.62133, and if it happens to be great, we must use the least co-efficient 0.61716.

In order to determine the velocity with which the fluid is discharged, we must first obtain the theoretical velocity, which is $V=\sqrt{32.174}\sqrt{H}=8.016\sqrt{H}$ in English inches. That is, the velocity acquired by falling through any height H is found by multiplying the square root of the height by 8.016. But as the real velocity of the issuing fluid is to its theoretical velocity as 0.6194 to 10, we have $4.965\sqrt{H}$ as the measure of the real velocity, or in round numbers $5\sqrt{H}$; that is, the velocity in a second of time in English feet is five times the square root of the height of the fluid in the reservoir; or, if we prefer expressing these values in inches, then since 32.2 feet = 772 inches, and $\sqrt{772} = 27.78$, we have $V = 27.78\sqrt{H}$ for the theoretical velocity, and $V = 17.206\sqrt{H}$ for the velocity at a simple orifice.

In order, however, to obtain the velocity more accurately, we should deduce the co-efficient of $\sqrt{H}$, not from the medium co-efficient in the preceding Table, but from the co-efficient in the Table which approaches nearest to the circumstances of the experiment.

The following Table contains a series of experiments by M. Michelotti, which were made on a most magnificent

* See his *Architecture Hydraulique*, tom. i. p. 369.

† The measures are in French feet, which are to English feet as 1066 is to 1000.

scale, and with the utmost accuracy. As they extend to apertures of three inches both square and circular, and to altitudes twice as great as those employed by Bossut, they form an excellent supplement to his experiments. We consider them indeed as much more valuable than those of Bossut, as the quantities of water discharged in each experiment were prodigiously greater than his. The reservoir employed was 20 feet high, and three feet square within, and had openings at different distances from the top. The water flowed into a cistern whose area was 289 square feet, and whose figure was uniform, and the quantity of it was ascertained in French feet, by measuring its height in the cistern.

Table III. *Containing the Experiments of Michelotti on the quantities of Water discharged by different vertical orifices under different heads of Water.*

| Head above the Centre of the orifice. | | | | Size and nature of the orifice. | Time of running. | Cubic feet of water expended. | | |
|---|---|---|---|---|---|---|---|---|
| Feet. | Inch. | Lines. | Parts. | | Minutes | Feet. | In. | Lin. |
| 6 | 7 | 4 | 3 | Square, of 3 inches. | 10 | 463 | 7 | 3 |

| 6 | 7 | 6 | 0 | Square, of 2 inches. | 15 | 329 | 9 | 8 |
| 11 | 5 | 1 | 4 | | 15 | 423 | 5 | 7 |
| 21 | 5 | 3 | 7 | | 10 | 385 | 4 | 0 |
| 6 | 9 | 1 | 0 | Square, of 1 inch. | 30 | 158 | 6 | 7 |
| 11 | 10 | 8 | 1 | | 24 | 163 | 9 | 6 |
| 21 | 6 | 1 | 0 | | 60 | 562 | 11 | 4 |
| 6 | 8 | 4 | 0 | Circular, of 3 inches diameter. | 15 | 542 | 10 | 6 |
| 11 | 7 | 1 | 0 | | 12 | 570 | 11 | 8 |
| 21 | 7 | 4 | 0 | | 8 | 521 | 3 | 7 |
| 6 | 9 | 5 | 0 | Circular, of 2 inches diameter. | 30 | 488 | 8 | 3 |
| 11 | 8 | 8 | 0 | | 28 | 589 | 6 | 5 |
| 21 | 10 | 10 | 0 | | 20 | 575 | 5 | 10 |
| 6 | 10 | 6 | 0 | Circular, of 1 inch diameter. | 60 | 247 | 4 | 3 |
| 11 | 8 | 11 | 0 | | 60 | 324 | 1 | 5 |
| 22 | 0 | 2 | 0 | | 60 | 444 | 6 | 5 |

The preceding Table gives a co-efficient of 0.625, which is not very different from 0.619, the mean co-efficient obtained by Bossut.

The following experiments were made by Messrs Brindley and Smeaton. The water extended over a very large surface, and the heights above the orifice were measured from the surface to the tops of the orifices.

| Height of the surface above the tops of the orifices in Feet. | Nature of the orifices. | Time of running. | | Quantity of Water discharged in cubic feet. |
|---|---|---|---|---|
| 1 | 1 in. square | 9 min. | 22 sec. | 20 |
| 2 | 1 do. | 6 | 40 | 20 |
| 3 | 1 do. | 5 | 20 | 20 |
| 4 | 1 do. | 4 | 44 | 20 |
| 5 | 1 do. | 4 | 14 | 20 |
| 6 | $\frac{1}{2}$ do. | 17 | 33 | 20 |

The co-efficient deduced from these experiments is 0 63.

Sect. III. *On the quantities of Water discharged through openings in Reservoirs when very large, and in reaching to the surface.*

The following experiments were made by Messrs. Brindley and Smeaton on the quantities of water discharged by rectangular notches, through which the water flowed from a very extensive surface. The first column contains the width of the notches in inches: the second contains their depth; the third contains the quantity of water discharged; and the fourth the time in which that quantity was discharged.

Table IV. *Containing Messrs Brindley and Smeaton's Experiments on the Quantities of Water discharged by rectangular Notches.*

| Width of the notches in inches. | Depth in inches. | Quantity of water in cubic feet. | Time of discharging. | |
|---|---|---|---|---|
| 6 | 1 | 20 | 7 min. | 16 sec. |
| 6 | $1\frac{3}{8}$ | 20 | 4 | 55 |
| 6 | $2\frac{5}{16}$ | 20 | 2 | 19 |
| 6 | $3\frac{1}{8}$ | 20 | 1 | 33 |
| 6 | $6\frac{1}{2}$ | 20 | 0 | 30 |
| 6 | 5 | 20 | 0 | 46 |
| 6 | $1\frac{1}{4}$ | 20 | 5 | 26 |
| 6 | $1\frac{5}{8}$ | 20 | 3 | 55 |
| 6 | $5\frac{5}{8}$ | 20 | 0 | 42 |

The experiments of Bossut were not extended to any of the cases included in the present Section; but we are fortunately in possession of some good experiments by Du Buat on the quantity of water discharged over weirs and bars, which are cases in which the orifice extends to the surface.

A *weir* or jetty is represented in Figs. 7. and 8. of Plate CCCXVIII. Weirs are most commonly erected as in Fig. 4. where BCD is a weir of solid masonry or of timber, with a strong plank AB, called the wasteboard, over which the water flows. In this case, therefore, the depth of the orifice is measured by the depth of the upper edge of the plank AB below the level surface of the water in the river or reservoir. Du Buat made four accurate experiments on this subject, the result of which is given in the following Table, reduced to English inches, the length of the orifice being $18\frac{1}{3}$ inches.

Table V. *Containing Experiments by Du Buat on the quantity of Water discharged over Weirs.*

| Depth of the orifice in English feet. | Discharge of water in cubic feet observed. | Discharge calculated by the formula. |
|---|---|---|
| 1.778 | 506 | 524 |
| 3.199 | 1222 | 1218 |
| 4.665 | 2153 | 2155 |
| 6.753 | 3750 | 3771 |

M. Buat has given the following formula reduced to English inches, by which column 3d has been calculated, which shews its near agreement with observation. The formula, as altered by Dr Robison, is

$$D = l\sqrt{130.032\,H^3}\text{, or}$$

$$D = 11.4172\,l\,H^{\frac{3}{2}},$$

where D is the quantity of water discharged in cubic feet, $l$ the length of the wasteboard, and H its depth. That is, *multiply the square root of the cube of the depth of the upper edge of the wasteboard below the surface by* $11\frac{1}{2}$, *and by the length of the wasteboard, and the product will be the quantity discharged in English inches.*

In deducing the preceding formula, M. Du Buat has assumed that AF, Fig. 7. is one half of AL, and that the quantity by which we must divide the square of the mean velocity per second, to have the height of fall which is due to it, was 726. Dr Robison, however, had occasion to examine a numerous set of experiments, in which AF was always less than $\frac{1}{2}$ of AL, and was nearly $\frac{2}{7}$, and in which the quantity of water discharged was greater than what is given by Du Buat's formula.

It appeared, indeed, that AF depended on the form of the wasteboard, as might have been expected. When the board was very thin and had a considerable depth, AF was much greater than when the board was thick or narrow, and placed on the top of a broad damhead, as in Fig. 8.

Du Buat's general formula, viz.

$D = \frac{2}{3} l \sqrt{2} G \left(1 - (\frac{1}{2})^{\frac{3}{2}}\right) H^{\frac{3}{2}}$ may be accommodated to any ratio between AF and AL, in place of the ratio of $\frac{1}{2}$ adopted in the formula. Thus, if AF $= m \times$ AL, $m$ being a fractional co-efficient less than 1, the formula becomes

$$D = \frac{2}{3} l \sqrt{2G}\ (1 - m^{\frac{3}{2}}) H^{\frac{3}{2}}$$

Dr Robison has calculated the following Table from Du Buat's formula, which is suited to English inches.

TABLE VI. *Containing the quantity of Water discharged over a Weir.*

| Depth of the upper edge of the wasteboard below the surface in English inches. | Cubic feet of water discharged in a minute by every inch of the wasteboard, according to Du Buat's formula. | Cubic feet of water discharged in a minute by every inch of the wasteboard, according to experiments made in Scotland. |
|---|---|---|
| 1 | 0,403 | 0.428 |
| 2 | 1,140 | 1,211 |
| 3 | 2,095 | 2,226 |
| 4 | 3,225 | 3 427 |
| 5 | 4,507 | 4,789 |
| 6 | 5,925 | 6,295 |
| 7 | 7,466 | 7,933 |
| 8 | 9,122 | 9,692 |
| 9 | 10,884 | 11,564 |
| 10 | 12,748 | 13,535 |
| 11 | 14,707 | 15,632 |
| 12 | 16,758 | 17,805 |
| 13 | 18,895 | 20,076 |
| 14 | 21,117 | 22,437 |
| 15 | 23,419 | 24 883 |
| 16 | 25,800 | 27,413 |
| 17 | 28,258 | 30,024 |
| 18 | 30,786 | 32,710 |

We have added to this Table a third column, containing the quantities of water discharged, as inferred from experiments made in this country, and examined by Dr Robison, who found that they in general gave a discharge $\frac{1}{16}$ greater than that which is deduced from Du Buat's formula. We would recommend it therefore to the engineer to employ the third column in his practice.

The preceding Tables and formula suppose that the water from which the discharge is made is perfectly stagnant; but if it should happen to reach the opening with any velocity, we have only to multiply the area of the section by the velocity of the stream.

When the quantity of water discharged over a weir is known, the depth of the edge of the wasteboard, or H, may be found from the following formula.

$$H = \left(\frac{D}{11.4172\, l}\right)^{\frac{2}{3}}$$

The experiments of Michelotti give $0.2703 \sqrt{H}$ for the number of cubical inches discharged in a second over a weir when the height H is one inch, and the real discharge to the theoretical discharge as 9536 to 1000. These numbers, however, suppose the length of the weir to be infinite, or to be so great that the contraction at its two ends produces no perceptible effect in diminishing the discharge. The formula, therefore, of Michelotti includes only the contractions produced by the upper edge of the wasteboard.

In order to calculate the discharge of rectangular orifices reaching to the surface, M. Eytelwein represents the velocity, which varies as the square root of the height, by the ordinates of a parabola and the quantity of water discharged by the area of a parabola $\frac{2}{3}$ of that of the circumscribing rectangle. Hence the quantity of water discharged may be found by taking $\frac{2}{3}$ of the velocity due to the mean height, and allowing for the contraction of the vein. This mode of calculation M. Eytelwein has found to agree wonderfully with the experiments of Du Buat already given, as well as with several accurate experiments of his own.

M. Eytelwein takes the case of a lake, in which a rectangular opening is made without any lateral walls, three feet wide, and reaching two feet below the surface of the water. In this case, as appears from the following Table of co-efficients given by that engineer, the co-efficient for finding the velocity as corrected for contraction, is 5.1. Hence H being the height, we have $\frac{2}{3}\sqrt{H} \times 5.1$; and since $H = 2$ feet in the present instance, we have the corrected mean velocity $= 4.8$ feet; and as the area is $3 \times 2 = 6$, the quantity of water discharged in a second is 28.8 cubic feet. Putting C for the co-efficient corrected for contraction, W the width of the aperture, and H its depth below the surface, we have the general formula,

$$Q = \frac{2}{3} \sqrt{H} \times C \times \overline{H \times W}$$

for the quantity of water in cubic feet according to Eytelwein.

As the same co-efficient answers for a weir of considerable extent, we may deduce from the preceding formula the depth or breadth necessary for the discharge of a given quantity of water. Thus let it be required in a lake with a weir three feet broad, and in which the water stands five feet above the weir, to know how much the weir must be widened in order that the water may stand a foot lower, we have the velocity $= \frac{2}{3}\sqrt{5} \times 5.1$, and the quantity of water $= \frac{2}{3}\sqrt{5} \times 5.1 \times 3 \times 5$; but as it is required that the height H shall be reduced one foot, or from 5 to 4, we have the velocity suited to this $= \frac{2}{3} \sqrt{4} \times 5.1$, and consequently the section will be

$$\frac{\frac{2}{3}\sqrt{5} \times 5.1 \times 3 \times 5}{\frac{2}{3}\sqrt{4} \times 5.1} = \frac{\sqrt{5} \times 3 \times 5}{\sqrt{4}} = 7.5 \sqrt{5},$$

and the height is 4, the breadth must be $\frac{7.5}{4} \sqrt{5} =$ 4.19 feet.

If the surface of water always stands at the same height AB in the vessel ABCD, Fig. 9. and if the lateral orifice, of considerable magnitude, is *m n o p*, then we have only to determine by the preceding methods the quantities of water discharged by the open orifices *r p o s*, *r m n s*, and the difference between these quantities will give the discharge for the orifice *m n o p*. The same result may be obtained with nearly the same accuracy, by taking the velocity due to the centre of gravity of the orifice below AD, and correcting it by its proper co-efficient.

The following Table contains Eytelwien's co-efficients for different cases connected with those which belong to the present section. The whole velocity due to the height is 8.04, and the diminished velocity arising from contraction is shewn in the last column.

TABLE VII. *Containing Eytelwein's Co-efficients for Orifices of different kinds.*

| No. | Nature of the Orifices employed. | Ratio between the theoretical and real discharges. | Co-efficients for finding the velocities in Eng. Feet. |
|---|---|---|---|
| 1. | For the whole velocity due to the height . . . . | 1 to 1 00 | 8.04 |
| 2. | For wide openings whose bottom is on a level with that of the reservoir | 1 to 0.961 | 7.7 |
| 3. | For sluices with walls in a line with the orifice . . . | 1 to 0.961 | 7.7 |
| 4. | For bridges with pointed piers . . . . . | 1 to 0.961 | 7.7 |
| 5. | For narrow openings whose bottom is on a level with that of the reservoir | 1 to 0.861 | 6.9 |
| 6. | For smaller openings in a sluice with side walls . . . | 1 to 0 861 | 6.9 |
| 7. | For abrupt projections and square piers of bridges . . . | 1 to 0.861 | 6 9 |
| 8. | For openings in sluices without side walls . . . . | 1 to 0.635 | 5.1 |

SECT. IV. *On the Quantities of Water discharged from Vessels kept constantly full, by additional Tubes adapted to circular Orifices.*

IT was observed, even by Julius Frontinus, that a short tube inserted into an orifice produced a greater discharge of fluid than would have been obtained by a simple orifice of the same area.* Guglielmini noticed the same fact, and explained it by an augmentation in the weight of the atmosphere. He regarded the velocity at the end C Q, (Fig. 6.) of the tube BOQC, as that which is due to the whole height AC, upon the erroneous supposition that the pressure at C is the same in a state of motion as in a state of rest. Guglielmini did not consider the diminution of discharge arising from the friction of the same surface of the tube BOQC, nor the augmentation of discharge arising from the form of the tube, and, by a singular concurrence, these errors mutually compensated each other in his experiments.

M. Mariotte considers the water as issuing at CQ, with a velocity which is a mean proportional between the velocities due to the heights AB and AC. Daniel Bernoulli explained the increased expenditure from additional tubes, by the theory of the conservation of living forces; and Euler and d'Alembert† were of opinion, that the pressure of the atmosphere were concerned in the production of the effect. It was reserved, however, for Venturi, as we have already seen in the preceding chapter, to explain the phenomenon in the most satisfactory manner. Before we proceed to give an account of his experiments, we shall lay before our readers a full view of the experiments of M. Bossut.

M. Bossut inserted in the bottom CD (Fig. 10.) of the reservoir ABCD, a cylindrical tube *m n o p* made of copper, well polished within: it was two inches in diameter, and two inches long. Having stopped the aperture *m n* by means of a cork, and filled the reservoir with water to the height of eleven feet eight inches ten lines above *m n*, he found, upon removing the cork, that the water did not follow the sides of the tube, but that the vein was contracted as in a simple orifice, and could not be made to fill the tube without giving it a greater weight. He therefore took a cylinder *m n o p*, one inch in diameter, and two inches long, in which the water readily filled the tube. In repeating these experiments, however, he thought of stopping the discharge within the reservoir, instead of without, by means of a circular plate M, covered with felt, and placed at the end of a handle L. Upon withdrawing the plate M, he was surprised to find that the water sometimes followed the sides of the tube, and sometimes refused to follow them; and he was at last able to produce the effect at pleasure, even when the length of the tube was reduced from 2 inches to 1 inch and 6 lines. When the length of the tube was reduced to half an inch, he could never succeed in making the water touch its sides. Between the interval of half an inch and 1½ inches, it is not easy to observe what takes place with certainty.

The following Table shews the results which M. Bossut obtained.

TABLE VIII. *Containing the Quantities of Water discharged by Cylindrical Tubes one inch in diameter and of different lengths, whether the tubes were inserted in the bottom or in the sides of the vessel*

| Constant altitude of the fluid above the superior base of the tube 11 feet 8 inches and 10 lines. | | |
|---|---|---|
| Lengths of the Tubes expressed in lines. | | Cubical inches discharged in a minute. |
| The tube filled with the issuing fluid . . | 48 | 12274 |
| | 24 | 12188 |
| | 18 | 12168 |
| The tube not filled with the issuing fluid . | 18 | 9282 |

* Sed et calicis positio habet momentum, si in rectum et ad libram collocatus est; modum servat; et ad cursum aquæ si oppositus devexusque, amplius rapit; ad latus autem pretereuntis aquæ conversus et supinus, nec ad haustum pronus; segniter exiguumque sumit. Julius Frontinus *De Aquæductibus Urbis Romæ*, lib. i. juxta fin.

† See D'Alembert *Traité de l'Equilibre et du mouvement des Fluides*, § 149.

These results clearly prove, that the expenditure increases with the length of the tube, and that the quantities of fluid discharged are nearly as the square roots of the altitudes of the fluid above the interior orifice of the vertical tube.

It follows also from the above measurement, that *when the height of the reservoir and the orifice are the same, the theoretical discharge, the discharge by an additional tube, and the discharge by a simple orifice*, are nearly as the numbers 16, 13, 10. Hence Bossut concludes that the effect of contraction is not wholly destroyed by the tube, as the difference between the theoretical and the real discharges is too great to be ascribed to friction.

The following Table contains the effects produced by tubes of different diameters, and under different altitudes of fluid in the reservoir.

TABLE IX. *Containing the Quantities of Water discharged by Cylindrical Tubes two inches long, with different Diameters and under different heads of Water.*

| Constant altitude of the water above the orifice. | | Diameter of the tube. | | No. of cubic inches discharged in a minute. |
|---|---|---|---|---|
| Feet. | Inches. | Lines. | | |
| | | 6 | The tube not filled with the issuing fluid. | 1689 |
| 3 | 10 | 10 | | 4703 |
| | | 6 | | 1293 |
| | | 10 | | 3598 |
| | | 6 | | 1222 |
| 2 | 0 | 10 | | 3402 |
| | | 6 | | 935 |
| | | 10 | | 2603 |

From these results we may conclude,

1. That the discharges by different additional tubes under the same head of water, are nearly proportional to the areas of the orifices, or to the squares of the diameters of the orifices.

2. That the discharges by additional tubes of the same diameter under different heads of water are nearly proportional to the square roots of the heads of water.

*It follows, from the two preceding corollaries, in general, that the discharges during the same time, by different additional tubes, and under different heads of water in the reservoir, are to one another nearly in the compound ratio of the squares of the diameters of the tubes, and the square roots of the heads of water.*

M. Bossut has deduced from the above experiments the following Table, which contains a comparative view of the theoretical discharges from a tube one inch in diameter, with the real discharges by an additional tube of the same diameter, under different heads of water. The last column, containing the ratio between these two discharges, was computed by M. Prony.

TABLE X. *Comparison of the Theoretical with the Real Discharges from an additional Tube of a cylindrical form, one Inch in Diameter and two Inches long.*

| Constant altitude of the Water in the Reservoir above the Centre of the Orifice. | Theoretical Discharges through a circular Orifice one inch in Diameter. | Real Discharges in the same time by a cylindrical Tube *one* Inch in Diameter and *two* Inches long. | Ratio of the theoretical to the real Discharges. |

| 1 | 2 | 3 | 4 |

Hence it follows, that the velocity in English inches will be $V = 22.47\sqrt{H}$ for additional tubes. See p. 498. col. 2.

M. Prony has given the following formulæ, as deduced from the preceding Table. The letters have the same values as in p. 498.

$Q = 0.81\, AT\sqrt{2gH}$; but since $2g$ is constant, and is $= 7.77125$, we have

$$Q = 4.9438\, d^2 T\sqrt{H},$$

From which we obtain

$$d = \sqrt{\frac{Q}{4.9438\, T\sqrt{H}}},$$

$$T = \frac{Q}{4.9438\, d^2\sqrt{H}},$$

$$H = \frac{Q}{(4.9438\, d^2 T)^2}.$$

When the interior surface of the additional tube is of a conical form, the quantities of water discharged undergo considerable variations. M. Bossut made no experiments whatever with tubes of this kind, but the defect is fortunately supplied by those of the Marquis Poleni, which are published in his work *De Castellis per quæ derivantur Fluvium Aquæ*.

TABLE XI. *Containing the Experiments of the Marquis Poleni, on the Quantities of Water discharged by Conical Tubes of different Diameters.*

| Head of Water. | Length of the tube. | Nature of the Orifices employed. | Diameter of the Inner Orifice. | Diameter of the Outer Orifice. | Quantity discharged in a Minute in Cubic Feet, as calculated by Bossut. | Time in which 73035 Cubic Inches were discharged. |
|---|---|---|---|---|---|---|
| Constant height of the water in the reservoir, 256 lines, or 1 foot 9 inches and 4 lines. French. | Length of each tube 92 lines, or 7 inches 8 lines. French. | Orifice in a thin plate, | 26 lines | | 15877 | 4′ 36″ |
| | | Cylindrical tube, | 26 | | 23434 | 3 7 |
| | | 1st Conical tube, | 33 | 26 lines | 24758 | 2 57 |
| | | 2d Conical tube, | 42 | 26 | 24619 | 2 58 |
| | | 3d Conical tube, | 60 | 26 | 24345 | 3 0 |
| | | 4th Conical tube, | 118 | 26 | 23687 | 5 3 |

The discharge in the preceding Table, for a simple orifice, is less than that which is given by Bossut, which appears to arise from his having used a measure of the cubic inch of water, which errs in excess. From Poleni's results, we may conclude,

1. That the real discharges are always less with conical tubes than the theoretical discharges, which, in the present case, is 27425 cubical inches in a minute; and,

2. That in augmenting to a certain degree the diameter of the inner orifice of the conical tube, the quantity of water expended is also augmented; but that, when this enlargement is pushed too far, there is a tendency to produce an exterior contraction of the vein of fluid, and thus to make the circumstances of the case the same as in simple orifices, in which the discharges are the least possible.

When the conical tube is placed with its smallest orifice in the reservoir, it will yield more water than a cylindrical tube, the diameter of whose orifice is equal to the smallest orifice of the conical tube.

The best experiments on additional tubes have been made by M. Venturi, and fully described in his valuable work on the lateral communication of motion in fluids. We have thrown them, in an abridged state, into the following Table, and have computed the numbers in the last column.

TABLE XII. *Containing the Experiments of Venturi on additional Tubes of various forms.*

| Height of Water. | Nature and Dimensions of the Tubes and Orifices. | Time in which 4 Paris cubic feet were discharged. | Number of cubic inches discharged in a minute. |
|---|---|---|---|
| Inches. | 1. Circular orifice, 18 lines in diameter, . . . . . . . . . | 41″ | 10115 |
| | 2. Cylindrical tube, 18 lines in diameter, and 54 lines long, . . . . . | 31 | 13378 |
| | 3. Compound tube, Fig. 11. in which AC = GI = MN = 18 lines; DF = 14.5; AB = 11; BG = 10; GM = 37; AM = 58; the conical portion having nearly the form of the contracted vein, . . . . . . . | 31 | 13378 |
| | 4. Conical tube AC DF, Fig. 11. with the rest removed, . . . . . | 42 | |
| 32.5 | 5. A cylindrical pipe, 18 lines in diameter, and 54 lines long, having 12 small holes made in its circumference, at the distance of 9 lines from its inner orifice, . . . . . . . . . . . . . . . | 41 | 10115 |
| | No water passed through the holes, and the stream did not fill the tube. The same effect was produced when all the holes are open, as when any number of them is shut, provided *one* is open. | | |
| | 6. The same pipe, with all the holes shut with wet skin. The stream now filled the pipe, . . . . . . . . . . . . . . . | 31 | 13378 |
| | 7. Cylindrical tube, Fig. 12, 18 lines in diameter, and 57 lines long. The glass tube QRS was joined to the additional tube, and immersed in a coloured liquid T. The coloured liquid rose to S, 24 inches above T, and the time in which 4 cubic feet were expended was . . . . . . . . | 31 | 13378 |
| | 8. The compound tube of No. 3, or Fig. 11. in the same circumstances as No. 7. | 31 | 13378 |
| 27.5 | 9. The tube, No. 6, with its apparatus, was applied so as to throw the water upwards. The liquor rose 20 inches, . . . . . . . . | 34 | 12198 |
| | 10. Simple orifice, 18 lines in diameter, . . . . . . . . . . | 45 | 9216 |
| 40.0 | 11. Simple orifice, 18 lines in diameter, . . . . . . . . . . | 38 | 10915 |
| | 12. Horizontal tube, partly conical and partly cylindrical, like Fig. 13. diameter at A = 18 lines, AD = 31 inches, . . . . . . . . . . | 43 | 8640 |
| | 13. Same tube, placed vertically, . . . . . . . . . . . | 48 | 8640 |
| | 14. Simple orifice, 11.2 lines in diameter, . . . . . . . . . | 98 | 4232 |
| | 15. Tube of No. 12. placed horizontally, had AC of the form of the contracted vein, and the diameter A, 11.2 lines in diameter, . . . . . . | 130 | 3190 |
| | 16. Tube of No. 15. placed vertically, . . . . . . . . . . . | 129 | 3213 |
| | 17. Vertical tube BOCQ, diameter 18, length BC, 3 inches, Fig. 6. . . . | 41 | 10115 |
| | 18. Ditto, 18, 12, Fig. 6. . . . | 38 | 10915 |
| | 19. Ditto, 18, 24, Fig. 6. . . . | 35 | 11828 |
| | 20. Horizontal tube BOCQ, 18, 3, Fig. 6. . . | 42.5 | 9758 |
| | 21. Ditto, 18, 12, Fig. 6. . . . | 45 | 9216 |

| | 29. Same tube 204 lines long, by fixing a prominence within the tube at O, so as to make the fluid fill the tube . . . . . . . . . . . | 19 | 21830 |
| 32.5 | 30. Horizontal tube, Fig. 15. being made more divergent, 117 lines long and 36 in diameter, the rest remaining as before. The stream did not fill the whole section . . . . . . . . . . . . . . . . . | 28 | 14811 |
| | 31. By cutting off successive portions of the pipe until CE was only 20 lines long, and the external diameter 18 lines, the time always was . . . . | 28 | 14811 |
| | 32. When CE was 20 lines, and EF 20, the stream was detached from the sides of the tube, and the time was . . . . . . . . . . | 42 | 9874 |
| Height above lower extremity. | | | |
| 41.5 | 33. The tube, Fig. 15. was applied in place of BCQO of Fig. C . . . .. | 22 | 18850 |
| 23.0 | 34. The same tube, Fig. 15. applied to form an ascending jet . . . | 30 | 13824 |
| Above upper extremity. | | Time in which one cubical foot of water was discharged | |
| 31.7 | 35. Simple orifice, 4.5 lines in diameter from vertical jet . . . . | 161 | 644 |
| | 36. Ditto with an additional cylindrical tube of the same diameter, and ten lines long . . . . . . . . . . . . . . . . . | 121 | 856 |
| 56. | 37. The orifice of No. 35. with a vertical jet . . . . . . . . . | 123 | 843 |
| | 38. Ditto with an additional cylindrical tube of § 36. . . . . . . | 91 | 1139 |

The preceding Table contains a general abstract of the numerous experiments of Venturi, which were made publicly in the Theatre of Natural Philosophy at Modena. The following are the conclusions which he has deduced from them.

1. If the part of the additional tube nearest the reservoir has the form of the contracted vein, the expenditure will be the same as if the tube were not contracted at all.

This proposition is deduced from experiments 1, 2, 3, 4.

2. The pressure of the atmosphere increases the expence of water through a simple cylindrical tube when compared with that which flows through a simple orifice, whatever be the direction of the tube.

This proposition is deduced from experiments, 5, 6, 7, 8, 9, 10.

3. In descending cylindrical tubes, the upper ends of which have the form of the contracted vein, the quantity of water discharged is that which corresponds with the height of the fluid above the inferior extremity of the tube.

This proposition, which has been established theoretically in the preceding Chapter, is likewise deducible from experiments 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22.

4. In additional conical tubes, the pressure of the atmosphere increases the expenditure in the proportion of the area of the external section of the tube to the area of the section of the contracted vein, whatever be the position of the tube, provided that its internal figure is adapted throughout to the lateral communication of motion.

This proposition is established by experiments 23—33. These experiments also shew, that, by varying the divergence of the sides of the tube, the lateral communication of motion has a maximum and a minimum effect. The minimum is seen in experiment 32. The lateral communication of motion appears to cease to produce its effect when the angle of the sides of the tube exceeds 16°. Experiment 23d nearly determines the maximum effect when the same angle is about 30°.

5. The quantity of water discharged is less through cylindrical tubes than through conical tubes which diverge from the commencement of the contracted vein, and have the same exterior diameter.

This is established by experiments 35, 36, 37, 38.

6. By applying proper adjutages to a given cylindric tube, the expenditure of water through that tube may be increased in the ratio of 25 to 10, the head of water remaining the same.

In order to produce this singular effect, the inner extremity of the tube AD, Fig. 16. must be filled with a conical piece of the form of the contracted vein, which will increase the expenditure from the ratio of 12.1 to 10. At the other extremity of the pipe BC apply a truncated conical tube CD, of which the length must be nearly nine times the diameter at C, and its external diameter D must be 1.8 C. This additional tube will increase the expenditure in the ratio of 24 to 12.1, by experiment 27. Hence the expenditure will be increased by the two pieces in the ratio of 24 to 20.

### *Experiments on the Expenditure of Bent Tubes.*

In order to ascertain the effects of bent tubes, M. Venturi employed two tubes ABC, DEF, Fig. 17. 15 inches long, and 14.5 lines in diameter. The portions A, D have the form of the *vena contracta*, and were applied to the orifice of a reservoir, which was 18 lines in diameter, and in which the water was 32.5 inches high. The elbows or flexures BC, EF were made in the plane of the horizon. The tubes were made of copper soldered with silver, and the curvature BC was produced by filling the tube with melted lead, in order that the tube might preserve its diameter during the act of bending. The elbow DEF was rectangular. A rectilineal tube of similar dimensions was also tried, and the following were the results.

| | Four cubical feet were discharged in |
|---|---|
| Rectilineal tube . . . . . | 45″ |
| Curved tube . . . . . | 50 |
| Rectangular tube . . . . . | 70 |

The following results were obtained by Du Buat, respecting the effects produced by bent tubes 1 inch in diameter, and of different lengths.

| | Number of Bendings. | Angle of the bending. | Velocity per second, both in straight and bent tubes in inches. | Augmentation of the head of water which overcomes the resistance at the flexure. | Augmentation of the head calculated from the formula. |
|---|---|---|---|---|---|
| | | | | Inches. | Inches. |
| Tube 1 inch in diameter and 117 inches in length. | 3 | 36° 0 | 84 945 | 2.49 | 2.49 |
| | 2 | 36 0 | 84 945 | 1.5 | 1.66 |
| | 4 | 24 34 | 84 945 | 1.5 | 1.66 |
| | 3 | 24 34 | 84.945 | 1.12 | 1.24 |
| | 1 | 36 0 | 84.945 | 0.75 | 0.83 |
| | 2 | 24 34 | 84.945 | 0 75 | 0 83 |
| | 1 | 24 34 | 84 945 | 0.37 | 0.41 |
| | 10 | 36 0 | 71 59 | 5.905 | 5.905 |
| Tube 138 inches long. | 4 | 36 0 | 58.808 | 1.64 | 1.59 |
| Tube 117 inches long. | 4 | 36 0 | 58.438 | 1.5 | 1.57 |
| | 2 | 36 0 | 58.438 | 0 75 | 0.78 |
| | 4 | 24 34 | 58.438 | 0.75 | 0.78 |
| | 1 | 36 0 | 58.438 | 0.37 | 0.39 |
| Tube 138½ inches long. | 4 | 36 0 | 29.33 | 0.41 | 0.396 |
| Tube 737 inches long. | 4 | 36 0 | 28.657 | 0.39 | 0.378 |

The last column of the preceding Table is computed from the formula $\frac{V^2 s^2 n}{m}$; V being the velocity, $s$ the sine of the angle of the bending. $n$ the number of bendings, and $m$ a constant quantity, which is found to be nearly 300. Hence $\frac{V^2 s^2}{300}$ is the measure of the resistance.

M. Venturi employed a tube of the form shewn in Fig. 18. The orifice A has the form of the contracted vein, and the rest of the tube is interrupted by various enlargements of its diameter. The following are its dimensions:

| | Lines. |
|---|---|
| Diameter at A . . . . . . . | 11.2 |
| Diameter at B, C, F, G, . . . | 9 |
| Diameter of the enlarged parts . | 24 |
| Length of BC, FG, &c. . . . | 20 |
| Length of CD, EF, GH, . . . | 13 |

The length of the enlarged parts was variable, being at one time 38, and another 76 lines, with the same effect in both.

By means of this tube, the following results were obtained under a pressure of 32.5 inches.

| Number of enlarged parts. | Time in which four cubical feet of water were discharged. |
|---|---|
| 0 . . . . . . . . . . . . | 109″ |
| 1 . . . . . . . . . . . . | 147 |
| 3 . . . . . . . . . . . . | 192 |
| 5 . . . . . . . . . . . . | 240 |

Venturi afterwards applied to the same orifice a tube having the same form and the same diameter as ABC, but cylindrical throughout, and without any enlargements. It was 36 inches long, and the time in which four cubic feet were expended was 148″.

"When the fluid passes from C," says Venturi, "to the middle of the enlarged part DE, part of the motion is directed from the direction CF towards the lateral parts of the enlargement. This part of the motion is consumed in eddies, or against the sides. Consequently there remains so much the less motion in the following branch FG. This is also the cause which destroys or weakens the pulse in the arteries beyond an aneurism.

"From this consideration we are justified in concluding, that if the internal roughness of a pipe diminishes the expenditure, the friction of the water against these asperities does not form any considerable part of the cause. A right lined tube may have its internal surface highly polished. Throughout its whole length it may every where possess a diameter greater than the orifice to which it is applied; but, nevertheless, the expenditure will be greatly retarded if the pipe should have enlarged parts or swellings. This is a very interesting circumstance, to which, perhaps, sufficient attention has not been paid in the construction of hydraulic machines. It is not enough that elbows and contractions are avoided; for it may happen by an intermediate enlargement, that the whole advantage may be lost which may have been procured by the ingenious dispositions of the other parts of the machine."

*Eytelwein's Experiments on additional Tubes.*

The experiments of M. Eytelwein on additional tubes confirm the general results obtained by Venturi. The following are the leading results which he obtained:

| | Ratio of the Discharges. | Co-efficients for the velocity. |
|---|---|---|
| Shortest tube that will cause the stream to adhere every where to its sides . . | .8125 to 1.0000 | 6.5 |
| Short tubes, having their lengths from 2 to 4 times their diameters . . . | .82 | 6.6 |
| Conical tube approaching to the form of the *vena contracta* . . . . . . | .92 | 7.38 |
| The same tube with its edges rounded off . . . . | .98 | 7.86 |
| A tube projecting within the reservoir . . . . . | .50 | 4.0 |

M. Eytelwein is of opinion, that Venturi's assertion that the discharge of a cylindric tube may be increased in the ratio of 24 to 10, is not generally correct, and that when the tube is very long, scarcely any additional expenditure is obtained by the addition of such a tube. From a great number of experiments which he made with different pipes he infers, that a compound conical pipe, such as that shewn in Fig. 16, may increase the discharge to 2½ as much as through a simple orifice, or as 24 to 10, as stated by Venturi, or to more than half as much more as would fill the whole section with the velocity due to the height; but that where a considerable length of pipe intervenes, the additional orifice appears to have little or no effect.

Michelotti made many experiments for determining the real form of the *vena contracta*. He constructed a great variety of ajutages resembling it, till he found one which gave the greatest discharge. This ajutage was formed by the revolution of a trochoid round the axis of the jet. The diameter of the outer orifice was 36, that of the inner orifice 46, and the length of the axis was 96. This ajutage gave .9831 to 1000 as the ratio of the real to the theoretical discharge. The following are Michelotti's results:

| | |
|---|---|
| Theoretical discharge . . . . . . | 1.0000 |
| Trochoidal ajutage . . . . . . . . | 9831 |
| Tube 2 diameters long . . . . . . . | 8125 |
| For a tube projecting into the reservoir, and flowing full . . . . . . . | 6814 |
| For do. when the vein was contracted | 5134 |

SECT. V. *Experiments on the Exhaustion of Vessels.*

We have already seen, in stating the general principles of hydraulics, that a funnel-shaped cavity is formed in the surface of a fluid, when, in the course of its descent, it has nearly reached the orifice from which the fluid is discharged. This circumstance renders it impossible to determine the exact time in which a vessel is completely emptied. The superincumbent pressure of the head of water being removed by the formation of the funnel-shaped cavity above the orifice, the water is at last discharged in successive drops. M. Bossut therefore abandoned the idea of attempting to measure the time of emptying vessels, and confined his experiments to the determination of the time in which the upper surface of the fluid descends through a certain vertical height in prismatic vessels, in which the area of the horizontal section is constant. The following Table contains the results of his experiments.

TABLE XII. *Shewing the times in which Prismatic Vessels are partly exhausted.*

Altitude of the water in the reservoir 11.6666 Paris feet. Constant area of a horizontal section of the vessel in square feet.

| Diameter of the circular orifice. | Depression of the upper surface of the fluid. | Time in which the depression takes place, according to experiment. | | Time of the depression of the surface by the formula. | | Difference between the theory and the experiments. |
|---|---|---|---|---|---|---|
| Inches. | Feet. | Min. | Sec. | Min. | Sec. | Seconds. |
| 1 | 4 | 7 | 25½ | 7 | 22.36 | 3.14 |
| 2 | 4 | 1 | 52 | 1 | 50.59 | 1.41 |
| 1 | 9 | 20 | 24½ | 20 | 16 | 8 50 |
| 2 | 9 | 5 | 6 | 5 | 4 | 2 00 |

The first column of the Table contains the diameter of the circular orifice; the second the depression of the upper surface of the fluid in feet; the third the time in which the surfaces descend through this height, according to experiment; the fourth contains the time as calculated from the formula in Chapter I. corrected by substituting 0.62 A instead of A, in order to make allowance for the effect of contraction. The numbers in column fourth always err in defect, probably from 0.62 being taken too great. If the orifices are vertical, the altitude of the fluid must be measured from their centre of gravity.

A few experiments on the partial exhaustion of vessels were made by M. Venturi. An orifice, 4.5 lines in diameter was made near the bottom of a cylindrical vessel 4.5 inches in diameter. The altitude of the water in the vessel was 8.3 inches above the centre of the orifice. The surface of the water was then depressed 7 inches in 27½ seconds. A cylindrical tube of the same diameter as the orifice, and 11 lines in length, was applied to the same orifice. The vessel was filled to the same height as formerly, and its surface descended 7 inches in 21 seconds of time. These experiments were afterwards repeated under the receiver of an air pump, in which the mercurial gauge stood only at the height of 10 lines, and the surface of the fluid was depressed 7 inches, whether the water flowed through the simple orifice, or the cylindrical tube.

SECT. VI. *Experiments of Bossut on the discharge of Water into a submerged Vessel.*

In order to examine the discharge of water into submerged vessels, M. Bossut employed a vessel ABCD, (Plate CCCXIX. Fig 1.) two feet in diameter, in which a white-iron cylinder VMNT, 1 foot high, and 20 lines in diameter, was immersed. This cylinder is supported on a tripod, so that it can be set in a vertical line, and is furnished with graduated scales for measuring the water which it receives. The orifice in the cylinder VMNT being shut, water is poured into the vessel till it reaches a certain height, and when the orifice is opened, the water rushes in and fills the cylinder. The following are the results of Bossut's experiments.

| Depth of immersion or HM. | Diameter of the orifice. | Time in which the water rises to H on a level with the water in the vessel. | Calculated time. |
|---|---|---|---|
| 11 inches | 1 line | 119 seconds. | 155.97 |
| 11 | 3 | 15 | 17.33 |

The fourth column contains the time, as calculated from theory, which differs very considerably in the first experiment from the observed time. M. Bossut accounts for this, by saying, that at the first entrance of the water a jet is formed, which penetrates the plate of water in the cylinder VMNT, till it stands at a certain height, when the surface of the water becomes level. Now as this jet will continue longer with small than with large orifices, a greater quantity of water, in proportion, ought to be discharged. Bossut also made the following experiments.

*Exp.* 1. When the water entered the cylinder by an orifice one inch in diameter, it was necessary to immerse the cylinder 8 inches and 11 lines in the water of the vessel, in order that the water might raise itself to the upper margin VT of the vessel.

*Exp.* 2. The bottom MN being wholly removed, the cylinder required to be immersed 7 inches and 7 lines, in order that the water might rise to the upper margin VT.

*Exp.* 3. When a large plate of white-iron was put round MN, it was necessary to sink the cylinder 6 inches 11½ lines, in order that the water might rise to the upper margin VT.

SECT. VII. *Bossut's Experiments on the Motion of Water in a Vessel crossed with Diaphragms.*

The experiments of Bossut on this subject were made with two vessels, ABCD, DCBA, Fig. 2. and Fig. 3. whose internal diameter is 6 inches, and height 3 inches. The length of ED was one foot, and EA two feet. The diaphragm EF was pierced with an aperture G, 6 lines in diameter; covers DC, AB with different orifices, were placed successively on the cylinder, and the cylinders were inverted as shewn in the two Figures. A narrow opening, 18 lines broad, was cut through the whole length of the cylinders, and covered up with glass, in order to see what was going on within, and near the diaphragm EF was perforated a small aperture *t*, which could be either opened to admit the air, or shut up with wax. The following results were then obtained.

*Exp.* 1. The cylinder Fig. 2. being completely filled, and the hole *t* shut, orifices of 6, 12, and 21 lines were successively applied. In all these cases the water in the lower compartment abandoned the diaphragm when the height EH of the water was about 6 or 7 lines. At the instant of separation a whistling noise was heard, arising from the passage of the air from the upper to the under compartment.

*Exp.* 2. By inverting the cylinder as in Fig. 3. and applying the same orifices, the very same effects were produced.

*Exp.* 3. The vessel having the position in Fig. 2. the hole *t* being now opened, and the orifice at M being 6 lines, the separation took place when EH was about 14 inches.

*Exp.* 4. When the diameter of the orifice at M was four lines, the separation took place when EH was six inches.

## Sect. VIII. *Experiments on the ascent of Water in Jets d'eau, either vertically or obliquely.*

The custom which formerly prevailed of decorating pleasure grounds and public squares with jets d'eau, rendered the subject of the present Section much more interesting than it is at present. The phenomena of Jets, however, are still of importance in a scientific point of view; and as the fashions of former times may again return, it would be inexcusable to omit altogether the consideration of this branch of Hydrodynamics.

According to the theory of vertical jets, which has already been explained under Chap. I. of Part II. they ought to rise to the same height as that of the surface of water in the reservoirs from which they flow. This, however, is not found to be the case in practice. The friction of the water on the sides of the tubes, the resistance of the air, and the obstruction of the descending drops, all conspire in diminishing the altitude to which water would otherwise be projected.

In the experiments made by Bossut, he employed a large reservoir ABCD, Fig. 4. and 5. to which he fitted horizontally two tubes BE of white iron, closed at the end E, and open at the end next the reservoir. Each of these was six feet long. The diameter of the first was 3 inches 8 lines, and that of the second from 9 to 10 lines, and on the upper surface of these tubes ajutages of different sizes were placed. Around the ends of each ajutage was soldered a tube of white iron, whose diameter was greater than that of the ajutage, in order to be able to stop the jet by means of cork, which goes into the white iron tubes. The following Table contains the results of the experiments.

Table XIII. *Shewing the Altitudes to which Jets rise through Ajutages of different forms, the Altitude of the Reservoir being Eleven Feet, reckoning from the upper surface of the horizontal Tubes* OE, OE. *Fig.* 4. *and* 5.

| Diameter of the horizontal tubes CE, CE, each being 6 feet long. | | Form of the Orifices. | References to Fig. 4. and 5. | Diameter of the Orifice. | Altitude of the Jet when rising vertically, reckoning from OF. | | | Altitude of the Jet when inclined a little to the vertical. | | | Description of the Jets. |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Inch. | Lines. | | | Lines. | Feet. | Inch. | Lines. | Feet. | Inch. | Lines. | |
| 3 | 8 | Simple orifice, | F | 2 | 10 | 0 | 10 | 10 | 4 | 6 | The vertical jet very fine. |
| 3 | 8 | — | G | 4 | 10 | 5 | 10 | 10 | 7 | 6 | The vertical jet fine, and not much enlarged at the top. |
| 3 | 8 | — | H | 8 | 10 | 6 | 6 | 10 | 8 | 0 | All the jets occasionally rise to different heights. This is very perceptible in the present experiment. The vertical jet is much enlarged at top. The inclined one less so, and more beautiful. |
| 3 | 8 | Conical tube, | M | Length, 70; Lower diameter, 9; Upper diameter, 4 | 9 | 6 | 4 | 9 | 8 | 6 | The vertical jet fine. |
| 3 | 8 | Cylindrical tube, | N | Length, 70; Diameter, 4 | 9 | 1 | 6 | 7 | 3 | 6 | The vertical jet is very fine. |
| 0 | 9½ | Simple orifice, | M | 2 | 9 | 11 | 0 | — | — | — | The jet is here fine. |
| 0 | 9½ | — | L | 4 | 9 | 7 | 10 | — | — | — | The jet is much deformed, and very much enlarged at top. |
| 0 | 9½ | — | K | 8 | 7 | 10 | 0 | — | — | — | The column is much broken; and the successive jets are detached from each other. |

In comparing the three first experiments, it appears that great jets rise higher than small ones. This arises from the greater mass of the large jets; for, as both of them are projected with the same velocity, the large ones having a greater momentum, are more able to overcome the obstacles which are opposed to them. This, however, is true only of high jets. For when they do not exceed two or three feet in height, and when the ajutages are not below one line in diameter, small jets rise to the same height as large ones. This conclusion must also be limited to the case where the conduit pipe OE affords a sufficient supply of water; for it appears, from the three last experiments, when the conduit tube OE is very narrow, that the small jets rise to a greater height than large ones. Hence there is obviously a certain ratio which must exist between the diameter of the horizontal tube and that of the ajutage, to produce a maximum height in the jet.

In order to find this ratio, Bossut has given the following method. Let D be the diameter of the tube, $d$ that of the orifice, $v$ the velocity of the water in the tube, and $h$ the altitude of the fluid in the reservoir. Now $\sqrt{h}$ may be taken as the constant velocity at the ajutage. But by Hydraulics, Chap. I. Prop. 1. $\sqrt{h} : v = D^2 : d^2$, and $v = \frac{d^2}{D^2}\sqrt{h}$. In like manner, in any other tube, in which $D'$ $d'$, $h'$ and $v'$ represent the same quantities as before, we have $v' = \frac{d'^2}{D'^2}\sqrt{h'}$. But upon the hypothesis, which is conformable to experiment, that two jets will each rise to the greatest possible height when the velocities of the water in the two conduit tubes are equal, we have $v = v'$ and $\frac{d^2}{D^2}\sqrt{h} = \frac{d'^2}{D'^2}\sqrt{h'}$; consequently, $D^2 : D'^2 = d^2 \sqrt{h} : d'^2 \sqrt{h'}$; that is, *the squares of the diameters of the horizontal tubes ought to be to each other in the compound ratio of the squares of the diameters of the ajutages, and the square roots of the heights of water in the reservoir.*

Hence, if we know from one direct experiment the diameter which a tube ought to have to supply a given ajutage under a given height of fluid in the reservoir, we may find the diameter of every other tube which is necessary to supply any other ajutage under a given height of fluid in the reservoir.

With this view, M. Bossut made the following experiments. He applied a tin tube one inch in diameter to a reservoir. The point of the tube, bent upwards in order to project the water vertically, was made of lead, and was a little more than an inch long, and to the extremity of it seven different orifices were successively applied. The following were the results.

Table XIV. *Containing the Experiments of Bossut on the Height of Jets with different Orifices.*

| Diameter of the Ajutage. Lines. | Height of the Jet. Feet. | Inches. | lines. |
|---|---|---|---|
| 1 | 3 | 1 | 6 |
| 2 | 3 | 1 | 8 |
| 3 | 3 | 2 | 0 |
| 4 | 3 | 1 | 7 |
| 5 | 3 | 1 | 5 |
| 6 | 3 | 0 | 4 |
| 7 | 2 | 10 | 6 |

From these results it follows, that for a height of water in the reservoir of 3 feet 2 inches and 11 lines, and a conduit tube which has a diameter of 1 inch, the diameter of the orifice should be about $3\frac{3}{4}$ lines. Now Mariotte found, from experiment, that for a head of water of 52 feet, and an ajutage 6 lines in diameter, the diameter of the conduit tube should be 36 lines; whereas the preceding rule will give 38, agreeing very nearly with the experimental result.

It appears, from a comparison of the experiments of Bossut and Mariotte, that the *differences between the height of vertical jets and the height of the reservoir are nearly as the square of the heights of the jets themselves.* Hence, if we know this difference in one case, the difference in any other will be found by simple proportion. If the height of the reservoir of the second jet is given, and if it is required to determine the height of the jet, we must resolve a quadratic equation. Thus, let $a$ be the height of the reservoir of the experimental jet, $b$ the height of the same jet, $c$ the height of the reservoir of the proposed jet, $x$ the height of the proposed jet; then by the rule $a - b : c - x = b^2 : x^2$, we obtain

$$x^2 = \frac{b^2\,(c-x)}{a-b}, \text{ or } x = \frac{-b^2 + b\sqrt{(4ac - 4bc + b^2)}}{2(a-b)}$$

In order to facilitate the application of the preceding principles to practice, Bossut has computed the following Table:

Table XV. *Containing the Altitudes of Reservoirs, the Diameters of the Horizontal Tubes, &c. for Jets of different heights.*

| Altitude of the jet. | Altitude of the reservoir. | | Quantity of water discharged in a minute from an ajutage 6 lines in diameter. | Diameters of the horizontal tubes suited to the two preceding columns. |
|---|---|---|---|---|
| Paris Feet. | Feet. | Inch. | Paris Pints. | Lines. |
| 5 | 5 | 1 | 32 | 21 |
| 10 | 10 | 4 | 45 | 26 |
| 15 | 15 | 9 | 56 | 28 |
| 20 | 21 | 4 | 65 | 31 |
| 25 | 27 | 1 | 73 | 33 |
| 30 | 33 | 0 | 81 | 34 |
| 35 | 39 | 1 | 88 | 36 |
| 40 | 45 | 4 | 95 | 37 |
| 45 | 51 | 9 | 101 | 38 |
| 50 | 58 | 4 | 108 | 39 |
| 55 | 65 | 1 | 114 | 40 |
| 60 | 72 | 0 | 120 | 41 |
| 65 | 79 | 1 | 125 | 42 |
| 70 | 86 | 4 | 131 | 43 |
| 75 | 93 | 9 | 136 | 44 |
| 80 | 101 | 4 | 142 | 45 |
| 85 | 109 | 1 | 147 | 46 |
| 90 | 117 | 0 | 152 | 47 |
| 95 | 125 | 1 | 158 | 48 |
| 100 | 133 | 4 | 163 | 49 |

The two first columns, containing the heights of the jets and the corresponding altitudes of the reservoirs, are taken from Mariotte. The heights of the jets and of the reservoirs, not included in the Table, may be found from the preceding formula. The third column contains, in Paris pints, of which 36 form a cubic foot, the water discharged in a minute by an ajutage six lines in diameter; and the fourth column contains the diameter which ought to be given to the conduit tubes for an ajutage of six lines relatively to the altitudes in column 2. This column is computed on the hypothesis, that for an ajutage six lines in diameter, and an altitude of 16 feet of water in the reservoir, the conduit tube must be $28\frac{1}{2}$ lines in diameter, and upon the principle that the squares of the diameters of the conduit tubes are as the squares of the diameters of the ajutages multiplied by the square roots of the altitude of water in the reservoir.

It appears from a comparison of columns 5th and 6th of Table XIII. that the jets never reach the height of the reservoir, and that a small inclination of the jet causes it to rise higher than when it is projected vertically, a fact which was long ago observed by Wolfius. (See *Elementa Matheseos Universæ*, tom. i. p. 802. schol. 4.) The diminution of the height of the jet has been very properly ascribed by Wolfius principally to the gravity of the falling waters, which obstruct the ascent of the water which is rising. When the velocity of the foremost particles of water is spent, the particles immediately behind strike against them, and lose their velocity, and in consequence of this constant collision between the ascending and descending particles, the jet continues at an altitude less than that of the reservoir. This consideration also affords a reason why the height of the jet is increased, by giving it a slight inclination; for the descending fluid falling a little to one side, no longer opposes the ascent of the rising fluid. In proof of the opinion that the diminution of the jet is produced by the gravity of the falling water, Wolfius states that he has found that mercury rises to a still less altitude than water.* This, however, is not owing to the greater specific gravity of mercury; for though the particles of mercury are heavier than those of water, yet the momentum with which they ascend is proportionally greater, and therefore there is the same ratio between the momentum and the resistance which opposes their ascent, as there is in the case of water.

Toricellius† seems to have been the first who observed, that when the water is first projected from the orifice it generally springs higher than the height at which it permanently settles, which no doubt arises from there being at first no descending fluid to retard its vertical ascent. Another phenomenon, however, more remarkable, has been noticed by other authors. When the water first escapes from the orifice, it generally springs higher than the reservoir from which it flows, but the elevation is momentary, and the water speedily settles at a constant height. This fact has been ascribed to the elasticity of the air which follows the water in its passage through the orifice: but it is manifest that this would only diminish its specific gravity, as in the hydreoles of M. Mannoury Dectot, (see page 826,) and would never give an additional impulse to the ascending fluid. In order to explain this phenomenon, Bossut supposes the ajutage to be stopped, and that the air which follows the water accumulates near the orifice in a condensed state; as soon therefore as the orifice is opened, the elasticity of the included air causes it to escape with rapidity, and the water rushing into the space which it leaves, acquires by this short fall in the tube a certain velocity, which increases at the orifice in the ratio of the section of the orifice to the section of the tube.

In Chap. I. of Hydraulics, we have considered the theory of oblique jets. The following experiments were made by Bossut.

| Height of the water above the orifice. Feet. | Diameter of the ajutage. Lines. | Height of the ajutage above a horizontal plane. Ft. | in. | lin. | Amplitude of projection on a horizontal plane. Ft. | in. | lin. |
|---|---|---|---|---|---|---|---|
| 9 | 6 | 4 | 3 | 7 | 12 | 3 | 3 |
| 4 | 6 | 4 | 3 | 7 | 8 | 2 | 8 |

Hence it follows, that the real amplitudes, which are always less than those deduced from theory, are nearly as the square roots of the altitudes of the water in the reservoirs. In order to find the amplitude of any other jet, when the height of the water in the reservoir is 25 feet, we have $\sqrt{9} : \sqrt{25} =$ 11 feet 3 inches 3 lines : 18 feet 9 inches 5 lines.

The following experiments on oblique jets were made by M. Venturi and M. Michelotti.

| Height of the water in the reservoir. Inches. | Nature of the orifice. | Height of the ajutage above a horizontal plane. Inches. | Amplitude of projection. Inches. |
|---|---|---|---|
| 32.5 | A simple orifice | 54 | 81.5 |
| 32.5 | Additional tube | 54 | 69 |
| | Plate CCCXVIII. Fig. 5. | | |
| | A simple orifice | 19.33 | 23.2 |
| | Additional tube | 19.33 | 20 |

M. Bossut took a tube, and having filled it with water, he allowed it to empty itself by orifices of different sizes. When no orifice was added, but when the tube was allowed to empty itself, the water did not issue with the greatest velocity when the tube was fullest, but when a certain quantity of the water had run out. In the case of small ajutages, the greatest velocity, and the greatest amplitude of projection, is always that which is due to the corresponding height of water in the reservoir; but, in very large orifices, this relation does not exist.

## CHAP. IV.

### On the Motion of Water in Pipes and Open Canals.

There is perhaps no branch of science so highly important as that part of Hydrodynamics which relates to the conveyance of water in pipes and canals, and there is none in which theory affords the engineer so little assistance.

When it is required to supply a town with water, the first step of the engineer is to discover one or more springs situated above the level of that part of the town from which the water is to be distributed to private houses, and to the public fountains. The water discharged by the springs is then to be collected into one or more reservoirs; and conduit pipes of lead, or wood, or iron, are then to be laid to convey the water to the principal reservoirs in the town. The quantity of water which is necessary for the supply of the inhabitants having been previously ascertained, an additional allowance being made for the probable extension

* "Ego quidem multum tribuo gravitati aquæ ascendentis, quia observavi quod argentum vivum ad minorem altitudinem elevatur quam aqua. Nimirum guttarum anteriorum motus si languescit, posteriores in eas incurrentes retardantur: id quod ipsismet oculis suis videre poterit, qui aquas salientes attentius contemplare voluerit. Atque inde est quod si lumen angulo quantolibet exiguo inclinetur, ut aqua saliens a perpendiculo non admodum declinare videatur, saltus altitudo statim major evadat." Wolfii *Elementa Matheseos Universæ*, tom. i. p. 802. Schol. 4.

† *De Motu Projectorum*, lib. iii. or his *Opera Geometrica*, p. 192.

of the town, the engineer has next to consider what diameter of pipe is necessary to convey the quantity of water required. The quantity of water discharged will obviously depend upon the diameter of the conduit pipe, and on the velocity with which the water issues from it. Hence, if we can find the velocity of the water, the diameter will be easily ascertained.

The experiments of which we have already given a full account, enable us to determine, with very great accuracy, the velocity with which water will issue from an orifice of any form, or from short cylindrical or conical tubes, either simple or compound; and hence we can easily ascertain the velocity with which the water will enter the pipe, or its *initial velocity;* but these experiments afford us no assistance in ascertaining the various obstructions which the water suffers in its passage, so as to determine the velocity with which it issues from a pipe of a given length and diameter.

In order to obtain practical rules relative to this interesting subject, many valuable and laborious experiments have been made. The most celebrated individuals who have devoted their attention to this branch of hydrodynamics, are Bossut, Du Buat, M. Prony, and M. Girard, by whose labours the art of conducting water has been brought to a very high degree of perfection. It shall therefore be our principal object in the present Chapter to give an account of the experiments of these eminent individuals.

SECT. I. *Account of the Experiments of Bossut and Couplet on the Motion of Water in Conduit Pipes and Open Canals.*

THE experiments of Bossut were made upon an eminence near the springs by which the town of Mezieres is supplied with water. Two reservoirs were excavated, one of which furnishes water to the second, in which it stood at a constant height. The first of these reservoirs contained from 25 to 30 cubic toises of water, and the second was considerably less in magnitude, so as to contain only about six cubic toises of water when it stood at its greatest height, which was about $4\frac{1}{2}$ feet. A horizontal tube of white iron, about eight or nine inches in diameter, communicated with the bottom of the small reservoir, and terminated in a cubical box of white iron, about one foot broad, and shut up on all sides. To one of the vertical faces of this box were fitted perpendicularly two straight pipes of white iron, one of which had sixteen lines of interior diameter, and the other twenty-four lines. Various lengths of these pipes were employed, between 30 and 180 feet. At different distances, small holes were perforated, in order to facilitate the exit of the included air. These apertures were afterwards stopped up by a little wax. In this way M. Bossut obtained the results contained in the following Table.

TABLE I. *Containing the Quantities of Water discharged by Conduit Pipes of different lengths and diameters, compared with the Quantities discharged from additional tubes inserted in the same Reservoir.*

| Constant altitude of the water in the reservoir above the axis of the tube. | Length of the conduit pipes. | Quantity of water discharged in a minute by an additional tube. (Tube and Pipe 16 lines diam.) | Quantity of water discharged by the conduit pipe in a minute. (Tube and Pipe 16 lines diam.) | Ratio between the quantities of water furnished by the tube and the pipe of 16 lines diameter. | Quantity of water discharged by an additional tube in a minute. (Tube and Pipe 24 lines diam.) | Quantity of water discharged by the conduit pipe in a minute. (Tube and Pipe 24 lines diam.) | Ratio between the quantities of water furnished by the tube and the pipe of 24 lines diameter. |
|---|---|---|---|---|---|---|---|
| Feet. | Feet. | Cubic Inches. | Cubic Inches. | | Cubic Inches. | Cubic Inches. | |
| 1 | 30 | 6330 | 2778 | 100 to 43.89 | 14243 | 7680 | 100 to 53 92 |
| 1 | 60 | 6330 | 1957 | 100 to 30 91 | 14243 | 5564 | 100 to 39.06 |
| 1 | 90 | 6330 | 1587 | 100 to 25.07 | 14243 | 4534 | 100 to 31.83 |
| 1 | 120 | 6330 | 1351 | 100 to 21.34 | 14243 | 3944 | 100 to 27.69 |
| 1 | 150 | 6330 | 1178 | 100 to 18.61 | 14243 | 3486 | 100 to 24.48 |
| 1 | 180 | 6330 | 1052 | 100 to 16.62 | 14243 | 3119 | 100 to 21.90 |
| 2 | 30 | 8939 | 4066 | 100 to 45.48 | 20112 | 11219 | 100 to 55.78 |
| 2 | 60 | 8939 | 2888 | 100 to 32.31 | 20112 | 8190 | 100 to 40.72 |
| 2 | 90 | 8939 | 2352 | 100 to 26.31 | 20112 | 6812 | 100 to 33 87 |
| 2 | 120 | 8939 | 2011 | 100 to 22 50 | 20112 | 5885 | 100 to 29.26 |
| 2 | 150 | 8939 | 1762 | 100 to 19 71 | 20112 | 5232 | 100 to 26.01 |
| 2 | 180 | 8939 | 1583 | 100 to 17.70 | 20112 | 4710 | 100 to 23.41 |
| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |

This Table contains two sets of experiments, one set on the relative quantities of water discharged by an additional tube 16 lines in diameter, and a pipe of various lengths of the same diameter; and another set on the relative quantities discharged by an additional tube 24 lines in diameter, and a pipe of various lengths and of the same diameter. The fifth and eighth columns contain the ratios of these discharges, which are also the ratios of the velocities with which the water issues from the additional tube and the extremities of the pipes.

Even at the short length of 30 feet, the velocity with which the water issues from the pipe is nearly one half of that with which it issues from the tube, and when the pipe is 180 feet long, and its diameter 16 lines, the ratio of the velocities is only 100 to 16.6, so that the water has lost 5-6ths of its initial velocity by its friction on the sides of the pipe.

It is obvious, from a comparison of columns 5 and 8, that the diminution of the velocity is greatest in small pipes; a result which arises from the friction having a much greater effect on the fluid in the axis of the small tube, than on the fluid in the axis of the great one.

By comparing the six first experiments with the six last experiments, it will be seen that as the height of the fluid in the reservoir is increased, the diminution of discharge, and consequently of velocity, is also increased. This fact is analogous to what takes place in the friction of solid bodies, which in general increases with the velocity. Perhaps, however, it may yet be found, that when a very great velocity is given to the water, its velocity may be augmented, as Coulomb found it to be in some cases in solid bodies. From the above experiments, M. Bossut concludes in general, that the quantities of water discharged in equal times by a horizontal pipe under the same height of water in the reservoir, and for different lengths, *are to one another in the inverse ratio of the square roots of the lengths*, provided that these lengths are not very different from one another. Hence when we know by experiment the quantity of water discharged for a given length of pipe, we may find the quantity discharged for any other length. Since the diminution of velocity is greatest when the head of water is small, we may conceive the head of water to be reduced to such a degree, that the velocity with which the water enters the pipe is not sufficiently powerful to overcome the resistances arising from the friction upon the pipe, and the mutual cohesion of the particles of water. In order to examine this point experimentally, M. Bossut employed a head of water only 16 lines, from which the water flowed into the two preceding pipes, when their length was a hundred and eighty feet. In this case the water was discharged in the form of a narrow fillet, and the drops succeeded each other almost as if they were insulated bodies. Hence it follows, that in order to have a perceptible and continuous discharge from conduit pipes, there should be a head of water of about 20 lines in 180 feet. If the current of water, however, is very large, such a great declivity as this will not be necessary.

As the preceding experiments relate only to pipes placed horizontally, M. Bossut proceeds to the consideration of vertical and inclined pipes. In the case of a vertical pipe, it is obvious that its motion will be accelerated during its descent through the tube, as appears in the experiment of Venturi already described. When the pipe is inclined, a similar acceleration takes place when the inclination is considerable; for if the angle of inclination were only one degree, the resistances which the fluid experiences would more than counterbalance the acceleration of gravity.

The following Table contains Bossut's experiments with a pipe, which formed the hypothenuse of a right angled triangle, the hypothenuse being to the altitude of the triangle as 2124 to 241. Its diameter was sixteen lines.

TABLE. II. *On the Quantity of Water discharged by inclined Pipes of different lengths.*

| Head of water in inches. | Diameter of pipe. | Length of the pipe. | Number of cubic inches discharged in a minute. |
|---|---|---|---|
| 10 | 16 lines. | 59 feet. | 5808 |
| 10 | 16 | 118 | 5801 |
| 10 | 16 | 177 | 5795 |

Now, an additional tube of the same diameter, and with the same head of water, would have discharged 5779 cubic inches in a minute, which is less than that which is discharged by the preceding pipes. By diminishing, however, the inclination of the above pipes, they would be brought to give the same discharge as the additional tube. This equality of discharge will take place when the inclination of the pipe is 6° 31′, or when the depression of the lower extremity of the pipe is one-eighth or one-ninth of its length. In this case the velocity, arising from the relative gravity of the water, is exactly counterbalanced by the resistance which the water experiences in the pipe.

### *On the Motion of Water in Bent Pipes.*

In order to determine the effects of flexures or bendings in conduit pipes, M. Bossut made the following experiments. The pipes were perforated with small holes to facilitate the ascent of the air. At the end of each pipe was soldered a tube M, about two inches in diameter, which communicated with the smallest of the reservoirs already mentioned. This additional tube is furnished with a stopcock R, perforated with an aperture of more than 18 lines in diameter.

TABLE III. *Shewing the quantities of Water discharged by rectilineal and curvilineal leaden Pipes, 50 feet long, 1 inch in diameter, and 1 line thick.*

| Altitude of the Water in the Reservoir. | | Form and position of the Conduit Pipes. See Plate CCCXIX. Figs. 6, 7, 8. | Quantities of Water discharged in a Minute. |
|---|---|---|---|
| Feet. | Inch. | | Cub. Inch. |
| 0 | 4 | The rectilineal tube MN, placed horizontally, Fig. 6 . . | 576 |
| 1 | 0 | The same tube similarly placed, | 1050 |
| 0 | 4 | The same tube, bent into the curvilineal form ABC, Fig. 7. each flexure lying flat on a horizontal plane, ABC being a horizontal section, . . . | 540 |
| 1 | 0 | The same tube similarly placed, | 1030 |
| 0 | 4 | The same tube placed as in Fig. 8, where ABCD is a vertical section, the parts A, B, C, D, rising above a horizontal plane, and the parts *a*, *b*, *c*, lying upon it, . . . . . | 520 |
| 1 | 0 | The same tube similarly placed, | 1028 |

It appears from this Table, that a curvilineal pipe, in which the flexures lie horizontally, discharges less water than a rectilineal pipe of the same length, and that a still greater diminution takes place when the flexures are placed in a vertical plane. When there is a number of contrary flexures in a large pipe, the air sometimes lodges in the highest parts of the flexures, and greatly retards the motion of the water. This effect may be prevented by air holes, or by stop-cocks, which can be shut when the motion of the water is perfectly established.

As the pipes employed by M. Bossut were extremely short, he has endeavoured to supply this defect by combining them with the experiments made by M. Couplet at Versailles, with pipes, several of which were more than one mile, and one nearly three miles long. The results are shewn in the following Table.

TABLE IV. *Containing the results of the Experiments of Couplet and Bossut on Conduit Pipes differing in form, length, diameter, and in the materials of which they are composed,—under different Altitudes of water in the Reservoir.*

| Altitude of the water in the reservoir. | | | Length of the conduit pipes. | Diameter of the conduit pipes. | Nature, Position, and Form of the Conduit Pipes. | Ratio between the quantities which would be discharged if the fluid experienced no resistance in the pipes, and the quantities actually discharged;—or the ratio between the initial and the final velocities of the fluid. |
|---|---|---|---|---|---|---|
| Feet. | Inch. | Lines. | Feet. | Lines. | | |
| 0 | 4 | 0 | 50 | 12 | Rectilineal and horizontal pipes made of lead . . | 100 to 3.55 |

The application of the preceding Table is very simple. Let it be required, for example, to find the diameter of a pipe capable of discharging 40,000 cubic inches of water in a minute, at a point four feet below the level of the spring, and by a pipe 2400 feet long. Now, a short cylindrical tube, one inch in diameter, will furnish 7070 cubic inches in a minute, when the head of water is four feet. Hence, to find the diameter which will discharge 40,000 cubic inches, we have the analogy $\sqrt{70720} : \sqrt{40,000} = 12$ lines : 28.54 lines, the diameter required. But it appears from the preceding Table, that when the length of the pipe is about 2400 feet, it will discharge only about one-eighth of the water, or 5000 cubic inches. Hence, in order that it may discharge the whole 40,000 cubic inches, its diameter must be increased. This new diameter will be found thus, $\sqrt{5000} : \sqrt{40,000} = 28.54$ lines to 80.72, or six lines $8\frac{7}{10}$ lines, the diameter of the pipe which will discharge 40,000 cubic inches of water in a minute.

The following Table contains the remaining experiments made by M. Bossut.

TABLE. V. *Containing Bossut's Experiments on the Quantities of Water discharged by different Pipes of various Lengths and with different Ajutages.*

| Head of Water in Feet. | Length of Pipe. | Diameter of Pipe. | Size of Orifice. | Ratio of the Real to the Theoretical Discharges. | Ratio of the Height due to the Velocity to the Head of Water. | Cubic Inches of Water discharged in a Minute. |

The preceding experiments were made at Mezieres, on the 8th and 9th October, 1779, upon the water discharged from the public and private fountains of that city.

*Bossut's Experiments on the Pressure exerted upon Pipes by the Water which they convey.*

In Chap. I. of this part of hydraulics, we have already considered theoretically the amount of the pressure exerted upon conduit pipes by the included water. When a tube placed horizontally discharges water without any additional aperture, it is obvious that the weight of the included water is the principal force which it has to bear. But if the water is discharged through a small ajutage, the velocity of the water in the pipe is diminished, and hence there results a pressure against the sides. In order to measure this pressure, Bossut perforated the pipes at different lengths or distances from the reservoir with small apertures exactly perpendicular to the axis of the pipe, and considered the quantity of water discharged in a given time as the exact measure of the lateral pressure which forced the fluid through the orifice. In this way he obtained the results in the three first columns of the following Table, which is suited to an orifice $3\frac{1}{4}$ lines in diameter.

TABLE VI. *Containing the Quantities of Water discharged by a Lateral Orifice, or the Pressures on the Sides of Pipes, according to Theory and Experiment.*

| Altitude of the Water in the Reservoir. | Length of the Conduit Pipe. | Quantities of Water discharged in 1 Minute, according to Experiment. | Quantities of Water discharged in 1 minute, computed from the Formula. |
|---|---|---|---|
| Feet. | Feet. | Cubic Inches. | Cubic Inches. |
| 1 | 30 | 171 | 176 |
| 1 | 60 | 186 | 186 |
| 1 | 90 | 190 | 190 |
| 1 | 120 | 191 | 191 |
| 1 | 150 | 193 | 192 |
| 1 | 180 | 194 | 193 |
| 2 | 30 | 240 | 244 |
| 2 | 60 | 256 | 259 |
| 2 | 90 | 261 | 264 |
| 2 | 120 | 264 | 267 |
| 2 | 150 | 265 | 268 |
| 2 | 180 | 266 | 269 |

The fourth column in the preceding Table is calculated from the formula $q = Q \times \frac{\sqrt{(D^4-d^4)}}{D^2}$, which is thus obtained. We have already seen in Chap. I. of Part II. that the pressure of the fluid on the pipe is measured by $h - \frac{d^4 h}{D^4}$. Then if Q is the quantity of water which would have been discharged in a given time under the head or pressure $h$, the quantity of water $q$ discharged in the same time under the head or pressure $h - \frac{d^4 h}{D^4}$, will be thus found Q: $q = \sqrt{h} : \sqrt{\left(h - \frac{d^4 h}{D^2}\right)}$, and

$$q = Q \times \frac{\sqrt{(D4-d4)}}{D^2}.$$

The agreement of the formula with the experiments is very striking. From this method of considering the subject, M. Bossut deduces a very simple method of determining the discharge from a long tube subject to friction from the expenditure of an orifice perforated in its sides. Let $x$ denote the ratio of the expenditure of the proposed pipe having regard to friction, to the expenditure upon the supposition that there is no friction; or, which is the same thing, let $x = \frac{d^2}{D^2}$. By substituting $x$ in place of $\frac{d^2}{D^2}$ in the preceding formula, we have $q = Q\sqrt{(1 - x^2)}$, and $x = \frac{\sqrt{(Q^2-q^2)}}{Q}$. Let us now suppose that the tube has two inches diameter, that the Q head of water is 3 feet, that the lateral orifice is 6 lines, and that it discharges at the orifice 1000 cubic inches in a minute. This orifice, as appears from former experiments, would give 1178 cubic inches in a minute, if the extremity of the pipe were stopped, that is, $Q = 1178$ cubic inches, whilst $q$ is only 1000 cubic inches. By putting these values in the equation $x = \frac{\sqrt{(Q^2-q^2)}}{Q}$, we have $x = 0.5289$. But by Table II. p. 839, this additional tube would give 24504 cubic inches in a minute, abstracting the effects of friction; hence the effects of friction being included, it will discharge $0.5289 \times 24504 = 12952$ cubic inches in a minute. The preceding observations are also applicable to inclined tubes, whether straight or curved.

In the formation of pipes, it is necessary to give them a much greater thickness than that which is necessary to resist the pressure indicated by the preceding Table, for the pipes are exposed to several forces which are not taken into consideration. The following Table contains the thickness of leaden and iron pipes, which were used in France in the time of Bossut.

| Leaden Pipes. | | Iron Pipes. | |
|---|---|---|---|
| Diameter in inches. | Thickness in lines. | Diameter in inches. | Thickness in lines. |
| 1 | 2½ | 1 | 1 |
| 1½ | 3 | 2 | 3 |
| 2 | 4 | 4 | 4 |
| 3 | 5 | 6 | 5 |
| 4½ | 6 | 8 | 6 |
| 6 | 7 | 10 | 7 |
| 7 | 8 | 12 | 8 |

The thickness of pipes ought to increase with the head of water, and the strain should always be calculated from the whole height of the reservoir, and upon the supposition that the pipe is stopped at one end.

*Bossut's Experiments on the Motion of Water in Canals.*

The experiments of Bossut on this subject were made upon an open canal, the bottom of which was on a level with the bottom of the reservoir from which the water flowed. The orifice by which the water issued into the canal from the reservoir had constantly a horizontal width of 5 inches, but the height of the orifice was made to vary by raising or depressing a slider so as to obtain a rectangular opening of various heights. In order to measure the velocity of the water in the canal, Bossut tried various ways; but he ultimately preferred the method of finding it by observing the time which elapsed between the opening of the orifice, and the arrival of the water at different parts of the canal. The velocity thus found is obviously less than the velocity of the water when the current is perfectly established. But there is a constant ratio between these two velocities, in consequence of which the one may be safely inferred from the other. The canal was 105 feet long, and was divided into five equal parts and also into three equal parts; so that each of the fifth parts was 21 feet, and each of the third parts 35 feet long. In order to ascertain the arrival of the water at these different parts of the canal, small wheels like those used by children were placed at each point of division; and the commencement of their motion, which indicated the arrival of the water at that point, was instantly perceived by the person who counted the oscillations of the pendulum. When the canal was horizontal, the following were the results.

TABLE VII. *Containing the Velocity of Water in different parts of a Rectangular Horizontal Canal* 105 *feet long, under different Altitudes of Fluid in the Reservoir.*

| Altitude of water in the reservoir. | *Ft. In.* 11 8 | *Ft. In.* 7 8 | *Ft. In.* 3 8 | *Ft. In.* 11 8 | *Ft. In.* 7 8 | *Ft. In.* 3 8 | Space run through by the water. |
|---|---|---|---|---|---|---|---|
| Vertical breadth of the orifice. | ½ an inch. | ½ an inch. | ½ an inch. | 1 inch. | 1 inch. | 1 inch. | *Feet.* |
| Time in which the number of feet in column 7th are run through by the water. | 2″ | 3″— | 3″+ | 2″ | 2″+ | 3″— | 21 |
| | 5— | 7 | 9 | 4 | 5 | 6+ | 42 |
| | 10— | 13— | 17+ | 7 | 9 | 11+ | 63 |
| | 16— | 20— | 27+ | 11 | 14 | 18+ | 84 |
| | 23+ | 28+ | 38+ | 16½ | 20 | 26 | 105 |

In the preceding Table the signs + and — indicate that the number of seconds is either a little too small or a little too great.

It appears from the above Table, that the time successively employed by the water in running through spaces of 21 feet each, are as the numbers 2, 3—, 5, 6, 7 +, which form nearly an increasing arithmetical progression, the difference of whose terms is nearly 1, so that the series may be continued, and the time determined in which the water will run through any number of feet. The two serieses of the times and spaces may also be continued for the other experiments in the Table, by means of the formula $t = 1'' \times \frac{4\,E}{5\sqrt{15\,H}}$, where E is the space described uniformly in the time $t$, with a velocity due to the height H. Bossut has calculated the times for the last line of the Table, or for the whole length of 105 feet. These times are,

| | | | | | | |
|---|---|---|---|---|---|---|
| Calculated by the formula, | 6″.350, | 7″.834, | 11″.330, | 6″.350, | 7″.184, | 11″.330 |
| Observed, | 23 | 28 | 38 | 16¼ | 20 | 26 |

from which it appears that the velocity of the water in the canal is very much retarded by the different resistances which it experiences; and that the retardation is less as the height of the orifice is increased.

The following experiments were made on the motion of water in inclined canals. The inclination of the canal is the depression of its lower extremity below a horizontal line which passes through its upper extremity.

| | 5 | 6 | 7 | | | | 42 |
| | 8+ | 10— | 11+ | | | | 63 |
| | 12 | 13+ | 15 | | | | 84 |
| | 15+ | 17 | 20 | | | | 105 |

In the preceding experiments, Bossut only observed the velocity of the first portion of the water that issued from the reservoir. In order to compare this velocity with that of the current after it is completely established, he made the experiments in the following Table; the time in which the first portion of the water moved through the spaces in col. 6. was measured by means of the small wheels already mentioned; and the time in which the established current moved through the same spaces, was ascertained by placing gently upon the water four pieces of cork, which followed exactly the current. The first portion of the canal was always run through in less time than any of the other divisions, and the velocity did not become sensibly uniform till the declivity was about the 10th part of the length of the canal.

TABLE IX. *Containing a Comparison between the Velocity of the First Portion of Water, and that of the Established Current.*

| Altitude of the water in the reservoir. | Vertical breadth of the Orifice 1 inch. | | Vertical breadth of the Orifice 2 inches. | | Space run through by the water. |
|---|---|---|---|---|---|
| | Time in which the space in col. 6. was run through by the 1st portion of water. | Time in which the space in col. 6. was run through by the established current. | Time in which the space in col. 6. was run through by the 1st portion of water. | Time in which the space in col. 6. was run through by the established current. | |
| Feet. Inch. | Seconds. | Seconds. | Seconds. | Seconds. | Feet. |
| | 10 | 8 | 8 | 7 | 100 |
| | 20+ | 17 | 17 | $14\frac{1}{2}$ | 200 |
| 4 0 | 31— | 26 | 26 | 22 | 300 |
| | 42— | 35 | 35— | 29+ | 400 |
| | $52\frac{1}{2}$ | 43+ | 43+ | 37— | 500 |
| | 62+ | 52 | 52— | 44+ | 600 |
| | 11 | 10 | 9 | 8— | 100 |
| | 23 | 20 | 19 | 16 | 200 |
| 2 0 | 35 | 30 | 29 | 24 | 300 |
| | 46+ | 40 | 39 | 32 | 400 |
| | 58 | 49 | 49 | 40 | 500 |
| | 69 | 58 | 58 | 48 | 600 |
| | 12+ | 12 | 15 | 13 | 100 |
| 1 0 | $25\frac{1}{2}$ | 23+ | 31 | $26\frac{1}{2}$ | 200 |
| | 39 | 33 | 47 | $39\frac{1}{2}$ | 300 |
| | 11— | 9 | $13\frac{1}{2}$ | $11\frac{1}{2}$ | 100 |
| 0 6 | 22 | 18— | $26\frac{3}{4}$ | 23 | 200 |
| | $32\frac{1}{2}$ | 27 | $39\frac{1}{2}$ | $33\frac{1}{2}$ | 300 |

It will be seen from these results, that the velocity of the first portion of water is always less than that of the established current, and that the one has to the other a ratio which is nearly constant. The difference between these two velocities is obviously owing to friction, and to the viscidity of the fluid. The velocity of the water in contact with the bottom of the canal is not only retarded by friction, but the weight of the superincumbent fluid; and the fluid must obviously have the greatest velocity at the surface at a point equidistant from the sides.

## SECT. II. *Account of the Researches and Experiments of the Chevalier Du Buat.*

IN the preceding investigations of Bossut, no attempt is made to deduce any very general principle or formula from which the quantity of water discharged by pipes and canals could be obtained in cases which are not comprehended in the limits of his tables. His experiments, indeed, were neither sufficiently numerous nor varied to lay the foundation of any very general rule; and it is perhaps too much to expect that the same person should have the honour both of laying the foundation, and of bringing to perfection, one of the most difficult branches of physico-mathematical science.

In the historical part of this article, we have given a full account of the origin of the labours of the Chevalier Du Buat, and have stated the general formula which he obtained for expressing in all cases the velocity of water, whether it is conveyed in a pipe or canal, or rolls in the beds of rivers. We shall now proceed to give as succinct and perspicuous a view as possible of the principal steps by which this formula was obtained, and shall then point out the method of applying the formula in practice, by means of copious Tables, which have never before been published.

Considering an inch as the unity of length, and a second as the unity of time, we may express the declivity of a canal by $\frac{1}{s}$, on the supposition that upon the length of the pipe or canal $s$ there is a fall of 1 inch. But, in order to find the slope of a conduit pipe when the height of the reservoir and the place of discharge are known, we must subtract from the height of the reservoir, the height or head of water H due to the real velocity, which, in additional tubes, is $H = \frac{V^2}{505}$; for we have already seen in p. 502, col. 2, that $V = 22.47 \sqrt{H}$. Hence $H = \frac{V^2}{22.47^2} = \frac{V^2}{505}$. The remainder which arises after this subtraction must be considered as a declivity to be distributed over the whole length of the pipe.

In considering theoretically the change which the resistances will experience by an increase of velocity, it will appear that they will increase as the squares of the velocity; for while the impulses on all the little asperities are increased in the proportion of the velocity, the number of impelling particles is also increased in the same proportion. Du Buat therefore supposes the resistances equal to $\frac{V^2}{m}$, $m$ being a constant quantity to be determined by experiment. Now, if $g$ expresses the velocity acquired by a heavy body at the end of a second, $\frac{g}{s}$ will be the accelerating force relative to the slope $\frac{1}{s}$. But from the fundamental axiom, *that when a stream moves uniformly, the resistance is equal to the accelerating force*, we obtain $\frac{V^2}{m} = \frac{g}{s}$ and $V \sqrt{s} = \sqrt{mg}$, that is, in the same pipe or canal, the product of the velocity by the reciprocal of the square root of the slope is a constant quantity; and the leading formula for all the uniform velocities is $V = \frac{\sqrt{mg}}{\sqrt{s}}$.

M. Du Buat now proceeds to examine the preceding equation experimentally, in order to ascertain if $V \sqrt{s}$ is actually a constant quantity. After comparing together the results of many accurate experiments, he finds that the values of $V \sqrt{s}$, though taken in the same pipe or canal, are not exactly equal, but that they increase a little in proportion as the velocities increase; and hence he concludes, *that the resistances are in a less ratio than the square of the velocities*. Hence the term $\sqrt{s}$ ought to be diminished. The fraction of the slope which Du Buat found to make $\sqrt{mg}$ a constant quantity, is $\sqrt{s} - \text{Log.} \sqrt{s + 1.6}$ in employing the hyperbolic logarithms. Let X represent this fraction; then we shall have $VX = \sqrt{mg}$ for the same pipe or canal.

It is manifest from theoretical considerations, as well as from direct experiment, that the resistances must have a relation to the magnitude of the section of the pipe or canal. As the resistances all arise from the friction of the water upon the sides of the tube or canal, it is obvious that they must be least in those pipes and canals in which the section has the greatest ratio to the perimeter in contact with the water; that is, the resistance of every particle of water will be in the direct ratio of the perimeter of the section, and inversely as the area of the section.

In cylindrical pipes, the section is the area of a circle; and the perimeter of the section is the circumference of the circle; and the quotient arising from dividing the one by the other is always one half of the radius; or one half of the radius multiplied by the circumference is always equal to the area of the section. In rectangular and irregular channels, there is still some line, which, multiplied by the perimeter of the section, will give an area equal to the area of the section of the channel. This line, which may be called $d$, has been named the mean radius by Du Buat, and the hydraulic mean depth by Dr. Robison.

Since the resistances increase as the ratio of the perimeter of the section to the area of the section increase, so the quantity $m$ must be proportional to $d$; and consequently $\sqrt{mg}$ must be proportional to $\sqrt{d}$ for different channels; and $\frac{\sqrt{mg}}{\sqrt{d}}$ should in every case be a constant quantity.

In examining, by experiment, if this was actually the case, Du Buat found, that $\sqrt{mg}$ was neither proportional to $\sqrt{d}$, nor to any power of $d$, but that it increased less and less in proportion as $\sqrt{d}$ increased. In very wide channels $\sqrt{mg}$ becomes sensibly proportional to $\sqrt{r}$, but in small channels the velocity diminished much more than the values of $\sqrt{r}$. Du Buat ascribes this effect to the viscidity of the water, and he found, that his experiments were completely represented by diminishing $\sqrt{d}$ by one-tenth of an inch, that is, by using $\sqrt{d} - 0.1$ insead of $\sqrt{d}$; and hence $\frac{\sqrt{mg}}{\sqrt{d} - 0.1}$ is always a constant quantity, which Du Buat found, from many experiments, to be equal to 297.

Now, since $\frac{\sqrt{mg}}{\sqrt{d} - 0.1} = 297$, we have $m = \frac{\overline{297}^2}{g}$ $(\sqrt{d} - 0.1)^2 = \frac{88209}{362} (\sqrt{d} - 0.1)^2 = 243.7 (\sqrt{d} - 0.1)^2$ (or making $n = 243.7$) $= n (\sqrt{d} - 0.1)^2$. But the resistances were expressed by $\frac{V^2}{m}$, consequently they will now be expressed by $\frac{V^2}{n (\sqrt{d} - 0.1)^2}$.

We have also $\sqrt{mg} = \sqrt{ng} (\sqrt{d} - 0.1)$, and since $VX = \sqrt{mg}$, we obtain $V = \frac{\sqrt{ng} (\sqrt{d} - 0.1)}{X} = 297 \frac{(\sqrt{d} - 0.1)}{X}$, which is an expression of the velocity V for any channel, which, X being a variable quantity, M. Du Buat next proceeds to determine.

We do not think that our readers will be much instructed in following our author in his experimental determination of X. Upon the supposition that the value X must be sensibly proportional to $\sqrt{s}$ when $s$ is great; that it must always be less than $\sqrt{s}$; that it must deviate, from the proportion of $\sqrt{s}$, so much the more that $\sqrt{s}$ is smaller; that it must not vanish when the velocity is infinite; and that it must agree with a series of experiments for every variety of channel and slope, M. Du Buat found, that these conditions would be fulfilled if we take $X = \sqrt{s} - \text{Hyp. Log.} \sqrt{s + 1.6}$. Hence $V = \frac{297 (\sqrt{d} - 0.1)}{\sqrt{s} - \text{Log.} \sqrt{s + 1.6}}$.

M. Buat next supposes, that there is a constant portion of the accelerating force employed in overcoming the viscidity, and producing the mutual separation of the adjacent filaments; and he expresses that part of the accelerating force by a part $\frac{1}{S}$ of that slope which constitutes the whole of it. If this were not employed in overcoming a resistance, it would produce a velocity which is really lost; so that, in reasoning upon this as we did upon the real velocity, its value will be $\frac{\sqrt{ng} (\sqrt{d} - 0.1)}{\sqrt{S} - \text{Log.} \sqrt{S}}$, a quantity which must always be subtracted from the velocity already determined. Hence the value of V will be $V = \frac{\sqrt{ng}(\sqrt{d}-0.1)}{\sqrt{s}-\text{Log.}\sqrt{s+1.6}} - \frac{\sqrt{ng}(\sqrt{d}-0.1)}{\sqrt{S}-\text{Log.}\sqrt{S}} = (\sqrt{d}-0.1)\left(\frac{\sqrt{ng}}{\sqrt{s}-\text{Log.}\sqrt{s+1.6}} - \frac{\sqrt{ng}}{\sqrt{S}-\text{Log.}\sqrt{S}}\right)$. But since the term $\frac{\sqrt{ng}}{\sqrt{S}-\text{Log.}\sqrt{S}}$ is composed of constant quantities, it may be expressed in a single number. The value of it was determined by many experiments to be 0.3 inches. By substituting, therefore, this value, we obtain

$$V = \frac{\sqrt{ng}(\sqrt{d}-0.1)}{\sqrt{s}-\text{Log.}\sqrt{s+1.6}} - 0.3(\sqrt{s}-0.1), \text{or in numbers,}$$

$$V = \frac{297(\sqrt{d}-0.1)}{\sqrt{s}-\text{Log.}\sqrt{s+1.6}} - 0.3(\sqrt{d}-0.1) \text{ in Fr. measure,}$$

$$V = \frac{307(\sqrt{d}-0.1)}{\sqrt{s}-\text{Log.}\sqrt{s+1.6}} - 0.3(\sqrt{d}-0.1) \text{in Eng. measure.}$$

In these expressions the following are the values of the letters employed.

V represents the mean velocity in inches per second of any current moving in a channel of indefinite length, of which the sections of the declivity are constant.

$d$ is the mean radius or hydraulic mean depth, or a quantity, which, when multiplied by the perimeter of the section of the channel, gives an area equal to the area of the section. In circular pipes $d$ is equal to half the radius.

$n$ is an abstract and constant number, which is found by experiment to be equal to 243.7.

$g$ is the velocity in inches, acquired by a falling body at the end of a second of time, being always equal to 32.174.

$s$ is the denominator of a fraction which expresses the slope of the channel, the numerator being supposed unity.

*Log.* denotes the hyperbolic logarithm of the quantity to which it is prefixed, and may be obtained by multiplying the common logarithm by 2.302581.

In order to shew the agreement of the preceding formula with experiment, M. Du Buat drew up the following Table, which contains the observed velocities as deduced from the experiments of Bossut, and from many new experiments made by Du Buat himself, and also the velocities calculated from the formula.

In the first set of experiments on pipes, col. 1. contains the number of the experiment; col. 2. the length of the pipe; col. 3. the height of the reservoir; col. 4. the values of $s$ as deduced from col 2. and 3; col. 5. the observed velocities; and col. 6. the computed velocities.

In the second set of experiments on canals and rivers, col. 2. shows the area of the section of the channel; col. 3. the perimeter of the channel in contact with the water; col. 4. the square roots of $d$, or the mean radius or hydraulic mean depth; col. 5. the denominator $s$ of the slope; col. 6. the mean velocities observed; and col. 7. the mean velocities calculated.

TABLE X. *Containing a comparison of the Velocities calculated by Du Buat's Formula, with the Velocities observed in the Experiments of Couplet, Bossut, and Du Buat, on Pipes, Canals, and Rivers.*

The slightest inspection of the preceding Table will show the reader how much the science of hydrodynamics is indebted to the labours of M. Buat. The coincidence of the calculated with the observed velocities is extremely striking.

*New Tables for Facilitating the Application of Du Buat's Formula.*

In order to facilitate the application of the formula in practice, Dr Robison, in his dissertation on Water-works, published in his *System of Mechanical Philosophy*, has computed two tables, one of which contains calculated values of the numerator of the fractional formula, or value of V, also the value of the negative quantity 0.3 ($\sqrt{d}$—0.1) corresponding to the different values of $d$ from 0.1 to 100; while the other contains the value of the denominator of the formula for different values of $s$ from 1.0 to 24000.

As these Tables were neither sufficiently correct, nor extensive, we have inserted the following tables, which were calculated with great care and trouble by Mr John Lourie of Glasgow, who has permitted us to publish them for the first time.

The column of natural numbers has been added in this Table, which will enable the engineer to calculate the velocity V without having recourse to logarithms. The logarithmic differences are likewise added.

*Explanation of the Tables.*

Table I. contains values of the denominator of the fractional formula. Col. 1. contains the values of $s$ or the length of the pipe; and col. 2, 3, 4. the natural numbers, the hyperbolic logarithm, and the logarithmic difference from the denominator 307 ($\sqrt{d}$—0.1), all of which are computed from 1.0 to 2400.

Table II. which has not been calculated in any shape by Dr Robison, has been computed by Mr Lourie, and contains the values of the numerator 307 ($\sqrt{d}$—0.1), and the negative quantity 0.3 ($\sqrt{d}$—0.1) suited to conduit pipes of all diameters, from $\frac{1}{4}$ of an inch to 18 inches in diameter.

Table III. contains the values of the numerator of the fractional formula, and also the values of the negative quantity 0.3 ($\sqrt{d}$—0.1.) The first column contains the values of $d$, the mean radius or the hydraulic mean depth; col. 2 and 3. contain the natural numbers, and also the hyperbolic logarithms, and the logarithmic difference for the numerator 307 ($\sqrt{d}$—0.1); and col. 5. contains the values of the negative quantity 0.3 ($\sqrt{d}$—0.1), all of which are computed from 0.1 to 100.

## TABLE I.

*Containing values of* $\sqrt{s}$—Hyp. Log. $\sqrt{s+1.6}$, *the Denominator of the Fraction* $\dfrac{307(\sqrt{d}-0.1}{\sqrt{s}-\text{Hyp. Log.}\sqrt{s+1.6}}$ *for every Value of the Slope s.*

| Slope of the Pipe, or s. | $\sqrt{s}$—Hyp. Log $\sqrt{s+1.6}$ | | Log. Differ. | Slope of the Pipe, or s. | $\sqrt{s}$—Hyp. Log $\sqrt{s+1.6}$ | | Log. Differ. | Slope of the Pipe, or s. | $\sqrt{s}$—Hyp. Log. $\sqrt{s+1.6}$ | | Log. Differ. |

*Method of Using the preceding Tables.*

Example I. Water is brought into Edinburgh by several pipes, one of which is 5 inches in diameter. This pipe is 14,367* feet long, and the reservoir at Comiston is 44 feet higher than the reservoir on the Castle-hill into which the water is delivered. It is required to know how many Scots pints the pipe should deliver in a minute.

1. In this case we have $d = \frac{5}{4} = 1.25$ inches.

2. We have $s = \frac{14,367}{44} = 326.36$.

Now, by entering Table III. with 1.25 as the value of $d$, and Table I. with 326 as the value of $s$, we obtain

2.49490 as the logarithm for the *numerator*, and
1.18065 as the logarithm corresponding to 326.36.
——— the difference of which logarithms is
1.31425 the logarithm of 20.618, or the value of

$$\frac{307(\sqrt{d}-01)}{\sqrt{s} - \text{Hyp. Log.} \sqrt{s+1.6}}$$

In order to find the value of the negative quantity 0.3 ($\sqrt{d}$—0.1) enter Table III. col. 1. with 1.25, and in col. 5. will be found, by taking proportional parts, 0.305 ; hence we have the velocity V=20.618—0.305=20.313, the velocity of the water in inches per second.

The whole of the preceding operation may be saved by Table II.; for, by entering col. 1. of this Table with five inches as the diameter of the pipe, we obtain at once 2.49490, and 0.305 as the values of the numerator and the negative quantity. In order to obtain the number of Scotch pints per minute, each of which contains 103.4 cubic inches, we must multiply the velocity by 60″, and this product by $5^2$ or 25, and then by 0.7854, the area of a circle whose diameter is 1, and then divide by 103.4. Thus,

| | | |
|---|---|---|
| Log. of | 20.313 | 1.3077741 |
| Log. of | 60″ | 1.7781513 |
| Log. of | $5^2$ or 25 | 1.3979400 |
| Log. of | 0.7854 | 9.8950909 |
| | From | 4 3789563 |
| Subtract Log. of | 103.4 | 2.0145205 |
| Remains Log. of | 231.44 | 2.3644358 |

Scots pints which should be delivered by the pipe.

Now, the pipe, when in its best order, yielded 250 pints in a minute, as we have learned from a MS. note of Dr. Robison.

Since the logarithm of 60, of .7854, and of 103.4 is constant, we may take 1.7781513+9.8950909— 2.0145205 =9.6587217, and the operation will stand thus :

| | |
|---|---|
| Log. of 20.313 | 1.3077741 |
| Log. of $5^2$ | 1.3979400 |
| Log. for reducing to Scotch pints | 9.6587217 |
| Log. of 231.44 as before. | 2.3644358 |

Hence we have the following Rule: Add together the logai. hm of the velocity in inches per second, as found by the formula, the logarithm of the square of the diameter of the pipe, and the constant logarithm 9.6587213, and the sum is the logarithm of the Scotch pints discharged in a minute.

The facts in the preceding example respecting the supply of Edinburgh with water was taken from Dr Robison's article on Waterworks already quoted. We are informed, however, by James Jardine, Esq. civil engineer, that the facts are wholly erroneous, and we have been indebted to the kindness of this gentleman for the following state of the Edinburgh water pipes, to which we shall apply the formula of Du Buat.

Example II. An excellent cast leaden pipe was laid from the fountain head at Comiston to the reservoir on the Castlehill of Edinburgh in the year 1720. The interior diameter of the pipe was $4\frac{1}{2}$ inches, the fountain-head was 51 feet above the point of delivery, and the length of the pipe was 14,930 feet. Its maximum discharge during the years 1738, 1739, 1740, 1741, and 1742, was $11\frac{1}{3}$ cubic feet, or 189.4 Scotch pints per minute.

In this example we have $d = \frac{4\frac{1}{2}}{4} = 1.125$

$$s = \frac{14930}{51} = 292.745$$

| | | |
|---|---|---|
| Log. of numerator | | 2.46971 |
| Log. of denominator | | 1.15431 |
| Log. of | 20.673 | 1.31540 |
| Subtract negative quantity | .288 | |
| Remains | 20.385 the velocity per second. | |
| Hence | | |
| Log. of 20.385 | | 1.3093107 |
| Log. of $\overline{4\frac{1}{2}}^2$ or 20.25 | | 1.3064250 |
| Log. for reducing to Scotch pints | | 9.6587217 |
| Log. of 188.13 Scotch pints | | 2.2744574 |

A result which agrees in a very wonderful manner with 189.4, the quantity actually delivered by the pipe.

Example III. A flanch cast iron pipe is laid from Swanston cistern to the reservoir on the Castlehill, Edinburgh. Its diameter is seven inches ; the cistern at Swanston is 222 feet higher than the point of delivery, the length of the pipe is 21,350 feet, and in its best state it delivers $3\frac{1}{2}$ cubic feet, or 593.3 Scotch pints in a minute.

In this case we have $d = \frac{7}{4} = 1.75$

$$s = \frac{21350}{222} = 96.17.$$

| | | |
|---|---|---|
| Log. of numerator | | 2.57452 |
| Log. of denominator | | 0.87595 |
| Log. of | 49.964 | 1.69857 |
| Subtract negative quantity | .367 | |
| Remains | 49.597 the velocity per second. | |
| Log. of | 49.597 | 1.695447 |
| Log. of | $7^2$ or 49 | 1.690196 |
| Log. for reducing to Scotch pints | | 9.658721 |
| Log. of 1107.5 | | 3.044364 |

* Dr Robison, who applied his tables to this example, makes the length of the pipe 14,637 by mistake, and has corrected it to 14,367 in his MS. notes.

Hence the discharge is 1107.5 Scotch pints, which differs so widely from 593.3, the quantity actually delivered, that there must have been some unknown obstruction in the pipe.

The cast iron main, five inches in diameter, which is laid from Comiston to Edinburgh, was always very defective in its delivery. Though its length is only 13.518 feet, and the height of the fountain above the point of delivery 88 feet, yet it yields only ten cubic feet, or 167.7 Scotch pints per minute.

Example IV. Mr Watt found, from very careful measurements, that a canal in his neighbourhood, which was 18 feet wide at the surface, 7 feet wide at the bottom, 4 feet deep, and had a declivity of 4 inches in a mile, moved with a velocity of 17 inches per second at the surface, 14 inches in the middle, and 10 at the bottom: the mean velocity being 13.3.

Now, since the sloping side of a canal corresponding to 4 feet deep, and $\frac{18-7}{2}=5\frac{1}{2}$ of projection, is 6.8 feet, we have for the perimeter of the section in contact with the water, $6.8+7+6.8=20.6$. The area of the section will therefore be $4\times\frac{18+7}{2}=50$ square feet. Hence $d=\frac{50}{20.6}=2.4272$, or 29.126. The logarithm corresponding to this in Table III. is 3.21117, and the value of the negative quantity in col. 5. is 1.589.

Now, since the slope is 4 inches, or $\frac{1}{3}$ of a foot in a mile, we have $s=15.840$, and the corresponding logarithm in the table 2.08280. Hence

| | |
|---|---|
| From | 3.21117 |
| Subtract | 2.08280 |

| | | |
|---|---|---|
| And there remains | 1.12837 = Log. of 13.439 inches | |
| Subtract the negative quantity | | 1.589 |
| And there remains | | 11.850 inches, |

the velocity of the canal per second required, which differs considerably from 13.33, the mean velocity observed by Mr Watt.

In the two first examples, the reader will observe that the formula errs in defect. Dr Robison considers it as most correct in small canals, where it is most needed, such as in mill courses and other derivations for working machinery. From several comparisons with direct observation, he proposes to substitute in place of the expression Hyp. Log. $\sqrt{s+1.6}$ the expression $2\frac{1}{4}$ Com. Log. $\sqrt{s}+1.6$, which he considers both as more simple and more accurate.

Instead of the part of the numerator Hyp. Log. $\sqrt{s}+1.6$, Dr Young proposes to substitute $0.85\ s^{\frac{11}{60}}$, which is nearly the same for moderate velocities. He proposes also $V=307\ (\sqrt{d}-1).\left(\frac{1}{\sqrt{s}}+\frac{1.6}{s^{.88}}-.001\right)$ and since $s^{0.875}$, may be substituted without much inaccuracy in place of $s^{0.88}$, the term $\frac{1.6}{s^{0.88}}$ will become $\frac{1.6s^{\frac{1}{8}}}{l}$ which may be determined without logarithms. Hence the whole formula will become

$$V=153\ (\sqrt{d}-0.2).\sqrt{\left(\frac{h}{l+45\,d}\right)}+1.6\left(\frac{h}{l+45\,d}\right)^{\frac{7}{8}}-.001$$

$l$ being the length of the pipe, $h$ the height of the whole head of water, and $d$ the diameter of the pipe. In this formula $s=\frac{l+45d}{h}$. The formula may be applied to rivers, by taking $\frac{1}{s}$ as the sine of their inclination.

M. Langsdorf has proposed to substitute 482 in place of the number 478 used by Du Buat in his formula $V^2=\sqrt{478\ h}$ in French inches, which gives $V=\sqrt{509\ h}$ in English inches.

When the pipe is bent in one or more places, the effect of the bending may be found by adding into one sum $\sigma$ the squares of the sines thus,

$$s=\frac{l}{h-\left(\frac{V^2}{509}+\frac{V^2\sigma}{3000}\right)}$$

Or more simply,

$$V=\sqrt{\left(\frac{509\ d\ h}{d+\frac{1}{45}l+0.16\ d\ \sigma}\right)},$$

which is Langsdorf's formula reduced to English measure.

M. Eytelwein conceives the head of water to be divided into two parts, one of which is employed in producing velocity, while the other is employed in overcoming the resistances to which it is exposed. He considers the height employed in overcoming the resistances to be directly as the length of pipe, and as the circumference of the section, or as the diameter of the pipe, and inversely as the area of the section, or as the square of the diameter, that is, on the whole inversely as the diameter. This height too, must, like the resistance arising from friction, vary as the square of the velocity. Hence if $f$ denote the height due to the friction, $\delta$ the diameter of the pipe, and $a$ a constant quantity, we shall have

$$f=V^2\frac{a\ l}{\delta},\ \text{and}\ V^2=\frac{f\ \delta}{a\ l}.$$

But the height employed in overcoming the friction corresponds to the difference between the actual velocity and the actual height, that is, $f=h-\frac{V^2}{b^2}$ where $b$ is the coefficient for finding the velocity from the height. Hence we have

$$V^2=\frac{b^2\ \delta h-\delta V^2}{a\ b^2\ l}\ \text{and}\ V=\sqrt{\frac{b^2\ \delta h}{a\ b^2\ l+\delta}}.$$

Now Buat found $b$ to be 6 6, and $a\,b^2$ was found to be 0.0211, particularly when the velocity is between 6 and 24 inches per second. Hence we have

$$V^2=\frac{43.6\ \delta h}{0.0211\,l+\delta},\ \text{or}\ V=45.5\sqrt{\left(\frac{\delta\ h}{l+47\ \delta}\right)}.$$

Or, what is considered more accurate,

$$V=50\sqrt{\left(\frac{\delta\ h}{l+50\ \delta}\right)}.$$

If the pipe is bent, the velocity thus found must be diminished by taking the product of its square, multiplied by the sum of the sines of the several angles of flexure, and then by 0.0038. This will give the degree of pressure employed in overcoming the resistance occasioned by the angles; and subtracting this height from the height corresponding to the velocity, we may thence find the corrected velocity.

In applying this formula to *Example* 2. in p. 867, relative to the $4\frac{1}{2}$ inch pipe, which supplies Edinburgh with water, we have $h=51$ feet, $\delta=0.375$ of a foot, $=14930$, hence we shall obtain 1.7136 for the velocity in feet per second, or 20.5632 for the velocity in inches, which, by the rule already explained, gives 189.77 Scotch pints per minute.

| | |
|---|---|
| Quantity of water delivered by the pipe, . . . . . | 189.4 Scotch pints per minute. |
| Ditto determined by Eytelwein's formula, . . . . . . . | 189.77 |
| Ditto by Du Buat's formula, | 188.13 |

From which it appears, that in this case Eytelwein's formula is the most correct of the two, the error being only 0.37, while in Du Buat's it is 1.27 Scotch pints. The accuracy of both the formulæ is very remarkable.

In order to obtain a rule for determining the velocity of water in canals and rivers, M. Eytelwein considers the friction as nearly proportional to the square of the velocity, not because a number of particles proportional to the velocity is torn asunder in a time proportionally short, but because, when a body is moving in lines of a given curvature, the deflecting forces are as the squares of the velocities; for it is obvious, that the particles of water which touch the sides and bottom of the canal must be deflected, in consequence of the elevations and depressions on the surface upon which they slide nearly into the same curvilineal path, whatever be the velocity with which they move. We may therefore consider the friction as nearly proportional to the square of the velocity, and as nearly the same at all depths. It will, however, vary according to the surface of the fluid which is in contact with the solid, in proportion to the whole quantity of fluid; that is, the friction for a given quantity of water will be directly as the surface of the bottom and sides of a canal, or as the perimeter of the section in contact with the water; or, supposing the whole quantity of water to be spread upon a horizontal plane equal to the bottom and sides, the friction will be inversely as the height at which the water would stand, which is the mean radius, or hydraulic mean depth.

But in a river flowing uniformly, and neither accelerated nor retarded by gravity, the whole weight of the water must be employed in overcoming this friction; and if the inclination of the plane varies, the relative weight, or the force that urges the particles along the inclined plane, will vary as the height of the plane when its length is given, or as the fall in any given distance. Hence it follows, that the friction, which is equal to the relative weight, must vary as the fall; and the velocity, which is as the square root of the friction, must be as the square root of the fall; and supposing the hydraulic mean depth to increase or diminish while the inclination remains the same, the friction would be diminished or increased in the same ratio, and therefore, in order to preserve its equality with the relative weight, it must be proportionally increased or diminished, by increasing the square of the velocity, in the ratio of the hydraulic mean depth, or the velocity in the ratio of its square root. We may expect, therefore, that the velocities will be conjointly as the square root of the hydraulic mean depth, and of the fall in a given distance, or as a mean proportional between these two lines. If we take two English miles for a given length, we must find a mean proportional between the hydraulic mean depth and the fall in two English miles; and having ascertained the relation which this bears to the velocity in a particular case, we may easily determine it in all other cases. According to M. Eytelwein's formula, this mean proportional is $\frac{11}{10}$ of the velocity, or 0.91 times the velocity in a second. Making $d$ the hydraulic mean depth in inches, $f$ the fall in two English miles in inches, $\sqrt{fd}$ being the mean proportional, we have

$$V = 0.91 \sqrt{fd}$$

In applying this formula to Example II. in p. 867, relative to the velocity in a canal as measured by Mr Watt, we have $d = 29.126$ and $f = 8$ inches.

$$\text{Hence } V = 0.91 \sqrt{8 \times 29.126} = 0.91 \times 15.264 = 13.890,$$

a result which agrees very nearly with the mean velocity as ascertained by Mr Watt.

The preceding formula is applicable only to a canal, or to a straight river flowing through an equable channel. M. Eytelwein has shewn that the velocity is in general a little greater when the bottom is horizontal, than when it is parallel to the surface, and that the velocity in curved channels is always greater on the convex than on the concave side. It is not easy to give a rule for the decrease of the velocity from the surface to the bottom of a stream of water, as it is sometimes found to be a maximum below the surface.

The following are the velocities in the Arno and the Rhine.

| Arno. Depth in feet. | Velocity in inches per second. | Rhine. Depth in feet. | Velocity in inches per second. |
|---|---|---|---|
| 2 | $39\frac{1}{2}$ | 1 | 58 |
| 4 | $38\frac{1}{2}$ | 5 | 56 |
| 8 | 37 | 10 | 52 |
| 16 | $33\frac{1}{2}$ | 15 | 43 |
| 17 | 31 | | |

M. Eytelwein considers that an approximate value of the mean velocity may be obtained by deducting $\frac{1}{130}$ for every foot of the whole depth.

## Sect. III. *Account of the Investigations of M. Prony, respecting the velocity of Water in Conduit Pipes and open Canals.*

In our history of Hydrodynamics, we have already given a general view of the labours of Chezy, Girard, and Prony, in the composition of formulæ for determining the velocity of water in conduit pipes and open canals. As the formulæ obtained by these eminent engineers have all the same character, both from their extreme simplicity, and from their containing only algebraical quantities, we have thought it proper to give an account of them in the same Section. In doing this, we shall adopt the notation of M. Prony, and retain the coefficients as he has given them in French metres.

The following are the symbols which he employs:

$\lambda$ = the length of the pipe or canal.
$\zeta$ = the difference of level between the two extremities of the pipe.
$\omega$ = the area of the section of the pipe or canal.
$\chi$ = the perimeter of the section in contact with the water.
$g$ = the accelerating force of gravity, or 32.174.
D = the diameter of the tube.
$R = \frac{\omega}{\chi}$ = the mean radius, or the hydraulic mean depth.
I = the sine of the inclination of the pipe or canal.
U = the mean velocity in the section $\omega$.
V = the velocity of the surface } In open canals, &c.
W = the velocity at the bottom }

According to this notation, the formula of Du Buat, in English inches, is

$$U = \frac{\sqrt{307\,g}\left(\sqrt{\frac{\omega}{\chi}} - 0.1\right)}{\sqrt{\frac{\lambda}{\zeta}} - \text{Hyp. Log.}\sqrt{\frac{\lambda}{\zeta} + 1.6}} - 0.3\left(\sqrt{\frac{\omega}{\chi}} - 0.1\right)$$

Or when reduced to French metres,

$$U = \left(\frac{\sqrt{243.79}}{\sqrt{\frac{\lambda}{\zeta}} - \text{Hyp. Log.}\sqrt{\frac{\lambda}{\zeta} + 1.6}} - 0{,}049359\right)\left(\sqrt{\frac{\omega}{\chi}} - 0{,}016453\right)$$

About eleven years before the publication of the second edition of Du Buat's work, M. Chezy obtained an expression of the velocity much more simple than the preceding. He assimilates the resistance of the sides of the pipe or canal to known resistances, which follow the law of the square of the velocity; and he supposes that the ratio of $\chi U^2 : \frac{\zeta\,\omega}{\lambda}$ is constant for all currents of the same fluid. Upon this hypothesis, it is sufficient to determine, by experiment, the values of U, $\chi$, $\zeta$ and $\lambda$ for any known current of water, and to deduce from it the general value of U in terms of $\chi$, $\zeta$ and $\lambda$ belonging to any other current. The formula of Chezy, deduced from these principles, is

$$U = \sqrt{\frac{g\,\omega\,\zeta}{\beta\,\lambda\,\chi}}.$$

A single experiment only is necessary for determining $\beta$, which is an abstract number, or $\frac{g}{\beta}$, which is a linear quantity.

The fine researches of Coulomb respecting the resistance of fluids, were first applied by M. Girard to the discovery of a correct formula for expressing the velocity of water. He proposed to adopt for the value of the resistance, the product of a contant quantity, by the sum of the first and second powers of the velocity; and having determined this constant quantity after 12 experiments of Chezy and Du Buat, he obtained a formula, which, as we shall presently see, represents the experimental velocities as accurately as the more complicated one of Du Buat. He expresses the resistance due to the cohesion by $R'\chi U$; $R'$ being a quantity to be obtained from experiment; and supposing that the adhesion to the *paroi mouillée*, or the film which adheres to the sides of the pipe, of the asperities which are there disseminated, is the same as that which retains the fluid molecules to one another, he makes the resistance due to these asperities equal to $R'\chi U^2$, so that the sum of the two resistances is $R'\chi(U+U^2)$, which leads to the formula $\frac{g\,\omega\,\zeta}{\lambda\,\chi} = R'(U+U^2)$.

M. Girard assigns, from the experiments of Du Buat, 0.0012181 as the value of R, and his formula becomes $U = -0.5 + \sqrt{\left(0.25 + 8052{,}54\,\frac{\omega\,\zeta}{\lambda\,\chi}\right)}$ or making $\frac{\zeta}{\lambda} = \frac{1}{b} = I$, and $\frac{\omega}{\chi} = R$, the formula becomes $U = -0.5 + \sqrt{(0.25 + 8052.54\,RI)}$.

In order to obtain a formula for the mean velocity of fluids, M. Prony found, that an expression of the mean velocity, deduced from the theory of fluids, and composed of terms relative to gravity, to the dimensions or figure of the pipe or canal, ought to be equal to a certain function of this mean velocity; and in determining this function, he observed, that in all the hypotheses respecting the unknown function of the velocity to which the resistance is proportional that makes the motion uniform, it may always be developed in a series, arranged according to the whole powers of the mean velocity, or the variable quantity. That is,

$$\frac{g\,\omega\,\zeta}{\lambda\,\chi} = c + \alpha U + \beta U^2 + \gamma U^3, \text{ \&c.}$$

in which $c$ is a function independent of U, and which, along with the co-efficients $\alpha$, $\beta$, $\gamma$, &c. must be determined by experiment.

The first term $c$ of this series is related on the one hand to the inclination which the canal or tube ought to have, in order that the motion may be ready to commence; and on the other hand, to the form and dimensions which must be given to the transverse section, in order that the whole fluid which is contained in the canal or pipe may adhere to it. The determination of this first term depends on very delicate experiments, which have not been made; but it is quite certain that, from its extreme smallness, it may be safely neglected.

The second term $\alpha U$ is naturally related to very small velocities; and as it is known from good experiments, that the first and second powers of the velocity satisfy all the phenomena included within certain limits, it is requisite first to examine if these limits contain the greatest velocities, which are necessary to be considered in practice. M. Prony therefore takes the equation

$$\frac{g\,\omega\,\zeta}{\lambda\,\chi} = \alpha U + \beta U^2,$$

and he then endeavours to determine the values of the constant quantities $\alpha$ and $\beta$, which may be conformable with the best experiments which have been made on the motion of water in canals.

In the execution of this task, M. Prony has availed himself of the fine methods for the correction of anomalies, which M. La Place has applied in his *Mecanique Celeste*,* for determining the figure of the earth. La Place has given no fewer than three of these methods, the last of which Prony considers as the best.

If we have obtained, for example, a series of experimental values of any variable quantity, these values may be connected together by a law, by applying small corrections to each of the experimental results. The equation which expresses this law may be put under the form

$$Z = \alpha + \beta X,$$

where Z and X are functions of one or more variable quantities, of which we have a certain number of values either directly observed, or calculated from observations. It is then required to assign to the unknown constant quantities $\alpha$ and $\beta$ such values, that the phenomena may be represented in the best possible manner by the preceding equation.

The explanation of these methods does not belong to the present article; but in some part of our work, probably under the article Physics, we shall lay them before our readers.

* See *Mecanique Celeste,* Part I. Lib. iii. Sect. 39. and 40.

If we divide by U both sides of the equation, $\frac{g\,\omega\,\zeta}{\lambda\,\chi} = \alpha\,U + \beta\,U^2$, we obtain $\frac{g\,\omega\,\zeta}{\lambda\,\chi\,U} = \alpha + \beta U$, and putting $\frac{g\,\omega\,\zeta}{\lambda\,\chi\,U} = y$, we have an equation of the first order $y = \alpha + \beta U$, in which all the quantities are linear except $\beta$, which is an abstract number.

By calculating as many values of $y$ corresponding to the determined values of U, as we have experiments on the velocity observed in canals, where $\zeta$, $\lambda$, $\omega$, and $\chi$ have been measured, and by finding $\alpha$ and $\beta$ by the methods already mentioned, we obtain an expression of the velocity.

M. Prony has applied these methods to the twelve experiments, from which Girard deduced the value of the coefficient R in his formula, chiefly with the view of comparing the results obtained by Du Buat's formula, Girard's formula, and his own formula. Two of these twelve experiments were made by M. Chezy upon the Rigole of Courpalet, and upon the Seine. The other ten are taken from Du Buat's work, and are those which Girard employed. From these experiments, Prony finds $\alpha = 0.00093$, and $\beta = 0.00266$. Hence we obtain

$$\frac{g\,\omega\,\zeta}{\lambda\,\chi} = 0.00093\,U + 0.00266\,U^2,$$

which, when reduced, gives

$$U = -0{,}174812 + \sqrt{\left(0.0305592 + \frac{3687.52\,\omega\,\zeta}{\lambda\,\chi}\right)}$$

The particulars of the twelve experiments are given in the following Table, in columns 1, 2, 3, 4, 5, 6. Column 7 is calculated from Du Buat's formula already given, column 8 from Girard's, and column 9 from the preceding formula of Prony's. The four experiments marked with an asterisk are rejected as anomalous.

## TABLE I.

*Containing the mean Velocities of Currents of Water deduced from eight Experiments, compared with the Velocities as calculated by the Formulæ of Du Buat, Girard, and Prony.*

| No. of Experiment. | Names of the Currents. | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
|---|---|---|---|---|---|---|---|---|---|---|
| | | Velocities observed, directly deduced from Observation. | | Total length of the Current or values of $\lambda$ | Total declivity on the length $\lambda$, or values of $\zeta$ | Area of the Section of the Current, or values of $\omega$ | Perimeter of the Section, or values of $\chi$ | Mean Velocities calculated, or values of U. | | |
| | | Superficial Velocity. | Mean Velocity. | | | | | By the Formula of Du Buat. | By the Formula of Girard. | By the Formula of Prony. |
| 1 | Rigole of Courpalet. | 0,142659 | 0,094051 | 31379,5 | 1,11438 | 0.674492 | 2,33863 | 0,130759 | 0,076449 | 0,086587 |
| 2 | Canal of Jard. | 0,196799 | 0,137345 | 467,769 | 0.016355 | 4 4883 | 8.77066 | 0.177309 | 0.131695 | 0,135891 |

| 5* | Canal of Jard. | 0,329414 | 0,248518 | 467,769 | 0,040605 | 8.72377 | 9,9076 | 0.393055 | 0,429232 | 0,384124 |
| 6 | River Hayne. | 0,368423 | 0.282091 | 359,272 | 0,010896 | 22 6466 | 15,3757 | 0,272865 | 0.280515 | 0,267086 |
| 7 | Canal of Jard. | 0,426081 | 0,332219 | 477.769 | 0,030454 | 7,6759 | 9,74518 | 0.314282 | 0,428938 | 0.293862 |
| 8 | River Hayne. | 0,432036 | 0,337349 | 359.272 | 0,010061 | 29,0468 | 16.3503 | 0.285046 | 0,317697 | 0.287803 |
| 9* | Canal of Jard. | 0,461532 | 0,372087 | 476,769 | 0.052448 | 11,9092 | 10,8821 | 0,508103 | 0,661130 | 0,520199 |
| 10* | River Seine. | 0,785029 | 0,652790 | 2592.22 | 0,297770 | 284.9 | 103.299 | 0,824497 | 1,17367 | 0,92010 |
| 11* | River Hayne. | 0,860012 | 0,720968 | 359,272 | 0,056012 | 28.4598 | 16.269 | 0.778532 | 1,0541 | 0,843152 |
| 12 | River Hayne. | 0,950426 | 0,803563 | 359.272 | 0,059596 | 23,0812 | 15.4082 | 0,747672 | 0,994162 | 0,796834 |

In the preceding Table, the mean velocities in column 2 were not directly observed, but were deduced from the superficial velocities by a formula of Du Buat, viz.

$$U = (\sqrt{V} - 0.08227)^2 + 0.0067675.$$

In this formula, which is reduced to metres, U is the mean velocity, and V the superficial velocity. Girard also calculated his mean velocities by an equivalent formula.

The relative accuracies of the three formulæ will be seen from the following Table of differences.

| | Absolute differences between the calculated and observed mean velocity. Positive difference. | Negative difference. |
|---|---|---|
| Formula of Du Buat | 0.0338 | 0.0391 |
| Formula of Girard | 0.0238 | 0.0970 |
| Formula of Prony | 0.0198 | 0 0060 |

In Du Buat's formula, the errors are between $\frac{3}{100}$ and $\frac{29}{100}$ of the observed results; in Girard's, they are between $\frac{16}{100}$ and $\frac{18}{100}$; and in Prony's between $\frac{7}{100}$ and $\frac{4}{100}$. The great superiority of Prony's formula is therefore manifest.

As the preceding formula of Prony was drawn only from a few observations, for the purpose of comparing it with the other formula, he has deduced more correct values of $\alpha$ and $\beta$ from 31 experiments, including the eight experiments of Du Buat in Table I. The 23 new experiments were performed with very great accuracy upon artificial canals, and have the advantage of giving the mean velocity from direct observation.

These experiments, which are contained in Table II. give the following values of $\alpha$ and $\beta$, viz.

$\alpha = 0\,000436$. $\beta = 0.003034$, from which we obtain

$$U = -0.0718523 + \sqrt{\left(0.00516275 + \frac{3232.96\,\omega\,\zeta}{\lambda\,\chi}\right)}.$$

Or more simply,

$$U = -0.07 + \sqrt{\left(0.005 + \frac{3233\,\omega\,\zeta}{\lambda\,\chi}\right)},$$ which will be sufficiently exact. With the first of these formulæ, the numbers in column 8 of Table II. were calculated.

### TABLE II.

*Containing the Velocities of Water in Canals, as observed in thirty one Experiments, compared with the Velocities calculated by Prony's Formula.*

| 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
|---|---|---|---|---|---|---|---|
| Number of Experiment. | Perimeters of the Sections or values of $\chi$ | Areas of the Sections, or values of $\omega$ | Inclination of the Canal, or values of $\frac{\zeta}{\lambda}$ | Values of the Functions. $\frac{g\omega\zeta}{\lambda\chi U}$ | Mean Velocities, or values of U | | Velocities, or values of U calculated. |
| | | | | | By direct Experiment. | Deduced from the superficial Velocity. | |

In comparing the calculated with the observed results in the preceding Table, it appears that the absolute positive differences are 0.0272, and that the absolute negative differences 0,0260, which shews the anomalies have been divided with great equality, and that the calculated results hold a just medium between those which were observed. The preceding formula may therefore be adopted in practice with much confidence.

M. Prony next proceeds to the investigation of a formula for the motion of water in conduit pipes. In this case we have $\frac{\omega}{\chi} = \frac{1}{4}$ D, D being the diameter of the tube; and if Z is the difference of level between the surface of water, in the superior reservoir, and that of the water in the lower basin, or the height of the head of water the equation will be

$$\frac{\frac{1}{4} g\, ZD}{\lambda} = \alpha\, U + \beta\, U^2.$$

In order to find $\alpha$ and $\beta$, M. Prony selected fifty-one of the best experiments made by Couplet, Bossut, and Du Buat, and by the application of the methods of correction, he obtained

$$\alpha = 0.00017,\ \beta = 0{,}003416.$$

From which we obtain

$$\frac{\frac{1}{4} g\, RD}{\lambda} = 0\ 00017\ U + 0.003416 U^2,$$

which, after reduction, gives

$$U = -0{,}0248829 + \sqrt{\left(0.000619159 + \frac{717.857\ DZ}{\lambda}\right)}.$$

By means of this formula, the numbers in column 8 of the following Table have been calculuted, which agree most surprisingly with the observed results. This agreement is the more remarkable, as the experiments were made by different observers, and with different apparatus, and upon pipes whose lengths varied from $11\frac{1}{2}$ feet to 7020, and their diameters from 1 inch to 18 inches.

The difference between the calculated and observed results amount only to $\frac{1}{40}$ or $\frac{1}{25}$.

The preceding formula should always be used in its present state when the velocities are very small; but when the velocities are considerable, we may in ordinary cases use the following very simple formula,

$$U = 26.79 \sqrt{\frac{DZ}{\lambda}}.$$

From which it appears, that the velocity is directly in the compound ratio of the square roots of the diameter of the pipe and the head of water, and inversely as the square roots of the length of the pipe; a result, which agrees with that which the Abbé Bossut obtained from his experiments; that is, for any given head of water and diameter of pipe, the velocity in a horizontal pipe is inversely as the square root of the length of the pipe. See page 511, col. 1.

In Table IV. we have given the observed measures in French inches, for the sake of those who may wish to compare them with the other experiments of Du Buat or Bossut.

TABLE III.

*Comparison of Prony's Formula with the results of Fifty-one Experiments by different Observers.*

M. Prony next proceeds to investigate a single formula which will serve both for canals and pipes. The resulting formula is

$$U = -0.0469734 + \sqrt{(0.0022065 + 3041.47\,G)}.$$

When this formula is applied to canals, we must take

$$G = RI\,;\ I = \frac{\zeta}{\lambda}\,;\ \text{and } R = \frac{\omega}{\chi}.$$

When it is to be applied to pipes, we must take

$G = \frac{1}{4}DJ$, $D =$ diameter of pipe, and $J = \frac{H' + \zeta - H''}{\lambda}$, when the pipe discharges itself in water, or $J = \frac{H' + \zeta}{\lambda}$, when the pipe discharges itself in air; as in this case, $H'' = 0$, $H'$ being the height of the head of water above the superior orifice of the pipe, and $H''$ the height of the head of water above the lower orifice of the pipe.

The formula in English feet is,

$$U = -0.1541131 + \sqrt{(0{,}023751 + 32806.6\,G.)}$$

*On the Relation between the Superficial Velocity and the Mean Velocity.*

The formula given by Du Buat for deducing the mean from the superficial velocity was, when reduced to the metre,

$$U = (\sqrt{V} - 0.08227)^2 + 0.0067675,$$

which is deduced from the equation

$$U = (\sqrt{V} - \sqrt{\tfrac{1}{2}W})^2 + \tfrac{1}{4}W,$$

where $W$ is a constant velocity $= 0.0270699 = 1$ inch of the old measure, and $\sqrt{W} = 0.16453$.

Although this formula is sufficiently simple, and harmonizes with many of Du Buat's experiments, it is nevertheless incompatible with observation, as it makes the mean velocity U have a finite value, when the superficial velocity V is nothing. Now, as Prony has observed, every formula, which does not make both these velocities vanish at the same time, is evidently erroneous; and, as it follows from the examination of the experiments, that the ratio between these velocities approaches to equality as they increase, so that at one limit we have $V = 0$, $U = 0$, and at another limit $V = \infty$, $U = \infty$; and $V = U$.

In order to obtain a formula which should satisfy these conditions, and at the same time be simple, and suited to the nature of the phenomena, M. Prony gives it the form

$$U = \frac{V(V + a)}{V + b},$$

which may be put under the form,

$\frac{V}{V - U} = \frac{b}{b - a} + \frac{V}{b - a}$, and making $\frac{b}{b - a} = \alpha$, and $\frac{1}{b - a} = \beta$, and using the values of V and U, given in col. 2. and 3. of the following Table, he obtained, by the methods already mentioned,

$\alpha = 4.036$; $\beta = 1.280$, from which we have
$a = 2.37187$; $b = 3.15312$, and

$$U = \frac{V(V + 2\,37187)}{V + 3.15312},$$

a formula, which is not only more commodious, and more easily calculated, but also more conformable with experiments than that of Du Buat. This formula may be put under the form

$$U = V - 0.78125 + \frac{2.46338}{V + 3.15312},$$

from which we obtain,

$$V = \tfrac{1}{2}\left(U - 2.37187 + \sqrt{(U - 2.37187)^2 + 3.15312\,U}\right)$$

The numbers in column 5 of the following Table have been computed from the formula

$$U = 0,816458\ V,$$

which gives a precision of between $\frac{1}{25}$ and $\frac{1}{18}$, and is a simplification of the preceding formula.

| 17 | 1,2994 | 1,1099 | 1,12538 | 1,0609 | 6,8569 | 1,0714 |

The agreement of the numbers in column 7, with those in column 3, is very striking; and it is remarkable that the numbers in column 5, calculated from Prony's simple formula, viz. $U = 0,816458\ V$, are more accordant with experiment than those in column 4, computed from Du Buat's formula. This formula may be reduced to

$$U = 0.82\ V, \text{ or even } U = 0.8\ V,$$

from which it follows, that the mean velocity is four-fifths of the superficial velocity.

In order to introduce into the equation which expresses the velocity, the value of the volume of water which flows through any section in a given time, Prony calls Q the volume of water, and $3.1416 = \pi$; and hence $U = \frac{4\,Q}{\pi D^2}$, and these being introduced into the equation $\frac{1}{4}\,g j\,D = \alpha\,U + \beta\,U^2$, where $\alpha = 0.00017$, and $\beta = 0.003416$, gives $\alpha + \frac{4\,\beta Q}{\pi D^2} = \frac{\pi g j D^3}{16\,Q}$, which making $\frac{16\,\alpha}{\pi\,g} = \alpha'$, and $\frac{64\beta}{\pi^2 g} = \beta'$ gives

$$j\,D^5 - \alpha'\,Q\,D^2 - \beta'\,Q^2 = 0, \text{ or since}$$

$$\alpha' = 0.000088268 \text{ and } \beta'\ 0.002258305, \text{ we have}$$

$$j\,D^5 - 0.000088268\ Q\,D^2 - 0.00225830\ Q^2 = 0,$$

which expresses the relation between the diameter of a pipe, the quantity of water which it discharges in a second, when its length, its declivity, and the heads of water above its upper and lower orifices, are known.

$$\text{In this equation } j = \frac{H + \zeta - H'}{\lambda}.$$

In order to facilitate the application of this formula, Prony has computed the following Table, which gives the relations between D, Q and $j$, as deduced from the above equation.

TABLE VI. *Containing the Declivity of the Pipe and its Diameter for different Quantities of Water discharged in a Second.*

| 0.49 | 0.0000738 | 0.0000917 | 0.0001112 | 0.0001323 | 0.0001550 |
| 0.50 | 0.0000684 | 0.0000848 | 0.0001027 | 0.0001221 | 0.0001429 |

In order to shew the method of using this Table, let us take the case of the $4\frac{1}{2}$ inch pipe which conveys water to Edinburgh. In this case, (see p. 526, Example II.) we have

| | Reduced to Metres.* |
|---|---|
| $H = 51$ feet . . . . . | 15.54 |
| $D = 0.375$ . . . . . | 0.1143 |
| $l = 14930$ . . . . . | 4550.4 |
| $j = \frac{15.54}{4550.4} =$ . . . . | 0.0034151 |

Since the value of $D = 0.1143$ is in tenth parts of a metre, we must enter the lower part of Table VI. in column 1, and by taking proportional parts, it will be found that the value of Q corresponding to D, and to the value of $j = 0.0034151$ is 0.005104 parts of a cubic metre, which being multiplied by 61023.5, the number of English cubic inches in a cubic metre, gives 311.46 cubic inches discharged in a second. By multiplying this by 60″, and dividing the product by 103.4, the number of cubic inches in a Scotch pint, we obtain 180.7, as the number of Scotch pints that the preceding pipe ought to discharge in a minute, according to Prony's Table.

The following comparison of the results of the different formulæ will be interesting to the reader.

| | Scotch Pints. |
|---|---|
| Quantity of water actually discharged by the pipe | 189.4 |
| Do. by Eytelwein's formula . . . . | 189.77 |
| Do. by Girard's formula . . . . | 188.26 |
| Do. by Du Buat's formula . . . . | 188.13 |
| Do. by Prony's simple formula . . . | 192.32 |
| Do. by Prony's Table . . . . . | 180.7 |

This comparison is by no means favourable to Prony's formulæ.

## Sect. IV. *Account of the Experiments of Du Buat and Girard, on the effect of Heat upon the Motion of Water in narrow Pipes.*

The effect of heat, in augmenting the fluidity of water, seems to have been noticed at a very early period. Plutarch informs us, that the clepsydræ, or water clocks, went faster in summer than in winter, which he seems to ascribe to an increase of fluidity. Ελάυνουσα γαρ η ψυχροτης το ύδωρ ποιει βαρυ και σωματωδες, ως εστιν εν ταις κλεψυδραις καταμαθειν, βραδιον γαρ ελκουσι χειμωνος η θερους. *Quest. Natural.*

M. Du Buat made a series of experiments on the effect of heat upon the velocity of different fluids discharged from small tubes; but these effects were not very striking, as he employed tubes of too great a diameter. The results which he obtained are shewn in the following Table.

TABLE, *Containing Du Buat's Experiments on the Motion of different Fluids, at different degrees of temperature in Tubes of Glass.*

| Diameter and length of the Pipe. | Names of the Fluids. | Degrees of Heat above the freezing point. | Head of water above the head of the tube. | Height of the expense in a minute expressed in inches. | Velocity in a second in inches. |
|---|---|---|---|---|---|
| Horizontal tube 2.9 lines, or 0.24166 of an inch in diameter, and 36.25 inches long . . . . | Rain water | 3 | 2.0833 | 5.2777 | 13.057 |
| | Salt water | 3 | 2 0833 | 5.1666 | 12.7823 |
| | Salt water | 11 | 2.0833 | 5.2222 | 12.9197 |
| | Salt water | 10 to 11 | 4 9166 | 9.25 | 22 8845 |
| | Alcohol | 12 | 5 0000 | 7.5833 | 18.7611 |
| | Mercury | 10 to 12 | 0.8124 | 3.75 | 9.2775 |
| | Mercury | 10 to 12 | 0.9166 | 4.0833 | 10.1021 |
| | Mercury | 10 to 12 | 2.1944 | 6.6111 | 16.3558 |
| Horizontal tube 2 lines, or 0.16666 of an inch in diameter, and 36.25 inches long . . . . | Rain water | 55 | 8.875 | 5.2777 | 27.455 |
| | Rain water | 30 | 15 2916 | 6 9166 | 35.980 |
| | Rain water | 36 | 15.2916 | 7.0833 | 36.847 |
| | Rain water | 56 | 15.2916 | 7.2013 | 37.461 |
| | Alcohol | 12 | 5.292 | 2.50 | 13.005 |
| | Alcohol | 12 | 5.875 | 3.8338 | 19.941 |
| | Mercury | 10 to 12 | 1.125 | 1.75 | 9.103 |
| | Mercury | 10 to 12 | 2.7082 | 3.00 | 15.606 |
| | Mercury | 10 to 12 | 5.1666 | 4.25 | 22.108 |
| | Mercury | 10 to 12 | 0.0555 | 0.0000 | 0.000 |
| Horizontal tube $1\frac{1}{2}$ line in diameter and 34.16666 inches long . . . . | Alcohol | 12 | 9.292 | 1.125 | 10.402 |

From these results Du Buat concludes, that water moves less rapidly as it approaches to congelation, and that it runs more rapidly as its temperature increases; that salt water runs more slowly than rain water at the same temperature; that spirit of wine runs perceptibly less rapidly than water, on account of its viscosity, or its great adhe-

* English feet are reduced to metres by dividing them by 3.281.

sion to the sides of the tube; and that mercury, which, when it is very pure, is not attracted by the glass, flows more rapidly than water.

These experiments are, however, very far from satisfactory; and it was reserved to M. Girard to ascertain the precise influence of temperature on the motion of water in capillary tubes. The experiments of this eminent engineer were made with tubes of copper accurately calibred, and whose lengths could be varied at pleasure. The first series of tubes had a diameter of 2.96 millimetres, and each tube was two decimetres long, having at each of its ends a brass virrel, one of which had a male, and the other a female screw, so that the tubes could be all put together, so as to form different lengths, from 20 to 222 centimetres. The second series of tubes was formed in a similar manner, and each tube had a diameter of only 1.83 millimetres. The experiments were made in the manner which we have already described in our History of Hydrodynamics.

In applying to these experiments the general formula

$$\frac{g\,\omega\,\zeta}{\lambda\,\chi\,U} = \alpha + \beta\,U \text{ or } \frac{g\,D\,H}{4\,\lambda\,U} = \alpha + \beta\,U$$

which expresses the condition of a linear and uniform motion, M. Girard has obtained the following results:

1. That whatever be the head of water, provided the capillary tube is of a sufficient length; the term $\beta\,U$, proportional to the square of the velocity, disappears from the general formula, so that it becomes $\frac{g\,D\,H}{4\,\lambda\,U} = \alpha$ which expresses the conditions of the uniformity of the simplest linear motion.

2. That in every case where the conditions of the motion are expressed by this formula, the variations in the temperature of the water have a very great influence on the velocity with which it flows in the tube, so that if the head of water, and the length and diameter of the pipe remain the same, the velocity which is expressed by 10 at 0° of the centigrade thermometer is expressed by 42 at 85° of that thermometer.

3. That in every case where the formula $\frac{g\,D\,H}{4\,\lambda\,U} = \alpha$ does not satisfy observation, that is, when the length of the tube is below a certain limit, the variations of temperature have but a slight influence on the velocity with which the water is discharged; so that if this velocity by a pipe 55 millimetres long, and at 5° of temperature, is represented by 10, it will be represented by 12 at 87 degrees, every other circumstance in the experiments being the same.

4. That at equal temperatures the expression $\frac{g\,D\,H}{4\,\lambda\,U} = \alpha$ decreases with the diameter of the tube employed.

5. That the influence of temperature upon the velocities follows the same law in capillary tubes of an unequal diameter, that is, that the successive differences of the expression $\frac{g\,D\,H}{4\,\lambda\,U} = \alpha$ becomes as much less for equal differences of temperature as the temperature is raised.

6. That this law shews itself with more regularity, as the observations are made upon tubes of a smaller diameter, or, which is the same thing, that the linearity of the motion is more perfect.

7. That the values of the formula $\frac{g\,D\,H}{4\,\lambda\,U} = \alpha$, calculated in the same circumstances for two tubes of unequal diameters, differ more from one another as the temperature becomes lower, and that these values appear to have a tendency to become identical in proportion as the temperature increases; so that if their difference is represented by 6 at 0° of temperature, it is represented only by 1 when the temperature approaches to 80°.

8. And lastly, that the temperature which exercises so great an influence on the phenomena of the uniform discharge of water by capillary tubes has scarcely any influence in ordinary conduit pipes, whose diameters exceed the limits of capillarity.

An account of the preceding experiments was laid before the Institute of France on the 28th Nov. 1814, and on the 16th January and 13th February 1815. The remaining part of the paper was laid before the same learned body on the 13th January, 1817, and contained various experiments on the discharge of different fluids through capillary tubes. In some future article, we expect to have it in our power to lay before our readers a fuller view of the very interesting results which M. Girard has obtained.

### Sect. V. *Account of Mr Smeaton's Experiments on the Friction of Water in Pipes.*

Mr Smeaton seems to have made a number of valuable experiments on the discharge of water through openings, and from conduit pipes; but no particular account of these has been left among his papers. We have been favoured, however, by Mr Farey, with two Tables, containing the results of Mr Smeaton's experiments, which were found among his MSS. and have never before been published. Although the last of the Tables relates to the subject of a preceding Section, we shall make no apology for inserting it in this place, as it was not in our possession when that part of the volume was printed.

The following Table, computed by Mr Smeaton from his own experiments, shews the head of water which is necessary to overcome the friction, &c. in horizontal pipes 100 feet long, and to produce the velocity contained in the two first columns of the Table. Hence, if a certain supply of water is required from a given pipe, the Table shews us the different heads or heights of the reservoir, by which the velocity necessary to afford this supply will be produced. By comparing this Table with the formula of Du Buat, it will be seen that Mr Smeaton makes the effects of friction considerably greater than that formula, the velocities given by the Table being less than those given by the formula.

## TABLE I.

*Computed by Mr Smeaton, for shewing the Friction of Water in Horizontal Pipes. The Bore of the Pipe being given, and the Velocity of the Water therein, the Height of Head, or Column necessary to overcome the Friction and produce that Velocity, is shewn by this Table for* 100 *Feet in length.*

*Bore of the Pipes.*

N. B. Find the velocity of the water per second in feet and inches in the first column, or in inches in the second; and underneath the diameter of the bore in inches, (disposed in the uppermost row,) you will find the perpendicular height of a column of water in feet and inches, and 10ths necessary to overcome the friction of that pipe of 100 feet in length, to obtain the given velocity.

TABLE I.—Continued.

*Computed by Mr Smeaton, for shewing the Friction of Water in Horizontal Pipes. The Bore of the Pipe being given and the Velocity of the Water therein, the Height of Head, or Column necessary to overcome the Friction and produce that Velocity, is shewn by this Table for* 100 *Feet in length.*

| | | | *Bore of the Pipes.* | | | | | | | | | | | | | | | | | | | |

N. B. Find the velocity of the water per second in feet and inches in the first column, or in inches in the second; and underneath, the diameter of the bore in inches (disposed in the uppermost row) you will find the perpendicular height of a column of water in feet and inches and 10ths, necessary to overcome the friction of that pipe for 100 feet in length, to obtain the given velocity.

The second Table, which is copied from the original one used by Mr Smeaton, shews the expence of water through a rectangular notch, or over a waste-board of different widths and depths. The term thickness of water, employed by Mr Smeaton, is the same as the depth of the lower edge of the waste-board below the level surfaces of the water in the river or reservoir. The water gauge is nothing more than the rectangular orifice or notch through which the water issues.

## TABLE II.

*For finding the Expence of Water by the Water Gauge, having an Aperture of* 1, 2, 3, 6, 12, *or* 18 *Inches in width, at any given thickness of Water running through the same.*

*1 Inch Gauge.*

It will be seen, from a comparison of this Table with Du Buat's formula in p. 841, that there is a considerable agreement between them. For great depths of the wasteboard, Du Buat's formula gives a much greater discharge than Smeaton's Table. At small depths of the wasteboard, Du Buat's formula gives results less than those of Smeaton's Table, while for intermediate depths the results approach very near each other. The 18 inch gauge, for example, with a depth of 18 inches, discharges, according to Smeaton, 515.54 cubic feet in a minute; whereas, according to Buat, it should discharge 554.15 cubic feet. The same gauge, at a depth of only one foot, discharges 7.71 cubic feet; whereas, according to Du Buat, it should discharge only 7.254 cubic feet. The same notch, with a depth of 8 inches, discharges 164.86 cubic feet; and, according to Du Buat, it should discharge 164.20 cubic feet, which is very nearly the same result.

## CHAP. V.

### On the Percussion and Resistance of Fluids.

As the laws of the resistance of fluids can be determined only from experiment, we shall not occupy our pages with theoretical discussions, which are of no practical utility. It will be necessary, however, to make the reader acquainted with the ordinary theory of the resistance of fluids, which may be comprehended in a few propositions.

### Sect. I. *On the Theory of the Resistance of Fluids.*

If a body is moved through a fluid medium, it experiences an obstruction in its motion, which is called the resistance of the fluid; but if the fluid is in motion, and strikes the body at rest, the force sustained by the body is called the percussion of the fluid. The force exerted upon the body is obviously the same in both these cases; and the percussion and the resistance of fluids follow the same laws. The ordinary theory which we are about to explain, may be used without much risk of error in all cases where the angle of impulse is not below 60°, which is the case in wheels moved by the force of water.

Prop. I.

If a fluid, whose particles have all the same velocity, strikes a plane surface, the resistance will be as the product of the squares of the velocity of the fluid, the density of the fluid, and the area of the plane.

The resistance must obviously be equal to the force with which each particle strikes the plane, multiplied by the number of particles which strike it in a given time. But the force of each particle is as its velocity, and the number of particles which strike the plane in any given time must also be as the velocity. Hence the resistance will be as the square of the velocity. It is obvious also, that the resistance will be proportional to the density of the fluid, as the number of particles which strike the plane in the same time must be proportional to the density; the number of particles which strike the plane must likewise increase with the area of the plane; and therefore the whole resistance must be proportional to the square of the velocity of the fluid, the density of the fluid, and the area of the surface of the plane.

Prop. II.

If a fluid in motion strikes a plane surface at rest, inclined to the direction in which the fluid moves, the resistance perpendicular to the plane is proportional to the square of the sine of the angle of inclination.

Let AB, Plate CCCXIX. Fig. 9. be the plane surface, inclined at an angle ABC to the direction DE, or CB of the motion of the fluid. Draw AC perpendicular to DE. Then it is obvious that the number of particles which strike against the surface AB is proportional to AC, for none of those which are beyond A and C can have any effect upon the plane. Likewise, if we take EF to represent the velocity of the fluid, and resolve this velocity into the two velocities FG, perpendicular to the surface of the plane, and GE parallel to the same surface, it is manifest that the part GE has no effect in acting against the plane. Hence the part of the force which acts perpendicular to the plane is FG, or the sine of the angle GEF $=$ ABC, the inclination of the plane. That is, the force which acts perpendicular to the plane is proportional to sin. ABC; and the number of particles which strike the plane is also proportional to sin. ABC; consequently the resistance must be protional to sin. ABC $\times$ sin. ABC $=$ $\sin.^2$ ABC, or the square of the sine of the angle of inclination.

Cor. The resistance which the plane experiences in the direction of its motion is proportional to the cube of the sine of the angle of inclination. For as the resistance in a direction FG, perpendicular to the plane, is proportional to the square of the sine of the angle of inclination, it must itself vary as the sine of the angle when reduced to the direction DE; that is, the whole resistance must vary as $\sin.^2 ABC \times \sin. ABC = \sin.^3 ABC$, or the cube of the sine of the angle of inclination.

SCHOLIUM.

The two preceding propositions enable us to compare together the resistance experienced by plane surfaces moving in a fluid with different velocities, and at different angles of inclination. It is necessary, however, to know the absolute measure of the resistance for perpendicular impulses, in order that we may determine the absolute measures in all other cases. It follows from the experiments of Bossut, that the resistance experienced by a plane surface, which strikes directly and perpendicularly an indefinite fluid, is sensibly equal to the weight of a column of the fluid, which has for its base the area of the plane surface, and for its altitude the height due to the velocity of the surface; that is, if R is the resistance, A the area of the resisted surface, $s$ the specific gravity of the fluid, and $h$ the height due to the velocity, we have $R = s A^2 h$.

If the fluid is not of indefinite extent, but is merely a vein which strikes a plain surface at rest, the absolute measure of the resistance is quite different, being equal to a little less than the weight of a column of fluid whose base is the area of the surface, and whose height is double the height which is due to the velocity of the issuing vein, or $R = s A^2 2h$. This measure of the resistance was first determined accurately by G. W. Krafft. Duhamel had made experiments on the same subject in 1669, and several other philosophers followed in the same path; but the result which they obtained was, that the height of the column was equal only to that which was due to the velocity. Krafft employed a rectangular lever, against the vertical arm of which the water issuing from an additional tube impinged, while the weights requisite to balance that force were placed in a scale placed on the horizontal arm. In this way he obtained the results which we have already given in p. 415. See *Comment Petropol.* 1736, vol. viii. p. 253.

M. Bossut has given an account of similar experiments in the 2d edition of his Hydrodynamics, vol. ii. p. 293, from which it follows, that the resistance is a little less than the weight of a column whose height is double that which belongs to the velocity. In Bossut's experiments the water issued vertically from the bottom of a reservoir, upon one of the arms of a horizontal balance; and he observed that the resistance was always less when the flat arm of the balance touched the orifice, than when there were some interval between them.*

These two simple propositions constitute the whole of the ordinary theory of the resistance of fluids. They are founded upon two suppositions, neither of which are correct. 1. That after any particle of fluid strikes the plane, it is supposed to be annihilated, or to produce no farther effect; and, 2. That the part of the force which in oblique impulses is parallel to the surface of the plane, has no influence whatever upon the resistance which the plane experiences from the perpendicular part of the force. The first of these suppositions is obviously incorrect, for as the particles are not annihilated after impulse, they must some how or other get out of the way of the particles which succeed them, which can only be done by acting upon them, and consequently affecting their velocity. The second supposition appears also to be incorrect, for Mr Vince found that the part of the force which is parallel to the plane is not entirely lost.

By proceeding upon the principle laid down in the preceding proposition, it is easy to determine the resistance experienced by globes, cones, cylinders, and, in short, bodies of any form. Such determinations, however, are of no use, as they differ too widely from the experimental results to be capable of any practical application.

For a general account of D'Alembert's theory of the resistance of fluids, we must refer our readers to the historical part of this article, where a short notice of Don George Juan's theory is also given. The explanation of this last theory, however, belongs more properly to Mechanics, as it is a deduction from that author's physico-mathematical theory of percussion.

SECT. II. *Account of Experiments on the Resistance of Fluids.*

1. *Account of Bossut's Experiments.*

IN our History of HYDRODYNAMICS, we have already given a general account of the experiments made by Bossut, D'Alembert, and Condorcet, in the year 1775, and by Bossut alone in 1778, on the resistance of fluids. The following were the leading results which they obtained.

1. That the resistance of the same body of any figure which divides a fluid with different velocities, are sensibly proportional to the squares of these velocities.

2. That the direct and perpendicular resistances of plane surfaces, are sensibly proportional for the same velocity to the area of the surface.

3. That the resistances which arise from oblique impulses are not in the ratio of the squares of the sines of the angles of incidence; but that, when the angles of incidence are between 50° and 90°, the ordinary theory may be employed as an approximation, by observing that it always gives resistances a little less than experiment, and as much less as the angle differs from 90°.

4. That the absolute measure of the direct and perpendicular resistance of a plane surface in an indefinite fluid, is the weight of a column of the fluid, which has for its base the area of the surface, and for its altitude the height due to the velocity.

The resistance is much greater, and nearly double, in a mill course, which conveys the water to the float-boards of an undershot wheel.

5. That the tenacity of the water is a force which may be regarded as infinitely small, in relation to that which a body experiences in striking the water, particularly when the velocity is considerable.

The next set of experiments by Bossut were made on the resistances experienced in narrow canals. Dr Franklin had ascertained, by a rude experiment, when he was tra-

* The experiments of the Chevalier Borda gave a different result. He employed a cube, which floated upon the stagnant water of a large basin, and he found that the height due to the resistance did not much exceed that which was due to the velocity. See *Mem. Acad. Par.* 1763, 1767.

velling in Holland, that barges experienced a greater resistance when the waters of the canal were low; but no precise measure of this increase of resistance, nor any explanation of its cause, were given till Bossut published his experiments. The following were the general results which he obtained.

1. That in narrow canals the resistances are proportional to the squares of the velocities, following the same law as in a fluid of indefinite extent.

2. That the resistances in narrow canals, and canals which have little depth, is greater than in fluids of indefinite extent.

The cause of this is obvious. When the velocity of the body is considerable, the fluid which that body pushes before it has not liberty to expand itself on every side, but forms a current more or less rapid, as the velocity of the body is more or less great. If the body entirely filled the canal, it would push all the water before it like the piston of a pump; but as, in narrow canals, there is always some room for the water to run both below the boat and at its sides, a part of the fluid escapes in this way, while another part is driven back; and in this way a variety of contrary currents are formed, by which the resistance is increased. This augmentation of resistance is produced, not only by the heaping up of the fluid on its anterior part, but also by the want of hydrostatical support behind.

The preceding results furnish an excellent lesson to the engineer, in so far as they point out the advantage of making all canals of navigation as wide and deep as is consistent with a proper economy.

In 1778, M. Bossut undertook, in conjunction with Condorcet, a series of experiments, the object of which was to determine the law according to which the resistance varied in an indefinite fluid like the sea, by varying the angle of the prow of a vessel from a straight line, or 180°, to an angle of 12°. These experiments were made in the great reservoir, now destroyed, which formerly existed on the north side of the Boulevards of Paris. This reservoir was 200 long, 100 wide, and 8½ deep. The form of the apparatus employed is shewn in Plate CCCXIX. Fig. 10. where MQNOP is the small vessel. The prow, MQN, had various angles, from 180° to 12°. The vessel was drawn along by a cord C attached to its centre of gravity, which passing below a pulley on the same level with *c*, rises nearly in a vertical line, and passing again over a pulley descends and is attached to the weights, by the descent of which the motion of the vessel is produced. A rope QR stretching across the whole length of the reservoir, serves to regulate the motion of the vessel. The vessel was then brought, by another rope fixed at *o*, to one end of the reservoir, and the time in which it described 96 feet uniformly by different weights suspended to the end of the rope, was carefully measured by an excellent seconds watch. Each experiment was repeated five times, and the mean of these times was adopted as the true measure. The general results of these experiments are given in the following Table, and compared with those given by the ordinary theory. The Table contains the resistances for fifteen different kinds of prows. The base MN, Fig. 10. remains always the same, while the angle MQN of the prow, formed into an isosceles triangle, is made variable.

*Comparative Table of the Resistances experienced by 15 Angular Prows, as deduced by Bossut from his Experiments.*

| Angles of the Prow, or values of MQN = $x$. | Calculated Resistances, according to the common theory, or values of Cos.$^2 x$ | Observed Resistances. | Difference between the observed and calculated Resistances. |
|---|---|---|---|
| 180° | 10000 | 10000 | 0 |
| 168 | 9893 | 9890 | 3 |
| 156 | 9578 | 9568 | 10 |
| 144 | 9084 | 9045 | 39 |
| 132 | 9446 | 8346 | 100 |
| 120 | 7710 | 7500 | 210 |
| 108 | 6925 | 6545 | 380 |
| 96 | 6148 | 5523 | 625 |
| 84 | 5433 | 4478 | 955 |
| 72 | 4800 | 3455 | 1345 |
| 60 | 4404 | 2500 | 1904 |
| 48 | 4240 | 1654 | 2586 |
| 36 | 4142 | 955 | 3187 |
| 24 | 4063 | 432 | 3631 |
| 12 | 3999 | 109 | 3890 |

The resules in column third, as given by the ordinary theory, are calculated by the formula 1000 Cos. $^2 x, x$ being the angle of the prow. In order to obtain a formula which will express the law of the experimental resistances, Bossut observes, that when the angle $x$ undergoes a variation of 12°, each of the angles at the base of the isosceles prow will vary 6°. Calling this variation $q$, Bossut finds that the experimental resistance may be expressed by the formula

$$10000 \times \text{Cos.}^2 x + 3153 \left(\frac{x}{q}\right)^{3.25}.$$

This formula, however, though it answers well for prows with large angles, yet when the angle is small, it errs considerably in excess. In a prow of 12°, for example, the term $3.153 \left(\frac{x}{q}\right)^{3.25}$ becomes 4766 instead of 3631.

### 2. *Account of Du Buat's Experiments.*

The attention of Du Buat was first directed to the determination of the resistance experienced by an immoveable surface, when struck by an insulated vein of fluid. whose area is either greater than, or equal to, the area of the surface. In order to measure this resistance, he balanced it by a column of fluid, the height of which measured the height due to the impulse. A tube of glass, about 1½ lines of interior diameter, was bent into a right angle at its lower extremity. Into this bent part were fitted different surfaces for receiving the impulse of the fluid vein, which was to be balanced by the weight of column which ascended in the tube.

The result of these experiments was, that the height due to the impulse is the same as the height due to the velocity of the vein; whereas Bossut made it equal to the height due to twice the velocity. Du Buat accounts for this difference with great success. The vertical vein of fluid in Bossut's experiments enlarged itself in striking the surface upon the balance; and the fluid filaments took a horizontal direction, after they had given the shock to the surface. The resistance, therefore, measured by Bossut was not merely the impulse of a vein whose diameter was that of the orifice, but also the additional pressure of a ring of fluid of a certain extent, around the circular base of the vein in contact with the resisted surface.

M. Du Buat next proceeds to ascertain the amount of the resistance, when an immoveable surface is placed in a current of indefinite extent. The instrument which he used for this purpose was a box of white iron, presenting a surface of one square foot. It had a thickness of nearly four lines, and was shut on all sides except a small opening in its posterior surface, into which was soldered the horizontal branch of a rectangular tin tube sixteen lines in diameter, which received a float that indicated the height to which the water rose within the tube. By means of a bar of iron of about ten feet long, which could be attached to the back of the box, the box could be fixed at any distance below the surface of the current. Five holes, each about a line in diameter, were perforated in the anterior side of the tin box. The first was in the middle, the second equidistant, in a horizontal line, from the middle and the edge, and the third in the same horizontal line, but only ten lines distant from the edge; the fourth was quite close to the edge; and the fifth in the lower angle of the square. When the box was fixed, and the current of water was allowed to enter one or more of these holes, the fluid rose in the rectangular tin tube to a height due to the pressure of the current. In this way Du Buat made several experiments, which gave very singular results. The pressure was not only found to diminish from the centre of the surface to the edge or margin, but it became nothing at a certain distance from the centre, and afterwards negative at the margin. That is, when the water entered through the central hole, it rose to a certain height in the tin tube above the level of the stream. This height diminished when the water entered at a hole nearer the margin, the height became nothing at a certain distance, and still nearer the margin the fluid was actually depressed in the tin tube below the surface of the current. Du Buat explains this remarkable fact by saying, that the real pressure against any part of the surface is only the difference of the pressure against that part considered separately from the rest of the surface, and the height due to the variable velocity with which the water moves along the surface which is struck; that is, the water in escaping along the surface always diminishes the real pressure of the current; but towards the edges it becomes more powerful than the real current, and therefore that part is less pressed than if the fluid were immoveable, and will therefore sink in the tin tube.

In order to ascertain the mean pressure upon the whole surface, Du Buat shut up the holes already mentioned, and perforated the same surface with 625 holes, disposed symmetrically, with 25 on each side. By exposing this surface to the current, it appeared that the height of the water in the tube was $25\frac{1}{2}$ lines, when the mean velocity was 36 inches per second, which is due to a height of $21\frac{1}{2}$ lines. Hence the height due to the mean resistance is equal to 1.186 times the height due to the velocity.

By a similar contrivance Du Buat measured the diminution of pressure, or the *non-pressure*, as he calls it, experienced by the posterior part of a body fixed in a current. He found, 1*st*, That the diminution of pressure increased considerably by lengthening the body; 2*d*, That it increased a little from the circumference of the body to its centre; and 3*dly*, That the diminution of pressure is proportional to the area of the surface that is submerged.

It had hitherto been supposed by all authors, that the resistance experienced by a surface at rest from a fluid in motion, was exactly equal to the resistance of the same surface when it moved in stagnant water, with a velocity equal to that of the current. M. Du Buat resolved to examine this point experimentally, and from a variety of experiments made on the river Hayne, between Mons and Condé, he concluded, 1*st*, That the phenomena are by no means the same when the body is at rest as when it is in motion. 2*d*, That in the latter case, the pressure does not diminish so sensibly from the centre to the circumference, and instead of a negative pressure towards the sides, that the pressure is then so great, as to be measured by the third of the height due to the velocity, which shows that the water runs along the anterior surface with less velocity, or with more uniformity. 3*d*, That the pressures diminish in a less ratio than the square of the velocity, when the velocities are less than three or four feet per second. 4*th*, That the mean pressures are measured by the exact height due to the velocity, instead of 1.186 times the height, as before: And, 5*thly*, That the diminution of pressure diminishes little from the centre to the circumference in the same order as the pressures.

The next object of M. Du Buat is to determine the quantity of fluid which globes and plane surfaces drag along with them, when oscillating in a fluid. The globes were of wood, lead and glass. They oscillated in a vessel 51 inches long, 17 inches wide, and 14 inches deep: They were entirely immersed about three inches below the surface, and the wire which suspended them was as delicate as their weight would permit. The general result of these experiments is, that a globe oscillating in water drags along with it, both before and behind, a portion of fluid, whose volume exceeds a little its own volume, or nearly $\frac{585}{1000}$ of its own volume.

Similar experiments were made with various plane surfaces of white iron cylinders oscillating in the plane of their axes, quadrangular prisms oscillating in the plane of their axes, triangular prisms oscilliating in the plane of their axes, cubes oscillating directly, cubes oscillating by the common section of two of their bounding planes, cubes oscillating by a solid angle, quadrangular prisms oscillating by the common section of two oblique faces, cylinders oscillating in the direction of their diameters, and cones, pyramids and mixed bodies oscillating in the plane of their axes; but our limits will not permit us to give any account of these experiments, which will be found in Part III. sect. 1. chap. viii. of Du Buat's *Principes D'Hydraulique*, tom. ii.

The attention of Du Buat is next directed to the important subject of the resistance opposed to vessels in narrow canals. From a comparison of several experiments, he has deduced the following formula:

$$R = \frac{K}{\frac{C}{b} + 2} \qquad \text{or } R = \frac{8.46}{\frac{C}{b} + 2},$$

in which C is the area of the section of the canal, $b$ the area of the section of the vessel, and R the resistance; the resistance in a fluid of indefinite extent being = 1.

In order to compare this formula with experiments, Du Buat employed five kinds of prismatic boats, several feet in length, and terminated both before and behind by a plane surface, The boat

No. 1, had the immersed part = a rectangle of one foot of base upon 1 foot of height.

NO. 2, had two feet of base upon one foot of height immersed.

No. 4, and 5, had 19 inches 8 lines upon 12 inches $5\frac{1}{2}$ lines immersed, and differed only in their lengths.

No. 6, has its section like the great section of a vessel, and the area of the part immersed was 190 square inches.

The following Table shews the results of the experiment :

Table *shewing the Resistance of Boats in Narrow Canals.*

| Numbers of the Boats. | Ratio of the Sections or Values of $\frac{C}{b}$ | Observed Resistances, or Values of R. | Resistances calculated by the Formula. |
|---|---|---|---|
| *Canal* 28½ *Inches Wide, and* 15 *Inches* 2 *Lines Deep.* | | | |
| 1 | 3.00 | 1.66 | 1.69 |
| 2 | 1.50 | 2.50 | 2.41 |
| 4 & 5 | 1.76 | 2 25 | 2.25 |
| 6 | 2.275 | 1.94 | 1.97 |
| *Canal* 40 *Inches Wide, and* 15 *Inches* 2 *Lines Deep.* | | | |
| 1 | 4.212 | 1.33 | 1.36 |
| 2 | 2.106 | 2.11 | 2 05 |
| 4 & 5 | 2.476 | 1.90 | 1.89 |
| 6 | 3.192 | 1.62 | 1.62 |

From these experiments Du Buat has concluded that a canal cannot be considered as of indefinite width, unless its width is 4.46, or 4½ times that of the vessel; or what is the same thing, that when this is the ratio between the width of the vessel and the canal, the vessel experiences the same resistance as if it moved in the open sea. In order to confirm this result, the following experiments were made, in which $\frac{c}{b}$ and R in the last column are calculated by reducing the canal to 4½ times that of the vessel.

| Numbers of the Boats. | Ratio of the Sections or Values of $\frac{C}{b}$ | Observed Resistances, or Values of R. | Resistances calculated by the Formula. |
|---|---|---|---|
| *Canal* 75 *Inches Wide, and* 15½ *Deep.* | | | |
| 1 | 5.81 | 1.053 | 1.08 |
| 2 | 4.036 | 1 384 | 1.40 |
| *Canal of Indefinite Width, and* 15 *Inches* 4 *Lines Deep.* | | | |
| 2 | 5.75 | 1.125 | 1.09 |
| 5 | 5 53 | 1 143 | 1.12 |
| *Canal of Indefinite Width, and* 27 *Inches* 3 *Lines Deep.* | | | |
| 2 | 4.46 | 1.1 | 1.00 |

The law of oblique resistances does not appear to be the same in a narrow canal as in a fluid of indefinite extent, and an angular prow added to a prismatic vessel produces a less diminution of the resistance as the canal becomes more narrow. M. Du Buat expresses the resistance of an angular prow in a narrow canal by the following formula :

$$r = R - \frac{\left(R - \frac{R}{q}\right)\left(\frac{C}{b} - 1\right)}{5\,46}, \text{ in which}$$

R is the resistance of a plane prow in a narrow canal.
$r$ the resistance of an angular prow of the same base.
$q$ the ratio between the resistances of these two prows, in an indefinite fluid ; and
$\frac{C}{b}$ the ratio of the section as formerly.

When the boat No. 2. had an angular prow of 45°, and moved in a canal 28½ inches wide, and 15½ deep, the resistance was 4.42 ; whereas, the formula gives $r = 4.444$.

When the same boat had an angular prow of 14° 3′, the resistance was = 3.2 ; whereas, the formula gives $r = 3.25$

When these experiments were repeated in a canal shut at both ends, the resistance of boat No. 1. was sensibly the same as when it was open ; but when No. 2. was used, the resistance was considerably augmented. The effects in this case become very complicated, particularly for a canal which is short. When the sluices in canals are three or four miles distant, the part of the canal may be considered as of indefinite length, and if approaching one of its extremities, the boats ought to experience more resistance from this cause, yet the heaping up and the driving back of the water obliges the boats to rise, and thus allows the fluid to escape more easily behind.

3. *Account of the Experiments of Vince on the Resistance of Fluids.*

The experiments of Mr Vince on the resistance of fluids, were published in 1798, in the *Transactions of the Royal Society of London*. They were made with bodies moving at a considerable depth below the surface of water, and the resistance was measured both when the body moved in the fluid, and when the body was struck by the fluid in motion. The results of his experiments on the resistance of a plane surface moving in a fluid, are given in the following Table.

Table *shewing the Resistance of a Plane Surface moving in a Fluid with a Velocity of* 0.66 *of a Foot in a Second, and inclined at different Angles to the Line of its Motion.*

| Inclination of the Plane to the Line of its Motion. | Resistances Observed. | Resistances calculated from Theory. | Power of the Sine of the Inclination to which the resistance is proportional. |
|---|---|---|---|
| Degrees. | Ounces Troy. | Ounces Troy. | Experiments. |
| 10 | 0.0112 | 0.0012 | 1.73 |
| 20 | 0.0364 | 0 0093 | 1.73 |
| 30 | 0 0769 | 0.0290 | 1.54 |
| 40 | 0.1174 | 0 0616 | 1.54 |
| 50 | 0.1552 | 0.1043 | 1.51 |
| 60 | 0.1902 | 0.1476 | 1.38 |
| 70 | 0.2125 | 0.1926 | 1.42 |
| 80 | 0.2237 | 0.2217 | 2.41 |
| 90 | 0.2321 | 0 2321 | |
| 1 | 2 | 3 | 4 |

In the preceding Table, column 1st contains the angles of inclination at which the plane surface struck the fluid. Column 2d shews the resistance by experiment in the direction of their motion in Troy ounces. Column 3d shews the resistance by theory, the perpendicular resistance being supposed the same as that which is deduced from experiment. Column 4th contains the exponent of the power of the sine of the angle to which the resistance is proportional. This column was computed in the following manner: Calling $s$ the sine of the inclination, and $r$ the corresponding resistance; then, if $r$ is proportional to the $m$th power of $s$, or to $s^m$, we have sin. 90°, or $1^m s^m = 0.2321 : r$ and $s^m = \frac{r}{0.2321}$; and, consequently, $m = \frac{\text{Log. } r - \text{Log. } 0.2321}{\text{Log. } s}$. According to theory, the resistance in the direction of the motion of the plane should vary as the cube of the sine (Prop. II. Cor. p. 883); but it appears from the Table, that it varies in a much less ratio, but not as any constant power, or as any function of the sine and cosine. The actual resistance, therefore, must always exceed the theoretical resistance, which Mr Vince attributes partly to the part of the force parallel to the plane being neglected in the theory, but which appears to be really a part of the force which acts upon the plane.

When the plane surface was struck by the fluid in motion, Mr Vince obtained the results contained in the following Table.

Table *shewing the Resistance of a Plane Surface struck by a Fluid in Motion, and inclined at different Angles to the line of its Motion.*

| Inclination of the Plane to the Sine of its Motion. | Resistances observed. | | | Resistances calculated from Theory. | | |
|---|---|---|---|---|---|---|
| Degrees. | Oz. | Dwts. | Grs. | Oz. | Dwts. | Grs. |
| 90 | 1 | 17 | 12 | 1 | 17 | 12 |
| 8 | 1 | 17 | 0 | 1 | 16 | 22 |
| 70 | 1 | 15 | 12 | 1 | 15 | 6 |
| 60 | 1 | 12 | 12 | 1 | 12 | 11 |
| 50 | 1 | 18 | 10 | 1 | 18 | 17 |
| 40 | 1 | 4 | 10 | 1 | 4 | 2 |
| 30 | 0 | 18 | 18 | 0 | 18 | 18 |
| 20 | 0 | 12 | 12 | 0 | 12 | 19 |
| 10 | 0 | 6 | 4 | 0 | 6 | 12 |

The coincidence between the experimental and the theoretical results is very surprising, the difference being nothing more than might have been expected from the ordinary inaccuracy of experiments. It follows, therefore, from Mr Vince's experiments, that when the fluid is in motion, the resistance varies as the sine of the angle of the plane's inclination.

The difference between the resistances in the two cases confirm the results obtained by Du Buat, and prove, that the resistance when the plane moves is to the resistance when the fluid moves as 5 to 6, a result which Mr Vince ascribes to the action of the fluid behind the body when in motion.

4. *Account of Coulomb's Experiments on the Resistance of Fluids in Slow Motions.*

Notwithstanding the great value of the experiments of Bossut and Du Buat, yet none of these authors succeeded in determining the true law of the resistance of fluids. This honour was reserved for the late M. Coulomb, who first entertained the happy idea of ascertaining the laws of the resistance of fluids in slow motions, by the oscillation of horizontal discs in consequence of the torsion, or the twisting and untwisting of the wire by which they were suspended. In the present Section we shall endeavour to lay before our readers as distinct an account as possible of the investigations of this celebrated philosopher.

When a body in motion strikes a fluid at rest, it experiences two kinds of resistance. One of these arises from the cohesion of the fluid particles, which are separated from each other by the moving body; and as the number of molecules thus separated is proportional to the velocity of the body, this part of the resistance, depending upon the cohesion, will likewise be proportional to the simple velocity.

The other part of the resistance arises from the inertia of the fluid particles, which, being struck by the body, acquire a degree of velocity proportional to the velocity of the body; but as the number of these parts is proportional to the velocity, there ought to arise a resistance proportional to the square of the velocity. Hence the theory seems to inform us, that the *resistance of fluids should be represented by the sum of two quantities, one of which is proportional to the simple velocity, and the other to the square of the velocity.* This theoretical result was completely verified by Coulomb's experiments.

In order to submit these views to the test of experience, the ordinary methods of measuring the resistance of fluids are of no avail. When the moving body has a velocity about eight or nine inches per second, the resistance is always proportional to the square of the velocity; but when the velocity does not exceed four-tenths of an inch per second, the part proportional to the simple velocity becomes sensible; but as the velocity is extremely small, the resistance is also very small, and therefore the ordinary means cannot be used either in measuring the resistance, or in separating the parts due to the different terms of the formula. Coulomb therefore found it necessary, 1. To employ a measure, by which he could determine with great exactness very small forces. And, 2. To have it in his power to give to the moving body a degree of velocity so small, that the part of the resistance proportional to the square of the velocity might be compared with the other terms of the function which represent the resistance; or to be able to make the part of the resistance proportional to the square of the velocity, so small compared with the other terms, that it might be safely neglected.

These objects were completely gained, by employing the apparatus represented in Plate CCCXIX. Fig. 11. where ABC is a stand, having a horizontal arm BC, to which is fixed the small circle *e f*, perforated in the centre for the purpose of admitting the cylindrical pin *b a*. Into a slit in the extremity of this pin is fastened, by means of a screw, the brass wire *a g*, whose force of torsion is to be compared with the resistance of the fluid; and its lower extremity is fixed in the same way into a cylinder of copper *g d*, whose diameter is about four-tenths of an inch. The cylinder *g d* is perpendicular to the disc DS, whose circumference is divided into 480 equal parts. When this horizontal disc is at rest, which happens when the torsion of the brass wire is nothing, the index RS is placed upon the point 0, the zero of the circular scale. The small rule R $m$ may be elevated or depressed at pleasure round its axis $n$; and the stand GH which supports it may be brought into any position round the horizontal disc. The lower extremity of the cylinder $gd$ is immersed about two inches in the vessel of water MNOP, and to the extremity $d$ is attached the discs, or the bodies, whose resistance is to be determined when they oscillate in the fluid by the torsion of the brass wire.

In order to produce these oscillations, the disc DS, supported by both hands, must be turned gently round to a certain distance from the index, without deranging the vertical position of the suspended wire. The disc being then left to itself, the force of torsion causes it to oscillate, and the successive diminution of these oscillations is carefully observed. A simple formula gives in weights the force of torsion that produces the oscillations; and another formula well known to geometers, determines (by an approximation sufficiently accurate in practice,) by means of the successive diminution of the oscillations, compared with their amplitude, what is the law of the resistance, relative to the velocity which produces these diminutions.

The method employed by Coulomb in reducing his experiments, is nearly the same as that by which Newton and others determined the resistance of fluids from the successive diminution of the oscillations of a pendulum vibrating in a fluid; but Coulomb's apparatus is not liable to any of the objections which attach to the use of the pendulum. It would be impossible, without a previous explanation of the principles of torsion, and a discussion too long and minute for the limits of our work, to make our readers acquainted with the various steps of Coulomb's investigation. All that we can pretend to do is, to give an account of the different physical results which he obtained.

Having attached to the lower extremity of the cylinder $gd$ a circular white iron plate, about 6.677 inches in diameter, he found that when its oscillations were so slow, that the part of the resistance proportional to the square of the velocity was greatly inferior to the other part, the resistance which diminished the oscillations of the horizontal plate was uniformly proportional to the simple velocity, and that the other part produced no sensible effect upon the motion of the disc. He likewise found, in conformity with theory, that the momenta of resistance in different circular plates oscillating in a fluid, are as the fourth power of the diameters of these circles, when the resistance is proportional to the simple velocity; and that when a circle, 6.677 inches in diameter, oscillated with the velocity of 5.512 inches per second in its circumference, the momentum of resistance which the fluid opposed to its circular motion was equal to $\frac{1}{10}$th of a gramme, multiplied by a lever 143 millimetres long, or 1.544 English Troy grains, at the end of a line 5.63 English inches long. Hence it follows, that the resistance of the two circular surfaces of the disc is equal to a weight of 0.587 grammes.

If the plane or disc had only a velocity of ten millimetres, or one centimetre, the resistance would be only 0.042 grammes. In like manner it follows, that the resistance experienced by a surface of one square metre, moving with a velocity of one centimetre per second, is 0.703 grammes.

In order to determine comparatively with water the cohesion of different fluids, he filled a large vessel with clarified oil, such as is used in commerce for the lamps called *Quinquet;* and he found its temperature to be 16° of Reaumur's scale, which he marked, because the cohesion of oil varies with the temperature, though this variation is not sensible in water by small changes of temperature. By causing discs of different diameters to oscillate in the oil, he found that the momenta of resistance for two circles, moving round their centre in the plane of their superficies, varies as the fourth power of the diameter, a result which is also conformable with theory. The agreement of these results, Coulomb considers as leaving no doubt respecting the certainty of the term proportional to the velocity in the resistance of fluids.

From these experiments, Coulomb likewise concluded, that the difficulty which the same disc moving with the same degree of velocity experienced in separating the particles of oil, was to the difficulty which it experienced in separating the particles of water as 17.5 to 1, which will therefore express the ratio between the mutual cohesion of the particles of oil, and the mutual cohesion of the particles of water.

The next object of our author was to determine two important points. 1*st*, If the resistance of a body was influenced by the nature of its surface; and, 2*d*, if it was influenced by the pressure of the superincumbent fluid. In order to settle the first of these points, he covered the surface of a circle of white iron with a film of tallow, and wiped it slightly away, that the thickness of the plate might not be sensibly increased. He then caused this circle to oscillate as before; and he observed that the successive diminution of the oscillations was exactly the same as before the application of the tallow. Upon the coat of tallow he next scattered, by means of a sieve, a quantity of sand, which adhered to the surface; and he found that the resistance to the oscillations of the plate was not sensibly increased. Hence he concludes, that the part of the resistance proportional to the simple velocity arises from the mutual cohesion of the fluid particles, and not from the adhesion of these particles to the surface of the body. Whatever, indeed, was the nature of the surface, there was an infinite number of inequalities where the fluid particles were permanently lodged.

In order to determine the second point, M. Coulomb caused the bodies to oscillate at two different depths; one at a depth of .787 inches, and another at a depth of 19.6855 inches, and he found no difference in the resistances; but as the surface of the water supported the whole weight of the atmosphere, it was scarcely to be expected that a pressure of 19 inches of fluid would produce a very sensible increase of resistance. In order to decide the question, therefore, M. Coulomb employed another method.

Having placed a vessel full of water under the receiver of an air-pump, the receiver being furnished with a rod and collar of leather at its top, he fixed to the hook at the end of the rod a harpsicord wire numbered 7 in commerce, and suspended to it a cylinder of copper like $g$, $d$. Fig. 11. which plunged in the water of the vessel, and under this cylinder he fixed a circular plane, whose diameter was 101 millimetres (3.975 English inches). When the oscillations were finished, and consequently the force of torsion nothing, the zero of torsion was marked by the aid of an index fixed to the cylinder. The rod was then made to turn quickly round through a complete circle, which gave to the wire a complete circle of torsion, and the successive diminution of the oscillations were carefully observed. The diminution for a complete circle of torsion was found to be nearly a fourth part of the circle for the first oscillation, but always the same, whether the experiment was made in a vacuum or in the atmosphere. A small pallet, 50 millimetres long (1.969 English inches), and 10 millimetres broad (0.3937 English inches), which struck the water perpendicular to its plane, furnished a similar result. We may therefore conclude, that when a submerged body moves in a fluid, the pressure which it sustains, measured by the altitude of the superior fluid, does not perceptibly increase the resistance; and consequently that the part of this resistance proportional to the simple velocity, can in no respect be compared with the friction of solid bodies, which is always proportional to the pressure.

These experiments were twice repeated in the cabinet of the Institute, in the presence of M. Charles and M. Lassuze.

The attention of M. Coulomb was next directed to the determination of the resistance experienced by cylinders that moved very slowly, and perpendicular to their axes. When a cylinder, however small be its diameter, moves perpendicularly to its axis, the fluid particles which it strikes partake necessarily of its motion, and therefore it is not possible, in the reduction of the experiments, to neglect the part of the resistance which is proportional to the square of the velocity. Hence he was obliged to perform the experiments in such a manner that both parts of the resistance might be computed. The three cylinders, which were successively subjected to trial, had a length of 9.803 inches. The cylinders were fixed by their middle under the cylinder *g d*, so that they formed two horizontal radii, the length of each of which was $\frac{9.803}{2}=4.9015$ inches. The diameters of the cylinders were determined from their weight. After making the necessary experiments with cylinders whose diameters were 0.87 millimetres, 11.2 millimetres, and 21.1 millimetres, he found, from a comparison of the results, that the part of the resistance proportional to the simple velocity, which we shall call $r$, is not in different cylinders in the same ratio as the circumference of these cylinders, the ratio of their circumferences being as 24 to 1, while the values of $r$ were as 3 to 1. In order to explain this result, Coulomb supposes that the particles which immediately touch the cylinder take the same velocity as the cylinder; that the particles a little farther distant take a smaller velocity; and that at the distance of about one-tenth of an inch, the velocity ceases entirely. Hence it is at this last point that the cohesion ceases to have an influence on the resistance. Upon these suppositions, which Coulomb thinks require confirmation, he proposes to augment, by a constant quantity, the circumferences of all the cylinders, before comparing them with their resistance. This constant quantity to be added to the circumferences, he found to be 9.68 millimetres, or nearly an addition of three millimetres to their diameter; which shews that the portion of the fluid molecules detached from one another by the moving cylinder extends nearly to a distance of 1.5 millimetres from their circumferences.

In comparing the part of the resistance proportional to the square of the velocity, which we shall call R, with the diameters of the cylinders, it will be seen that these quantities in small cylinders are much greater than they ought to be in relation to their diameters, but in a much less ratio than in the preceding case. The augmentation of the circumferences is in this case only 1.77 millimetres, which is scarcely one-fifth of the former augmentation. Coulomb explains this difference from the theory in the following manner. All the fluid particles, when they are detached from one another, oppose the same resistance, whatever be the velocity which they take; so that as the quantity $r$ depends only on the cohesion, the resistance due to their cohesion will extend only to the point where the velocity of the molecules of the fluid is nothing. In the comparison of the quantities R, all the particles are supposed to take a velocity equal to that of the cylinder; but as it is only the molecules in immediate contact with the cylinder that take this velocity, it follows, that the augmentation of the diameter in determining the value of R, which answers the square of the velocity, should be less than in determining $r$, which is due to the cohesion. Besides, as Coulomb observes, these different degrees of lateral velocity, from the point of contact with the cylinder, where the velocity is equal to that of the cylinder, to the point where the cohesion renders the velocity nothing, ought to follow laws which new observations may soon determine, and which may throw great light upon this interesting branch of physics.

In determining by experiment the part of the momentum of resistance proportional to the velocity in two cylinders of the same diameter, but of different lengths, Coulomb found that the momentum of resistance was proportional to the cubes of their diameters. The same result is obtained from theory; for supposing each cylinder to be divided into the same number of parts, the length of each part will be proportional to the total length. The velocity of the corresponding parts will be as the same lengths, and also as the distance of these parts from the centre of rotation. The theory likewise indicates that the part of the momentum of resistance depending on the square of the velocity, in two cylinders of the same diameter, but of different lengths, is proportional to the fourth power of the length of the cylinder.

Coulomb now proceeds to determine the real resistance due to the simple velocity which a cylinder experiences while oscillating parallel to itself, and perpendicular to its axis. When the cylinder 9.803 inches long, and 0.04409 inches in circumference, was made to oscillate with a velocity of 5.512 inches per second, the part of the resistance $r$ was equal to 58 milligrammes, or .8952 troy grains; and when the velocity was 0.3937 inches per second, the resistance was 0.00414 grammes, or 0.637 troy grains. Hence we may conclude, that the resistance of a cylinder of the same diameter, but of a metre in length, or 39.37 inches, will be about 17 milligrammes.

The preceding experiments were repeated in the same oil which was formerly used, and at the same temperature; and he found, as formerly, that the cohesion of oil was to that of water as 17 to 1. He considers oil as preferable to water for determining $r$; for in the case of small velocities, the part R disappears almost entirely.

In these experiments Coulomb observed an effect which he could not have anticipated. Although the cohesion of the oil is 17 times greater than that of water, yet the augmentation of the diameters of the cylinders, which it was necessary to apply, was only 3 millimetres, the same as for water. He observed also another curious fact, which is more easily understood, viz. that the part of the resistance R is almost the same in oil as in water; for since this part arises merely from the inertia of the particles, it ought in different fluids to be proportional to their density.

Coulomb intended, in a second memoir, to determine numerically the value of the part of the resistance proportional to the square of the velocity; and to ascertain the resistance of globes, of pallets, of convex and concave surfaces; and also the difference between the resistance of a floating body and one entirely submerged; in consequence of his having found, that in slow motions the submerged body suffered a much less degree of resistance. We have to regret, however, that Coulomb did not live to complete these valuable researches. He died on the 3d August 1806, in the 70th year of his age; and left behind him the reputation of being one of the most able and original natural philosophers of the age in which he lived.

### 5. *Account of the Experiments of the Society for the Advancement of Naval Architecture.*

We regret that our limits will only permit us to lay before our readers some of the results of these excellent experiments.

The following experiments were made with a surface of 40 square feet, moving in its own direction with different velocities.

| Velocities in Natural Miles per hour. | Friction in Pounds. |
|---|---|
| 1 | 0.563 |
| 2 | 1.992 |
| 4 | 6.642 |
| 6 | 12 839 |
| 8 | 19.856 |

When the same body had prows differently inclined, the following results were obtained.

| Inclination of the Prows. | Friction. |
|---|---|
| 9° 44′ 10″ | 30.67 |
| 14 28 40 | 35.34 |
| 19 28 15 | 41.71 |
| 30 0 0 | 51.44 |
| 90 0 0 | 148.25 |

The Society likewise found, that the direct resistance varied in a ratio a little greater than that of the square of the velocity, being proportional to $V^{2.106}$. A body which has the form of a fish appeared to move with the least resistance; and soaked planks suffered a greater resistance than those which were not soaked.

### 6. *Comparison of the Results of different Formulæ and Experiments.*

Dr Thomas Young has drawn up the following valuable Table, containing a comparison of different formulæ with the experiments of Eytelwein, Bossut, and those of the Society for the advancement of Naval Architecture. In these formulæ, $a$ is the angle of inclination, and R the resistance.

Formula A deduced by Dr Young, is $R = \cos.^2 a + \frac{1}{10}$ tang. $a$.

Formula B deduced by Dr Young from theory is $R = \frac{2}{10} + \frac{4}{100}$ tang. $a + 288 \cos.^2 a : 360 + a°$.

Formula C deduced by Dr Young from experiments, is $R = \cos.^2 a + .0000004217\, a^{3.18}$ in which the last term is a little less than the millionth of the cube of the angle of incidence expressed in degrees.

Eytelwein's formula is $\cos.^2 a + \frac{4}{10}$ versed sin. $a$.

TABLE *containing Dr Thomas Young's Comparison of different Formulæ and Experiments.*

We have purposely omitted giving any account of the experiments of Hutton, Schober, and Colonel Beaufoy, on the resistance of air, as they do not belong to the present article.

## CHAP. VI.

### On the Oscillation of Fluids, and the Undulation of Waves.

#### Prop. I.

The oscillations of a fluid in a syphon are isochronous, and are performed in the same time as those of a pendulum, whose length is equal to half the length of the oscillating columns.

Let MNOP, Plate CCCXIX. Fig. 12. be a syphon, consisting of two vertical branches MN, OP, connected together by a horizontal branch NO, and having the same internal diameter throughout its whole length. If water is poured into the syphon till it stands at AB in one leg, it will stand at CD in the other, ABCD being a horizontal line. Let a piston be now introduced at P, so as to cause the water to descend through the space C$g$, it will of course rise in the other branch to the height $ef$, so that A$e$ = C$g$. Upon withdrawing the piston, the elevated fluid in MN will descend in order to recover its level; the fluid in PO will also rise above its natural level, and again descending, a series of oscillations will be performed by the fluid similar to those of a pendulum, the surface AB vibrating between $ef$ and $\epsilon\varphi$, and the surface CD between $gh$ and $\gamma\chi$. On account of the friction of the water, however, against the sides of the tube, the height

$C\gamma$ will not be so great as $Ac$; and consequently, from the same cause, the oscillations will gradually diminish like those of a pendulum, till the water resume its state of equilibrium.

It is obvious from the Figure, that the force which produces the oscillations is the weight of the column of fluid $ef\varphi\epsilon$, or twice the column $ABfe$, which is to the whole weight of the fluid column as 2 A $e$ to ANOD, or as A $e$ to the length of a pendulum EF, Fig. 13. which describes arcs FI equal to A$e$, or to one half of the oscillating column. Consequently since the length of the oscillating column ANOD is a constant quantity, the force which produces the oscillations is proportional to the space described by the water, and therefore the oscillations are isochronous.

Since the force by which the pendulum is made to describe the small arch FI is to the weight of the pendulum as FI is to FE, or as A $e$ : EF; and since the force which makes the water oscillate is to the weight of thé whole water in the same ratio, the oscillations of the pendulum and of the fluid being produced by the same forces, must be performed in equal times.

Cor. The oscillations of a column of fluid will be proportional to the square roots of the length of the column of fluid. For as this is true of the pendulum, it must be true also of the oscillating fluid, which follows the same laws. See Mechanics.

Those who wish to study farther the subject of the oscillation of fluids, are referred to the *Principia* of Sir Isaac Newton, lib. ii. Prop. 45, 46. and to Bossut's *Traité Theorique et Experimental d'Hydrodynamique*, tom. i. chap. ix. p. 403. edit. 1796, where they will find a general method of determining the oscillations of water in a syphon of any form, with an application of the method to a cylindrical syphon, and to a rectilineal syphon composed of three tubes, two vertical, and one horizontal. The subject is also treated in Bernoulli's *Works*, tom. iii. p. 125, and in Hutton's *Mathematical Tracts*, vol. iii. p. 350.

Prop. II.

The undulations of waves are performed in the same time as the vibrations of a pendulum, whose length is equal to AC or BD, Fig. 14. the breadth of the wave, or the distance between two adjoining eminences or depressions.

Let ABCDE represent the section of two waves. It is obvious that the eminences A, C must descend, by the force of gravity, or a force equal to the weight of the elevated portion, and that the undulations are performed like the oscillations of water in a syphon, the highest parts AC becoming the lowest, while the lowest BD become the highest. Hence, if we take a pendulum, whose length is equal to half the distance between A and C, or B and D, the parts A, C will descend so as to be the lowest in the time of one oscillation of the pendulum, and in the time of another oscillation they will become the highest parts; that is, the pendulum will make two vibrations in the time of one undulation, or the time that one of the summits C has described a space comprehended between two adjacent summits. And as a pendulum, whose length is four times that of the preceding, oscillates once in the same time that it oscillated twice, it follows, that the waves perform their oscillations in the same time as a pendulum, whose length is equal to AC or BD, the breadth of a wave. Hence a wave $3\frac{2}{9}\frac{5}{6}$ feet broad, will have a velocity of $3\frac{2}{9}\frac{5}{6}$ feet in a second; and a wave 18 inches broad will have a velocity of 26.538 inches per second.

The preceding doctrine of the oscillation of waves was first published by Sir Isaac Newton, in lib. ii. prob. 44. of the *Principia*. As the motion of waves, however, is partly circular, Sir Isaac considered his theory as only an approximation. M. La Place, in the *Memoirs of the Academy of Sciences* for 1776, has applied to this subject, particularly to rectilineal waves, the general laws of the motion of fluids, and obtained some interesting results, of which we have given a general account in our History of Hydrodynamics. La Grange has treated the subject in a general manner in the *Berlin Memoirs* for 1786, and M. Poisson and M. Cauchy have more recently written upon the same subject. The reader will find a general account of their labours in the History of Hydrodynamics. The same subject has likewise been treated by Dr Thomas Young, with his usual ability, in his *Lectures on Natural Philosophy*, vol. ii. p. 63.

## Part III. ON HYDRAULIC MACHINERY.

The term Hydraulic Machinery is, in strict propriety of language, applicable only to those machines which are driven by the force of water, whether it descends by its own weight, or acts by its impulsive power when in motion, or exerts a force in virtue of its re-action. It has, however, been applied in a more extended sense, so as to include various machines, by which water is raised or projected. The application of wind, and the force of animals, as the moving power of machinery, will be fully discussed under Mechanics, and the important application of steam will be considered at great length under the separate article of Steam *Engine*. As pumps and fire engines are pneumatical machines, they will be described under the articles Pneumatics and Pump.

### CHAP. I.

#### On Water Wheels.

The usual method of employing water as the moving power of machinery, is to apply it to the circumference of wheels, from the axis or axletree of which the power is conveyed to the other parts of the machine. When the water is introduced into buckets placed round the circumference of a wheel moving in a vertical plane, so as to put the wheel in motion merely by its weight in the buckets, the wheel is called an *overshot wheel*, from the water being introduced over or near the summit of the wheel. When the water, after having acquired a considerable velocity by its descent along an inclined plane, is made to strike plane surfaces, or floatboards, arranged round the wheel's circumference, so as to put the wheel in motion merely by its impulsive force, it is called an *undershot wheel*, from the water being introduced at or near the under part of its circumference. When the water is introduced neither at the upper nor the lower point of the wheel, but at a point between them, so as to fall upon floatboards fixed in the wheel's circumference, and to act both by its weight and by its impulse, it is called a *breast wheel*. When the water is made to issue from an aperture in the circumference of a wheel in the direction of the tangent, the wheel is said to be driven by the re-action or counter-pressure of the water. We shall now proceed to consider, in separate Sections, the best mode of constructing water wheels of these four different forms.

### Sect. I. *On the Construction of Overshot Wheels.*

An overshot wheel of the common kind, is represented in Plate CCCXIX. Fig. 15, where ABCD is the rim of the wheel, having a number of buckets *a*, *b*, *c*, *d*, arranged round its circumference. When the wheel is in a state of rest upon its axis O, and water is introduced into the bucket *c* from the horizontal mill course or canal EF, the weight of the water in the bucket, acting at the end of a lever equal to *m* O, puts the wheel in motion in the direction *c d*. When the subsequent bucket *b* comes into the position *c*, it is also filled with water, and so on with all the rest. When the bucket *c* reaches the situation of *d*, its mechanical effect to turn the wheel is increased, being now equal to the weight of water acting at the end of a lever *n* O, equal to the distance of its centre of gravity *d* from a vertical line passing through the axis O, so that the mechanical effect of the water in the bucket increases all the way to B, and of course diminishes while the buckets are moving from B to C.

The buckets, however, between B and C, have not the same power upon the wheel as those between A and B; for the water begins to fall out of the buckets before they approach to B, and are almost completely empty when they reach the point H. The construction of the buckets, therefore, as shewn in the Figure, is very improper, as it not only allows the water to escape before it has reached the point B, where its mechanical effect is a maximum; but also to escape completely, long before they have reached the lowest point C of the wheel. The power, therefore, of an overshot wheel must depend principally upon the form which is given to the buckets, which should always be fullest when they are at the point B, and should retain the water as long as possible. If the buckets were to consist of a single partition in the direction of the radii of the wheel, all the water would escape from the buckets before they passed the point B on a level with the axis O.

The form of a bucket, which has been regarded as the best, is represented in Fig. 16, by the line DCBAGIKL, where it is represented as composed of three partitions, viz. AB and GI, called the *start* or *shoulder*, which lies in the direction of the radius; BC and IK, called the *arm*, and inclined at an obtuse angle to the radius; and CD, KL, called the *wrest*, and inclined at an angle less than 180° to the arm BC or IK. The depth AG of each bucket is about $1\frac{1}{5}$ of GH; AB is $\frac{1}{2}$ of AM; and the angle ABC is such, that BC and GI prolonged would pass through the same point H. It ends, however, in C; so that FC is $\frac{5}{6}$ths of GH; and CD is placed so, that HD is nearly $\frac{1}{5}$th of HM. Hence it follows, that the arc FABC is nearly equal to DABC; so that the quantity of water FABC will still continue in the bucket when AD is a horizontal line, which happens when AB forms an angle of about 35° with a vertical line. The preceding construction of the buckets is obviously too complicated, and very little additional power is gained by the angle BCD. Hence the general practice is to continue BC to H, and AB is generally only $\frac{1}{3}$d of GH.

Such is the general view of the construction of buckets, which is given by Dr Robison; but we cannot agree with him in thinking that this form is the best. It must be obvious, upon the slightest consideration, that the power of the wheel would be a maximum, if the whole of its semi-circumference were loaded with water. This effect would be produced, if the buckets had the shape shewn in Fig. 17, where ABC is the form of the bucket, AB being in the direction of the radius, and BC part of the circumference of the wheel, and nearly equal to AD. This construction is, however, impracticable, as the aperture EC is not large enough either for the admission or the escape of the water, and when the last portion of the water flows out along BC, it would strike against the bottom DE of the bucket immediately above it. We must therefore consider what modification this form should receive, in order to give a free passage to the water at EC. This may be effected, by making BC (Fig. 18.) a little larger than BE, and diminishing AB, so as to make the angle ABC a little greater than 90°. In this way an aperture *d* E will be obtained, of sufficient magnitude both for the introduction and the discharge of the fluid; and the last portion of water will no longer strike against the bottom D *d* of the upper bucket. When the water is properly introduced by the methods afterwards to be described, this construction will be found to give great additional power to the wheel. Hence we see the reason why the inclination of DC, in Fig. 16, is advantageous, as it is an approximation to the preceding construction.

The late Mr Robert Burns of Cartside in Renfrewshire, a most ingenious millwright and mechanic, proposed what appeared to be a very great improvement upon the form of the buckets in overshot wheels. It consisted in using a double bucket, as shewn in Fig. 19, where LM is a partition almost concentric with the rim, and placed so as to make the inner and outer portions of the bucket hold equal quantities of water. When these buckets are filled $\frac{1}{3}$d, they retain the whole water at 18° from the bottom of the arch, and they retain $\frac{1}{2}$ of the water at 11°. Another great advantage of this construction is, that when there is little water to drive the wheel, it may be directed by a slight adjustment of the spout, into the outer bucket, so as to make up, by the additional length of lever, for the small quantity of water which is in use. These advantages, however, are found in practice to be counterbalanced by disadvantages which cannot be got the better of. The water is found never to fill the inner buckets, and on this account we believe Mr Burns did not put the construction in practice.

It has in general been assumed by writers on water wheels, that the diameter of overshot wheels should always be less than the height of the fall of water by which it is to be put in motion, and various ratios have been assigned between the height of the fall and the diameter of the wheel. The Chevalier de Borda has shewn, that overshot wheels will produce a maximum effect when their diameter is equal to the greatest height of the fall, but that a slight diminution of the wheel's diameter produces only a very small diminution of the maximum effect. If the height of the fall, for example, is 12 feet, and if the diameter of the wheel is made only 11 feet, the effect is diminished only $\frac{1}{12}$. This theoretical result has been confirmed by the admirable experiments of Mr Smeaton, who found, "*that the higher the wheel is in proportion to the whole descent, the greater will be the effect;*" because, as he remarks, "it depends less upon the impulse of the head, and more upon the gravity of the water in the buckets; and if we consider how obliquely the water issuing from the head must strike the buckets, we shall not be at a loss to account for the little advantage that arises from the impulse thereof, and shall immediately see of how little consequence this impulse is to the effect of an overshot wheel."

If the diameter of the wheel were equal to the whole height of the fall, the water would be laid in the buckets without having acquired any velocity; so that a portion of the power of the wheel would be spent in dragging this inert mass into motion, and also by the impulse of the buckets against the water, which will dash a part of it over the wheel. Hence it is necessary that the difference between the head of water and the diameter of the wheel should be such, that the water may acquire in its descent through that space a velocity a little greater than that of the circumference of the wheel. In this view of the subject, the water should fall through a height of $2\frac{1}{2}$ or 3 inches per second, in order to acquire the velocity of the wheel; and therefore the diameter of the wheel should be only 3 inches less than the height of the fall.

The determination of the diameter of an overshot wheel, as given by Borda, Smeaton, Robison, and other authors, is founded upon the assumption, that it never should exceed the height of the fall. Let us suppose that we have a fall of 12 feet, and that the wheel should have a diameter of 11 feet according to Borda, then it appears to us, that a great advantage will be derived from making the wheel 15 feet. Now it is obvious, that the advantage of using the 15 feet wheel is, that we apply the water where it will act most perpendicularly to the line OD, Fig. 15. or the radius of the wheel, whereas the disadvantage of such a wheel is, that it begins to lose its water much sooner than the small one. We differ in opinion from Robison when he says, that the loss of power in the latter case exceeds what is gained in the former case; but we shall admit that it is so, and still maintain the superiority of the 15 feet wheel. When the wheel has a diameter less than the height of the fall, any augmentation of the quantity of water discharged by the mill course is of no use in increasing the effect of the wheel. The issuing water indeed acquires a velocity greater than it usually has, but this additional velocity is injurious to the motion of the wheel instead of being of any advantage. In the case of a 15 feet fall, however, when the water rises 1 or 2 feet above its usual level, we have it in our power, by a particular form of the delivering sluice, which will afterwards be described, (see p. 555,) to introduce this water upon the wheel 1 or 2 feet higher up the wheel, so that we are actually enabled to increase the height of the fall by this quantity.

From a series of experiments on overshot wheels, by M. Deparcieux, and published in 1754, he has concluded, that most work is performed by an overshot wheel when it moves slowly, and that the more we retard its motion by increasing the work to be performed, the greater will be the performance of the wheel. These experiments were made with a wheel 20 inches in diameter, and having 48 buckets. Cylinders of different diameters were placed upon the axle, and the effect of the wheel under different velocities was measured by the height to which it raised a weight suspended to a rope, which was wound round the different cylinders; and the general result was, that the slower the wheel turns, the greater is the effect, or the height to which the weight is raised.

In opposition to these results, the Chevalier D'Arcy maintained that there is a certain velocity when the effect is a maximum; and he has shewn, from a comparison of Deparcieux's experiments with his own formulæ, that the wheel never moved with such a small velocity as would have given the maximum effect, and that if he had increased the diameter of his cylinders, he would have found that there was a velocity when the maximum effect began to diminish.

The experiments of Smeaton afford an excellent confirmation of the preceding reasoning. The wheel which he used was 25 inches in diameter. The depth of the buckets or of the shrouding, was 2 inches, and the number of buckets 36. When it made about 20 turns in a minute, the effect was nearly the greatest. When the number of turns was 30, the effect was diminished $\frac{1}{20}$th part. When the number was 40, the diminution was $\frac{1}{4}$th; when the number was less than $18\frac{1}{4}$, its motion was irregular; and when it was loaded so as not to be able to make 18 turns, the wheel was overpowered by its load.

"It is an advantage in practice," says Mr Smeaton, "that the velocity of the wheel should not be diminished farther than what will procure some solid advantage in point of power; because, *cæteris paribus*, as the motion is slower the buckets must be made larger; and the wheel being more loaded with water, the stress upon every part of the work will be increased in proportion. The best velocity for practice, therefore, will be such, as when the wheel here used made about 30 turns in a minute; that is, when the velocity of the circumference is a little more than three feet in a second.

"Experience confirms, that this velocity of three feet in a second is applicable to the highest overshot wheels as well as the lowest; and all other parts of the work being properly adapted thereto will produce very nearly the greatest effect possible; however, this also is certain from experience, that high wheels may deviate farther from this rule before they will lose their power by a given aliquot part of the whole, than low ones can be admitted to do; for a wheel of 24 feet high may move at the rate of six feet per second without losing any considerable part of its power; and, on the other hand, I have seen a wheel of 33 feet high, that has moved very steadily and well with a velocity but little exceeding two feet."

The experiments of the Abbé Bossut afford the same results. He used a wheel three feet in diameter. The height of the buckets was three inches, their width five inches, and their number 48; and the canal which conveyed the water furnished uniformly 1194 cubic inches in a minute. When the wheel was unloaded, it made $40\frac{1}{4}$ turns in a minute. The following Table, for which we have computed the fourth column, contains the results which he obtained.

| Number of pounds raised. | Number of seconds in which the load was raised. | Number of revolutions performed by the wheel. | Effect of the wheel, or the product of the number of turns multiplied by the load. |
|---|---|---|---|
| 11 | 60″ | $11\frac{46}{48}$ | $131\frac{32}{48}$ |
| 12 | 60 | $11\frac{11}{48}$ | $134\frac{36}{48}$ |
| 13 | 60 | $10\frac{25}{48}$ | $136\frac{37}{48}$ |
| 14 | 60 | $9\frac{40}{48}$ | $137\frac{32}{48}$ |
| 15 | 60 | $9\frac{10}{48}$ | $138\frac{6}{48}$ |
| 16 | 60 | $8\frac{31}{48}$ | $138\frac{16}{48}$ |
| 17 | 60 | $8\frac{9}{48}$ | $139\frac{9}{48}$ |
| 18 | 60 | $7\frac{32}{48}$ | 138 |
| 19 | The wheel turned very slowly. | | |
| 20 | The wheel stopped, though first put in motion by the hand to make it catch the water. | | |

From this Table it appears, that the effect is a maximum when the number of turns is $8\frac{9}{48}$, or when the velocity of the circumference is 1 foot 4 inches per second. The effect diminished by diminishing the velocity, and the wheel was at last overpowered by its load, as in Smeaton's experiments, which ought always to happen when the resistance or load is equal to the effect of all the buckets, when acting upon a semicircumference of the wheel with their respective quantities of water.

In comparing the relative effects of water wheels, the Chevalier de Borda maintains, that an overshot wheel will raise through the height of the fall a quantity of water equal to that by which it is driven; while Albert Euler affirms that the effect is greatly inferior to this. The experiments of Mr Smeaton shew, that when the heads and quantities of water are least, the ratio between the power and the effect at the maximum is nearly as 4 : 3 ; but when the heads and quantities of water were greater, it is as 4 : 2 ; and by a medium of the whole, it is as 3 : 2. When the powers of the water, computed for the height of the wheel only, are compared with the effects, they observe a more constant ratio, the variation being only between the ratio of 10 : 8.1 and 10 : 8.5. Hence the ratio of the power, computed upon the height of the wheel only, is to the effect, at a maximum, as 10 : 8, or as 5 : 4 nearly; and the effects, as well as the powers, are as the quantities of water and perpendicular heights multiplied together respectively.

The form of the delivering sluice, and the method of introducing the water into the buckets, will be best explained in the description of different overshot wheels.

*Smeaton's Overshot Wheel.*

The overshot wheel, as constructed by Mr Smeaton for the upper paper mill of Thornton, is shewn in Plate CCCXX. Fig. 1, where the diameter of the wheel is as nearly as possible equal to the height of the fall; and another wheel, which he considered as of an improved form, is represented in Fig. 2. where the diameter of the wheel exceeds the height of the fall. In both these Figures AB is the wheel, and MN the extremity of the mill course, where the water is delivered into the buckets. A vertical lever *a b c* turning round *b* as a centre, gives motion to the horizontal arm *c d*, and causes one of the shuttles *e f* to advance or recede ; in consequence of which the aperture on the right hand of *f* may be either increased or diminished, for the purpose of regulating the supply of water which the wheel may require. The iron bolt *g* goes through the bottom of the trough between the two shuttles, and is intended to prevent the bottom from sinking by the weight of the water. From the form of the aperture at *f*, it will be seen that the water will glide easily into the buckets without any waste. In both these machines, the water is turned back on the near half of the wheel ; the consequence of which is, that the resistance of the lower water is removed, as it runs off in the same direction with the motion of the wheel. The wheel in Fig. 1. is made to fit its sweep and the sides of the conduit as if it were a breast wheel, so that the water does not get out of the buckets till it reaches the lowest point.

*Improved Overshot Wheel.*

An excellent overshot wheel, which we understand is used in Yorkshire, is represented in Fig. 3. It differs from the wheel in Fig. 2. in the construction of the extremity of the mill course, and in the mode of delivering the water upon the wheel. A pinion *d*, turned with a handle, works in the teeth of a rack *c a*, having a roller *a*, whose breadth is equal to that of the mill course, fixed at its extremity. Upon this roller is fixed a large piece of leather, which, after wrapping round part of the cylindrical circumference, extends downwards to *b*, where it is fixed, as seen in the Figure, between two plates of iron or wood held together by screws. This leather forms the shuttle in the following manner. When the water stands so low in the mill course MN, that none of it runs over the roller so as to fall into the buckets, the pinion *d* is made to move from right to left, so as to cause the rack *c a* and roller *a* to descend. The leather shuttle is thus wound up upon the roller, and the water is allowed to pass over the surface *a*, and to fall into the buckets through the apertures made of iron bars, as shewn in the Figure. When the water, on the contrary, rises in the mill course, so that too much of it flows over the roller, the rack is made to move in the opposite direction, so as to diminish the supply. In this construction of the regulator, we see at once the advantages of having the diameter of the wheel AB greater than the height of the fall ; for we are at liberty to take advantage of the additional head which is gained by any increase in the quantity of water which is conveyed to the wheel.

*Description of Mr Burns' Overshot Wheel without a Shaft.*

This very ingenious machine was invented and erected by the late Mr Burns, whose mechanical ingenuity we have already had occasion to admire. It is represented in two different sections, in Figs. 4 and 5, and forms a large hollow cylinder by its buckets and sole, without having any shaft or axle tree.

This wheel is 12½ feet diameter, and 7 feet broad over all, and has 28 buckets. The gudgeon is 6 inches diameter, by 9 inches long. The flaunch is 1¼ inch thick at the extreme points. The arms are of redwood fir, 6 inches square ; one piece making two arms in length, where they cross one another at the wheel's centre, 1¼ inch of the wood remaining in each, connecting the two opposite arms as one piece. The wheel was made, by first fitting the gudgeon into a large piece of hard wood, with the flaunch parallel to the horizon, and in that position the arms and rings were trained and bound fast to it. All the grooves for starts or raisers, and buckets, were cut out before it was removed; first one piece was bolted to the flaunch at *a a*, and so of the others, leaving the distant openings for the cross bars that reach between each arm and its opposite arm. These bars, or pieces, were only 4 inches square, and were of good beech wood, turned round in the body. They were 10 inches square at each end, in which was fitted a strong nut for a bolt, 1¼ inch thick, to go through *b*, and connect the two sides together.

After the arms were trained and fixed right upon the gudgeons, the innermost ring was completed ; the tenons were trained on the arms first, and the rings, 4½ inches thick and 8 inches deep, put on by keys driven into the mortice. The remaining tenons were then reduced from 1½ to 1 inch thick, and the outermost ring, only 3 inches thick by 6 inches deep, was firmly wedged thereon, and bound fast at the other ends by three strong wooden pins, as at O C ; to the lower ring, the outside of the uppermost and undermost rings are flush, all the additional thickness of the lower ring projecting inside the buckets.

Some difficulty was found in laying the water properly into the buckets of this wheel, owing to the narrowness of the mouths of the buckets, by the high start or raiser, which was remedied by adopting the following plan.

The openings in the bottom of the troughing should be of iron, and so distant from each other that the water from them is thrown into two separate buckets. The iron curved parts should also be moveable, to adjust the openings to the quantity of water necessary for the wheel. Unless the head of water is 12 or 14 inches above these openings, it will be difficult to give it the proper direction into the buckets, especially if the openings are pretty wide for them ;

for then it deviates the more down from the line of direction, and tends to retard the wheel, by striking on the outside of the bucket.

The openings from which the buckets are filled, ought to be 10 inches less in length than the buckets, *i. e.* 5 inches at each side, otherwise the water is apt to jerk over on each side of the wheel, as the edge of the bucket passes by.

The mode of making and finishing the wheel at Cartside requires very little workmanship, compared to the usual method; and any good joiner will do it as well as a millwright. The joiner finished Cartside wheel in six or seven weeks. The construction will be better understood from the following reference to the figures.

Fig. 4. Represents three distinct transverse views. The part marked A, supposes a part of the shrouding in section shewing the pins; the part marked B, is a section of the wheel through any part of the buckets, and shewing three of the ties, 1, 2, 3, in section. Part C shews the manner in which the exterior ends of the wheel are finished, also the gudgeons, flaunch, &c.

Fig. 5. Is a longitudinal section of the wheel through one of the arms, shewing the projection of the shrouding—the manner in which the arms of the wheel are connected together—and likewise the manner in which the ties are connected to the gudgeon.

*Description of a Double Overshot Wheel with a Chain of Buckets.*

When there is a very small supply of water falling from a very great head, the overshot wheel which it is necessary to employ is so large and expensive, and so apt to be injured from its unwieldy size, that few persons would be disposed to erect one. We have seen at Coalbrook Dale a very excellent overshot wheel, of about fifty feet in diameter, which went remarkably well; and we understand that there are in Wales some wheels of nearly double this diameter. In circumstances like this, the double overshot wheel, with a chain of buckets, is a most invaluable machine, not merely from the small price at which it can be erected, but from the great power which it possesses. A machine of this kind seems to have been first erected by M. Francini in 1668, in the garden of the king of France's old library. This machine of Francini's was driven by waste water, and raised water from a natural spring, by means of another chain of buckets fixed upon the same wheel.

M. Costar substituted a similar machine in place of the overshot wheel; and more recently Mr Gladstanes, an ingenious millwright at Castle Douglas, without knowing that he had been anticipated in the invention, erected several in Galloway for the purpose of giving motion to threshing mills.

The double overshot wheel is represented in Plate CCCXX. Fig. 6, where A and B are two rag wheels, as they are called, and CDEF a series of buckets fixed to an endless chain, whose links fall into notches in the circumference of the rag wheels. The water issuing from the mill course at MN is introduced into the buckets on the side C. The descent of the loaded buckets on the side C puts the wheels A and B in motion, and the power is conveyed from the shaft of the wheel A to turn any kind of machinery. When the buckets reach F, they allow the water to escape, and ascending empty on the side E, they again return to the spout MN, to be filled as before. In this machine, the buckets have in every part of their path the same mechanical effect to turn the wheels, and they will not allow the water to escape till they have reached almost the lowest part of the fall.

This species of wheel possesses another advantage, which can be obtained from no other, namely, that by raising the wheel B, and taking out two or three of the buckets, it may be made to work when there is such a quantity of backwater as would otherwise prevent it from moving.

Dr Robison, in his Dissertation on Water Works, published in the second volume of his *System of Mechanical Philosophy*, has described a machine of this kind, in which plugs, or horizontal floatboards, are fixed to a chain. On the side C these plugs pass through a tube, a little greater in diameter than that of the floats, and the water acting by its pressure upon these floats, as it does in the case of a breast wheel, gives motion to the wheels A and B.

The double overshot wheel is the best and the most economical which can be adopted for a small supply of water falling from a great height; but it is liable to get out of order, unless the chain which carries the bucket is made with great care and nicety.

## Sect. II. *On Undershot Water Wheels.*

An undershot water wheel is a wheel with a number of floatboards, or plane surfaces arranged round its circumference for the purpose of receiving the impulse of the water, which is conveyed to the under part of the wheel from an inclined canal. A wheel of this kind of the ordinary construction, is shewn in Plate CCCXX. Fig. 7. where AB is the wheel with 24 floatboards, *c d* a floatboard receiving the impulse of the water, which moves with great velocity in consequence of having fallen from a considerable height down the inclined mill course MN. The principal points to be attended to in the construction of undershot wheels are, the construction of the mill course, the number, form, and position of the floatboards, and the velocity of the wheel in relation to that of the water when the effect is a maximum. The following rules for the construction of mill courses are given in the Appendix to Ferguson's *Lectures*, vol. ii.

"As it is of the highest importance to have the height of the fall as great as possible, the bottom of the canal, or dam, which conducts the water from the river, should have a very small declivity; for the height of the water-fall will diminish in proportion as the declivity of the canal is increased. On this account, it will be sufficient to make AB slope about one inch in 200 yards, taking care to make the declivity about half an inch for the first 48 yards, in order that the water may have a velocity sufficient to prevent it from flowing back into the river. The inclination of the fall, represented by the angle GCR, should be 25° 50′; or CR, the radius, should be to GR, the tangent of this angle, as 100 to 48, or as 25 to 12; and since the surface of the water S *b* is bent from *a b* into *a c*, before it is precipitated down the fall, it will be necessary to incurvate the upper part BCD of the course into BD, that the water at the bottom may move parallel to the water at the top of the stream. For this purpose, take the points B, D, about 12 inches distant from C, and raise the perpendiculars BE, DE: the point of intersection E will be the centre from which the arch BD is to be described; the radius being about $10\frac{1}{6}$ inches. Now, in order that the water may act more advantageously upon the floatboards of the wheel WW, it must assume a horizontal direction HK, with the same velocity which it would have acquired when it came to the point G: But, in falling from C to G, the water will dash upon the horizontal part HG, and thus lose a great part of its velocity; it will be proper, therefore, to make it move along FH an arch of a circle, to which DF and KH are tangents in the points F and H. For this purpose make GF and GH each equal to three feet, and raise the perpendiculars HI, FI, which will intersect one another in the point I distant about 4 feet 9 inches and $\frac{4}{10}$ths from the points F, and H, and the centre of the arch FH will be determined. The distance HK, through which the water runs before it acts upon the wheel, should not be less than two or three feet, in order that the different portions of the fluid may have obtained a horizontal direction: and if HK be much larger, the velocity of the stream would be diminished by its friction on the bottom of the course. That no water may escape between the bottom of the course KH and the extremities of the floatboards, KL should be about three inches, and the extremity *o* of the floatboard *n o* should be beneath the line HKX, sufficient room being left between *o* and M for the play of the wheel, or KLM may be formed into the arch of a circle KM concentric with the wheel. The line LMV, called by M. Fabre, the course of impulsion (*le coursier d'impulsion*) should be prolonged, so as to support the water as long as it can act upon the floatboards, and should be about 9 inches distant from OP, a horizontal line passing through O, the lowest point of the fall; for if OL were much less than 9 inches, the water having spent the greater part of its force in impelling the floatboards, would accumulate below the wheel and retard its motion. For the same reason, another course, which is called by M. Fabre, the course of discharge (*le coursier de decharge*) should be connected with LMV by the curve VN, to preserve the remaining velocity of the water, which would otherwise be destroyed by falling perpendicularly from V to N. The course of discharge is represented by VZ, sloping from the point O. It should be about 16 yards long, having an inch of declivity in every two yards. The canal which reconducts the water from the course of discharge to the river, should slope about 4 inches in the first 200 yards, 3 inches in the second 200 yards, decreasing gradually till it terminates in the river. But if the river to which the water is conveyed, should, when swollen by the rains, force the water back upon the wheel, the canal must have a greater declivity, in order to prevent this from taking place. Hence it will be evident, that very accurate levelling is necessary for the proper formation of the mill course."

The general ideas contained in the preceding constructions appear to have been first suggested by Du Buat, and afterwards fully explained by M. Fabre in his *Traité sur les Machines Hydrauliques*.

The diameters of undershot wheels must in general be accommodated to the nature of the machinery which they are to put in motion. If a great velocity is necessary, the wheel should for this purpose be made of a less diameter than would otherwise be advisable; but if a great velocity is not required, the diameter of the wheel ought to be considerable.

M. Pitot, one of the earliest writers who attended to this subject, recommended that the number of floatboards should be equal to 360° divided by the arch of the circle plunged in the canal, and that their depth should be equal to the versed sine of that arch. The slightest consideration, however, is sufficient to convince us that the number of floatboards obtained by this rule is greatly too small. M. Du Petit Vandin, and afterwards M. Fabre, have, on the other hand, maintained, that the greatest possible number of floatboards should be used, provided the wheel is not too much loaded by them.

In Mr Smeaton's model, by which his experiments were performed, the diameter of the wheel was 24 inches, and the number of floatboards 24. When the number was reduced to 12, a diminution in the effect was produced on account of a greater quantity of water escaping between the floats and the floor; "but a circular sweep being adapted thereto of such a length that one float entered the curve before the preceding one quitted it, the effect came so near to the former, as not to give hopes of advancing it, by increasing the number of floats beyond 24 in this particular wheel."

The experiments of Bossut were made with a wheel, whose exterior diameter was 3 feet 1 inch 10 lines. It was used successively with 48, 24, and 12 floatboards directed to the centre. They were exactly five inches wide, and from four to five inches high. The edges and the extremities of the floatboards were distant about half a line from the bottom and sides of the inclined canal in which the wheel was placed, and the arch plunged in the water was 24° 54′. When this wheel was tried, it made $33\frac{1}{2}$ turns in a minute, when it had 48 floatboards, and when the weight raised was 12 pounds. When 24 floatboards were put on, it made only 29 turns in a minute, the weight raised being the same; and when 12 floatboards were used, it made no more than $25\frac{1}{4}$ turns in a minute. The velocity of the water in the canal, which had a declivity of $10\frac{1}{2}$ feet in 50, was 300 feet in 33 seconds. Hence Bossut concludes, that the wheel ought to have at least 48 floatboards, whereas wheels 20 feet in diameter, and with only 25° or 30° of the circumference immersed, have generally only 40.

When wheels are moved by a river, they ought to have a different number of floatboards. In order to find the number, M. Bossut used a different wheel, in which the floatboards were so placed that he could set them at any inclination to the radius, and employ any number of them at pleasure. The exterior diameter was 3 feet, the width of the floatboards 5 inches, and their height 6 inches. This wheel was made to move in a current from 12 to 13 feet wide, and in a depth of water of from 7 to 8 inches. The floatboards were plunged 4 inches in the water, so that the circumstances were the same as in an open river. When 24 floatboards were used, a load of forty pounds was raised with a velocity of $15\frac{28}{48}$ turns in 40 seconds; whereas when 12 floatboards were used, the velocity with which the same load was raised was only $13\frac{15}{48}$ turns in the same time. When 48 floatboards were put on, 24 pounds were raised, with a velocity of $27\frac{19}{48}$ turns in a minute; and 24 floatboards raised the weight with a velocity of $\frac{27}{48}$, the difference being perfectly trifling. Hence 24 floatboards at least should be used in cases of this kind. A smaller number would be sufficient, if a greater arch of the wheel were plunged in the stream. In practice, it was the general custom to use only 8 or 10 floatboards, and sometimes fewer, on wheels placed in rivers; but the number ought to have been from 12 to 18.

From theoretical considerations, M. Pitot has shewn, that floatboards should always be a continuation of the radius; but this rule is found to be quite incorrect in practice. The advantages arising from inclining the floatboards were first pointed out in 1753 by Deparcieux, who shews, that the water will thus heap up upon them, and act by its weight as well as by its impulse. This opinion has been amply confirmed by the experiments of Bossut with the wheel already mentioned, moving in a canal where the velocity of the water was 300 feet in 27 seconds. When the floatboards were a continuation of the radius, a weight of 34 pounds was raised with a velocity of $\frac{26}{48}$ turns in forty seconds. When their inclination was 8°, the same load was raised with a velocity of $19\frac{20}{48}$ in forty seconds. When the inclination was 12°, the velocity was $19\frac{40}{48}$ in 40″; and when the inclination was 16°, the velocity was $20\frac{24}{48}$ turns in 40 seconds, nearly the same, but still a little less than when the floatboards were a continuation of the radius. Hence it follows, that a wheel placed upon canals which have little declivity, and in which the water is at liberty to escape easily after the impulse, the floatboards ought to be a continuation of the radius.

The same wheel being placed in the current already mentioned, viz. from 12 to 13 feet wide, and from 7 to 8 inches deep, floatboards which were a continuation of the radius raised 40 pounds with a velocity of $13\frac{17}{48}$ turns in 40 seconds. With those inclined 15°, the number of turns in the same time was $14\frac{21}{48}$; with those inclined 30°, the number was $14\frac{22}{48}$; and with those inclined 37°, the number was $14\frac{15}{48}$. Hence it follows, that the most advantageous obliquity is, in this case, about 15 or 30 degrees. The difference of effect, however, appears to be very trifling, particularly beyond 15°. M. Fabre is of opinion, that when the velocity of the stream is 11 feet per second or greater, the inclination should never be less than 30°; that, as the velocity diminishes, the number of floatboards should diminish in proportion; and that when the velocity is four feet or under, the floatboards should be a continuation of the radius. The experiment of inclining the floatboards a little in the opposite direction, has not been tried by any of the authors whom we have quoted, but we think it worth trying, as it might increase the effect, by allowing the water to escape more readily from below the floatboards.

In order to determine the ratio between the velocity of the wheel and that of the water which drives it, Parent and Pitot considered only the action of the fluid upon one floatboard, and consequently they made the force of impulsion proportional to the square of the relative velocity, or to the square of the difference between the velocity of the stream and that of the floatboard. Desaguliers, Maclaurin, Lambert, Atwood, Du Buat, and Dr Robison, have gone upon the same principle, and have therefore fallen into the same error, of making the velocity of the wheel $\frac{1}{3}$ of the velocity of the current when the effect is a maximum. The Chevalier de Borda, whose valuable Memoirs have been too much overlooked by later writers, has, however, corrected this error. He has shewn, that the supposition is perfectly correct when the water impels a single floatboard; for as the number of particles which strike the floatboard in a given time, and also the momentum of these, are each as the relative velocity of the floatboards, the momentum must be as the square of the relative velocity, that is, $M \div R^2$, M being the momentum, and R the relative velocity. But as the water acts on more than one floatboard at once, the number acted upon in a given time will be as the velocity of the wheel, or inversely as the relative velocity; for if we increase the relative velocity, the velocity of the water remaining the same, we must diminish the velocity of the wheel. Consequently, we shall have $M \div \frac{R^2}{R}$ or $M \div R$; that is, the momentum of the water acting upon the wheel varies as the relative velocity.

Now, let V be the velocity of the stream, F the force with which it would strike the floatboard at rest, and $v$ the velocity of the wheel. Then the relative velocity will be $V-v$; and since the velocity of the water will be to its momentum, or the force with which it would strike the floatboard at rest, as the relative velocity is to the real force which the water exerts against the moving floatboards, we shall have $V : V-v = F : F\times\frac{\overline{V-v}}{V} = \frac{F}{V}\times V-v$. But the effect of the wheel is measured by the product of the momentum of the water and the velocity of the wheel, consequently the effect of the undershot wheel will be

$$v\times\frac{F}{V}\times\overline{V-v} = \frac{F}{V}\times\overline{V-v^2}.$$

Now this effect is to be a maximum, and therefore its differential must be equal to 0, that is, $v$ being the variable quantity, $V\,dv - 2\,v\,dv = 0$, or $2\,v\,dv = V\,dv$. Dividing by $dv$, we have $2v = V$, and $v = \frac{V}{2}$, that is, the velocity of the wheel will be *one-half* the velocity of the fluid when the effect is a maximum.

This has been amply confirmed by the experiments of Mr Smeaton. "The velocity of the stream (says he, p.77,) varies at the maximum between one-third and one-half that of the water; but in all the cases in which most work is performed in proportion to the water expended, and which approach the nearest to the circumstances of great works, when properly executed, the maximum lies much nearer to *one-half* than *one-third*, one-half seeming to be the true maximum, if nothing were lost by the resistance of the air, the scattering of the water carried up by the wheel, &c. all which tend to diminish the effect more at what would be the maximum if these did not take place than they do when the motion is a little slower." Smeaton considers 5 to 2 as the best general proportion.

A result, nearly similar to this, was deduced from the experiments of Bossut. He employed a wheel whose diameter was three feet. The number of floatboards was at one time 48, and at another 24, their width being 5 inches, and their depth six. The experiments with the wheel, when it had 48 floatboards, were made in the inclined canal, in which the velocity was 300 feet in 27 seconds. The experiments with the wheel, when it had 24 floatboards, were made in a canal, contained between two vertical walls, 12 or 13 feet distant. The depth of the water was about 7 or 8 inches, and its mean velocity about 2740 inches in 40 seconds. The floatboards of the wheel were immersed about four inches in the stream.

| Time in which the weight is raised. | Weight raised. | Number of turns made by the wheel. | Weight raised. | Number of turns made by the wheel. |
|---|---|---|---|---|
| Seconds. | 48 Floatboards. | | 24 Floatboards. | |
| | Pounds. | Pounds. | Pounds. | Pounds. |
| 40 | $30\frac{1}{2}$ | $22\frac{12}{48}$ | 30 | $17\frac{22}{48}$ |
| 40 | 31 | $22\frac{4}{48}$ | 35 | $16\frac{26}{48}$ |
| 40 | $31\frac{1}{2}$ | $21\frac{42}{48}$ | 40 | $15\frac{28}{48}$ |
| 40 | 32 | $21\frac{32}{48}$ | 45 | $14\frac{31}{48}$ |
| 40 | $32\frac{1}{2}$ | $21\frac{20}{48}$ | 50 | $13\frac{34}{48}$ |
| 40 | 33 | $21\frac{8}{48}$ | 55 | $12\frac{37}{48}$ |
| 40 | $33\frac{1}{2}$ | $20\frac{44}{48}$ | 56 | $12\frac{28}{48}$ |
| 40 | 34 | $20\frac{32}{48}$ | 57 | $12\frac{19}{48}$ |
| 40 | $34\frac{1}{2}$ | $20\frac{21}{48}$ | 58 | $12\frac{10}{48}$ |
| 40 | 35 | $19\frac{44}{48}$ | 59 | $12\frac{1}{48}$ |
| 40 | $35\frac{1}{2}$ | $19\frac{15}{48}$ | 60 | $11\frac{40}{48}$ |
| 40 | 36 | $18\frac{28}{48}$ | 61 | $11\frac{30}{48}$ |
| 40 | | | 62 | $11\frac{19}{48}$ |
| | | | 63 | $11\frac{7}{48}$ |
| | | | 64 | $10\frac{41}{48}$ |
| | | | 65 | $10\frac{25}{48}$ |
| | | | 66 | $10\frac{5}{48}$ |

As the effect of the machine is measured by the product of the load raised, and the time employed, it will appear, by multiplying the second and third columns, that the effect was a maximum when the load was $34\frac{1}{2}$ pounds, the wheel performing $20\frac{21}{48}$ revolutions in 40 seconds. By comparing the velocity of the centre of impression computed from the diameter of the wheel, and the number of turns which it makes in 40 seconds, with the velocity of the current, it will be found that the velocity of the wheel, when its effect is the greatest possible, is nearly two-fifths that of the stream; the very same ratio which Smeaton has given. From the two last columns of the Table, where the effect is a maximum when the load is 60 pounds, the same conclusion may be deduced.

The following are the other results which Mr Smeaton deduced from his experiments. He found, that in undershot wheels, the power employed to turn the wheel is to the effect produced as 3 to 1; and that the load which the wheel will carry at its maximum, is to the load which will totally stop it as three to four. The same experiments inform us, that the impulse of the water on the wheel, in the case of a maximum, is more than double of what is assigned by theory, that is, instead of four-sevenths of the column, it is nearly equal to the whole column. In order to account for this, Mr Smeaton observes, that the wheel was not, in this case, placed in an open river, where the natural current, after it had communicated its impulse to the float, has room on all sides to escape, as the theory supposes; but in a conduit or race, to which the float being adapted, the water could not otherwise escape than by moving along with the wheel. He likewise remarks, that when a wheel works in this manner, the water as soon as it meets the float, receives a sudden check, and rises up against it like a wave against a fixed object; insomuch, that when the sheet of water is not a quarter of an inch thick before it meets the float, yet this sheet will act upon the whole surface of a float, whose height is three inches. Were the float, therefore, no higher than the thickness of the sheet of water, as the theory supposes, a great part of the force would be lost by the water dashing over it. Mr Smeaton likewise deduced, from his experiments, the following maxims.

1. That the virtual or effective head being the same, the effect will be nearly as the quantity of water expended.

2. That the expense of water being the same, the effect will be nearly as the height of the virtual or effective head.

3. That the quantity of water expended being the same, the effect is nearly as the square of the velocity.

4. That the aperture being the same, the effect will be nearly as the cube of the velocity of the water.

*Undershot Wheel moving at Right Angles to the Stream.*

Undershot wheels have sometimes been constructed like windmills, having large inclined floatboards, and being driven in a plane perpendicular to the direction of the current. Albert Euler, who has examined theoretically this species of water wheel, concludes that the effect will be twice as great as in common undershot wheels, and that in order to produce this effect, the velocity of the wheel, computed from the centre of impression, should be to the velocity of the water as radius is to thrice the sine of the inclination of the floatboards to the plane of the wheel. When the inclination is 60°, the ratio will be as 5 to 13 nearly, and when it is 30°, it will be nearly as 2 to 3. In this kind of wheel, a considerable advantage may also be gained by inclining the floatboards to the radius. In this case, the area of the floatboards ought to be much greater than the section of the current, and before one floatboard leaves the current, the other ought to have fairly entered it. This construction may be employed with advantage in deep rivers that have but a small velocity.

*Besant's Undershot Wheel.*

This wheel, invented by Mr Besant of Brompton, is constructed in the form of a hollow drum, to resist the admission of water; but its principal peculiarity consists in the arrangement of the floatboards in pairs on the periphery of the wheel. Each floatboard is set obliquely to the plane of the wheel's motion, and the corresponding floatboard is inclined at the same angle, but in an opposite direction, the plane of the wheel bisecting the angle formed by the two floatboards. The acute angle which the one floatboard forms with its corresponding one is open at the vertex; but one of the floatboards extends beyond the other. By this construction, the resistance from the tail water is diminished; but so far as we know, the machine has never come into use. See Ferguson's *Lectures*, vol. ii.

*Horizontal Water Wheels.*

Horizontal water wheels differ in no respect from common undershot wheels except in the circumstance of their extremities being placed vertically. The mill course is constructed nearly in the same manner for both. The principal object of this form of the water wheel is to save machinery, by placing the mill-stone directly on the vertical shaft of the wheel. The water wheel must therefore move with a very great velocity, so as to enable the mill-stones to perform their work. The water is turned into a horizontal direction before it strikes the floatboards, which may be either vertical or inclined to the radius, as in undershot wheels.

Horizontal wheels are often constructed so that the floatboards have a very great inclination to the radius. In this case, the water is not turned into a horizontal direction, but is made to strike the floatboards perpendicularly, as in Fig. 9. where AB is the wheel, MN the mill-course discharging its contents perpendicularly upon the floatboard C, which ought to have a surface more than twice the area of the section of the stream. In this construction, the maximum effect will be produced when the velocity of the floatboards is not less than $\frac{5.67\sqrt{h}}{2\sin.a}$, where $h$ is tho height of the fall, and $a$ the angle which the direction of the fall makes with a vertical line. But since this quantity increases as the sine of $a$ decreases, we may diminish the angle $a$, and thus increase the velocity of the floatboards, to suit the nature of the work to be performed, without lessening the maximum effect, which cannot be done in vertical wheels where a determinate velocity is necessary to produce the greatest possible effect. See Ferguson's *Lectures*, vol. ii. Appendix.

In the southern departments of France, the floatboards are made of a curvilineal form, so as to present a concave surface to the stream. This construction is shewn in Figs. 10, 11, where AB is the wheel, CD the vertical shaft, and *m*, *n*, the concave floatboards. The Chevalier Borda remarks, that in theory a double effect is produced when the floatboards have this form; but that the advantage is not so great in practice, from the difficulty of making the fluid enter and leave the course in a proper manner. They appear, however, to be decidedly superior to those in which the floatboards are plane, as the water acts by its weight as well as by its impulsive force. The ratio of the effects in the two cases, with five or six feet of fall, is nearly as 3 to 2. An advantage may be gained by dividing the current, and throwing it in separate portions upon different floatboards. See Leopold's *Theatrum Mach. General.*

A different kind of horizontal wheel, invented by Mr Robert Leslie, which works by the tide upon the principle of a smoke jack, is shewn in Figs. 12, 13. This machine, which is shewn in a vertical section in Fig. 12, and in a horizontal section in Fig. 13, consists of a circular box or drum *op*, widened at top into another circular drum AB, two parts of which, GO and EF, are made to open and shut, as shewn by the dotted lines. When the tide moves in the direction OE, the part GO shuts into the position GH, and admits the water upon the wheel; but when the tide returns, GH assumes the position GO, and EF shuts into the dotted position E*f*, and admits the water to the wheel. The axis EF, Fig. 12, stands vertically, and has the vanes *m*, *n* fitted upon it like those of a smoke jack. The water enters at O, and at F*f* when the tide returns, descends in the direction of the arrows, acts by its impulse and its weight on the oblique vanes *m*, *n*, and after turning the wheel about its vertical axis EF, escapes at the aperture P, or P′ when the tide returns.

*Wheels with Spiral Floatboards.*

In some of the southern provinces of France a conical horizontal wheel with spiral floatboards is frequently used. It has the form of an inverted cone, with a number of spiral floatboards winding round its surface, so as to be nearer one another at the smaller or lower end of the cone, than at the larger or upper end. When the water has acted upon these floatboards by its impulse, it descends along the spirals, and continues to drive the machine by its weight. A drawing of this machine will be seen in Ferguson's *Lectures*, vol. ii. App.

Dr Robison describes another wheel with spiral floatboards, which was moved by a screw. "It was," he says, "a long cylindrical frame, having a plate standing out from it, about a foot broad, and surrounding it with a very oblique spiral like a cork screw. This was plunged about ⅘th of its diameter (which was about 12 feet,) having its axis in the direction of the stream. By the work which it was performing, it seemed more powerful than a common wheel, which occupied the same breadth of the river."

For farther information on the subject of undershot wheels, see Pitot, *Mem. Acad Par.* 1729, 8vo. p. 359; Desagulier's *Experimental Philosophy*, vol. ii. p. 424; Du Petit Vandin, *Mem. des Scavans Etrangers*, tom. i.; Deparcieux, *Mem. Acad.* 1754, p. 614; Fabre *Sur les Machines Hydraulique*, p. 55; Bossut's *Traite d'Hydrodynamique*, vol. i. chap. xiv. xv p. 482; vol. ii. chap. xviii. edit 1797; Maclaurin's *Fluxions*, § 907, p. 728; Lambert, *Nouv. Mem. de l'Acad. Berlin.* 1775, p. 63; Smeaton's *Experiments on Mills*; Borda, *Mem Acad. Par*; *Leopold's Theatrum Machin General.*; *Repertory of Arts*, vol. i. p. 385; Ferguson's *Lectures*, vol. ii. App.; and Dr Robison's *System of Mech. Philosophy*.

## Sect. III. *On Breast Wheels.*

A breast water wheel is a wheel in which the water is delivered at a point intermediate between the upper and under point of a wheel with floatboards. It is generally delivered at a point below the level of the axis, as in Fig. 1, but sometimes at a point higher than the level of the axis, as in Fig. 2. On breast wheels, buckets are never employed, but the floatboards are fitted accurately, with as little play as possible, to the mill course, so that the water, after acting upon the floatboards by its impulse, is retained between the floatboards and the mill-course, and acts by it weight till it reaches the lowest part of the wheel.

A breast wheel as constructed by Mr Smeaton, is represented in Fig. 1, where AB is a portion of the wheel, MN the canal which conveys the water to the wheel, MOP the curvilineal mill-course accurately fitted to the extremities of the floatboards, and *c d* the shuttle moved by a pinion *a*, for the purpose of regulating the admission of water upon the wheel.

An improved breast wheel is shewn in Fig. 2. The water is delivered on the wheel through an iron grating *a b*, and its admission is regulated by two shuttles *c d*, the lowermost of which, *d*, is adjusted till a sufficient quantity of water passes over it; while the other, *c*, which is generally moved by machinery, is made to descend upon *d*, so as to stop the wheel.

According to Mr Smeaton, "the effect of a breast wheel is to the effect of an undershot wheel, whose head of water is equal to the difference of level between the surface of water in the reservoir and the part where it strikes the wheel, added to that of an overshot whose height is equal to the difference of level between the part where it strikes the wheel and the level of the tail water.

M. Lambert observes, that when the fall of water is between 4 and 10 feet, a breast water wheel should be erected, provided there is enough of water; that an undershot wheel should be used when the fall is below 4 feet, and an overshot wheel when the fall exceeds 10 feet. He recommends also, that when the fall exceeds 10 feet, it should be divided into two, and two breast wheels erected upon it. These rules are not of great value. The other results of Lambert's investigation will be found either in his *Memoir*, or in Ferguson's *Lectures*, Appendix, vol. ii.

*Comparative effects of Water Wheels.*

M. Belidor very strangely maintained that overshot wheels were inferior to undershot ones. It appears, however, from Smeaton's experiments, that in overshot wheels the ratio of the power to the effect is nearly as 3 to 2, or as

5 to 4, whereas in undershot wheels the ratio is only as 3 to 1; from which it follows, that the effect of overshot wheels is nearly double of the effect of undershot wheels. The Chevalier de Borda has concluded that overshot wheels will raise through the height of the fall a quantity of water equal to that by which they are driven; that undershot wheels moving vertically will produce $\frac{3}{8}$ths of this effect; that horizontal wheels will produce a little less than $\frac{1}{2}$ of it when the floatboards are plain, and a little more than $\frac{1}{2}$ when they are curvilineal.

Sect. IV. *On Wheels Driven by the Reaction or Counterpressure of Water.*

The first mills which were driven by the reaction of water were called *Barker's* mill, and sometimes *Parent's* mill. We are not acquainted with the nature of M. Parent's claim to the invention; nor can we determine whether the priority is due to him or to Dr Barker. Dr Desaguliers, who seems to have been the first person who published an account of the machine, describes it as having been invented by Dr Barker. "Sir George Savile says, he had a mill in Lincolnshire to grind corn, which took up so much water to work it, that it sunk his ponds visibly, for which reason he could not have constant work; but now, by Dr Barker's improvement, the waste water only from Sir George's ponds keeps it constantly to work."

Dr Barker's mill is shewn in Fig. 3. where CD is a vertical axis, moving on a pivot at D, and carrying the upper millstone *m*, after passing through an opening in the fixed millstone C. Upon this axis is fixed a vertical tube TT communicating with a horizontal tube AB, at the extremities of which A, B are two apertures in opposite directions. When water from the mill-course MN is introduced into the tube TT, it flows out of the apertures A, B, and by the reaction or counterpressure of the issuing water the arm AB, and consequently the whole machine, is put in motion. The bridgetree *a b* is elevated or depressed by turning the nut *c* at the end of the lever *c b*. In order to under stand how this motion is produced, let us suppose both the apertures shut, and the tube TT filled with water up to T. The apertures A, B, which are shut up, will be pressed outwards by a force equal to the weight of a column of water whose height is TT, and whose area is the area of the apertures. Every part of the tube AB sustains a similar pressure; but as these pressures are balanced by equal and opposite pressures, the arm AB is at rest. By opening the aperture at A, however, the pressure at that place is removed, and consequently the arm is carried round by a pressure equal to that of a column TT, acting upon an area equal to that of the aperture A. The same thing happens on the arm TB; and these two pressures drive the arm AB round in the same direction. This machine may evidently be applied to drive any kind of machinery, by fixing a wheel upon the vertical axis CD.

In the preceding form of Barker's mill, the length of the axis CD must always exceed the height of the fall ND, and therefore, when the fall is very high, the difficulty of erecting such a machine would be great. In order to remove this difficulty, M. Mathon de la Cour proposed to introduce the water from the millcourse into the horizontal arms A, B, which are fixed to an upright spindle CT, but without any tube TT. The water will obviously issue from the apertures A, B, in the same manner as if it had been introduced at the top of a tube TT as high as the fall. Hence the spindle CD may be made as short as we please. The practical difficulty which attends this form of the machine is, to give the arms A, B a motion round the mouth of the feeding pipe, which enters the arm at D, without any great friction, or any considerable loss of water. This form of the mill is shewn in Plate CCCXXI. Fig. 4. where F is the reservoir, K the millstones, KD the vertical axis, FEC the feeding pipe, the mouth of which enters the horizontal arm at C. In a machine of this kind which M. Mathon de la Cour saw at Bourg Argental, AB was 92 inches, and its diameter three inches; the diameter of each orifice was $1\frac{1}{6}$ inch, FG was 21 feet; the internal diameter of D was two inches, and it was fitted into C by grinding. This machine made 115 turns in a minute when it was unloaded, and emitted water by one hole only. The machine, when empty, weighed 80 pounds, and it was half supported by the upward pressure of the water. This improvement, which was published in Rozier's *Journal de Physique* for January and August 1775, appeared about 20 years afterwards as a new invention of Mr Waring's, in the *Transactions of the American Philosophical Society of Philadelphia*, who was probably not aware of the labours of M. Mathon de la Cour.

In the year 1747, Professor Segner of Gottingen published, in his *Exercitationes Hydraulicæ*, an account of a machine which differs only in form from Dr Barker's mill. It consisted of a number of tubes arranged as it were in the circumference of a truncated cone; the water was introduced into the upper ends of these tubes, and flowing out at the lower ends, produced, in virtue of its reaction, a motion round the axis of the cone.

Another form of this machine has been suggested by Albert Euler. He proposes to introduce the water from the mill course into an annular cavity in a fixed vessel of the shape nearly of a cylinder. The bottom of this vessel has several inclined apertures, for the purpose of making the water flow out with a proper obliquity into the inferior and moveable vessel. This inferior vessel, which has the form of an inverted frustum of a cone, moves about an axis passing up through the centre of the fixed vessel, and has a variety of tubes arranged round its circumference. These tubes do not reach to the very top of the vessel, and are bent into right angles at their lower ends. The water from the upper and fixed vessel being delivered into the tubes of the lower vessel, descends in the tubes, and issuing from theirs horizontal extremities gives motion to the conical drum by it reaction.

The excellence of this method of employing the reaction of water was first slightly pointed out by Dr Desaguliers, and no further notice seems to have been taken of the invention till the appearance of Segner's machine in 1747. The attention of Leonhard Euler, John Bernoulli, and Albert Euler, was then directed to the subject, and it would appear, from the results of their investigations, that this is the most powerful of all hydraulic machines, and is therefore the best mode of employing water as a moving power. Leonhard Euler published his theory of this machine in the *Memoirs of the Berlin Academy*, vol. vi. p. 311; and the application of the machine to all kinds of work was explained in a subsequent paper in the seventh volume of the same work, for 1752, p. 271. John Bernoulli's investigations will be found at the end of his *Hydraulics*.

Albert Euler concluded, that when the machine had the form given to it by Segner, the effect was equal to the power, and that the effect is a maximum when the velocity is infinite. Mr Waring, in the paper which we have already quoted, makes the effect of the machine equal only to that of a good undershot wheel driven with the same quantity of water falling through the same height. The Abbé Bossut has likewise investigated the theory of this machine, and has found that an overshot wheel, and a wheel of the form given to it by Albert Euler, will produce equal effects with the same quantity of water, if the depth of the orifice below the mill-course in the latter machine is equal to the vertical height of the loaded arch in the overshot wheel; and he, upon the whole, recommends the overshot wheel as preferable in practice. The preceding result, however, proves the inferiority of the overshot wheel, as the height of the loaded arch must be always much less than that of the fall. A new and ingenious theory of this machine has lately been given by Mr Ewart in the *Manchester Memoirs*.

For farther information on this subject, see Desagulier's *Experimental Philosophy*, vol. ii. p. 453; Segner's *Exercitationes Hydraulicæ*, Gotting. 1747; L. Euler, *Mem. Acad. Berl.* 1751, vol. vi. p. 311; *Id.* 1752, vol. vii. p. 271; Waring, *American Transactions*, vol. iii. p. 185; M. Mathon de la Cour in Rozier's *Journal*, Jan. and Aug. 1775; Krafft, *Nov. Comment. ### Sect. V. *On Machines for Raising Water, and various Hydraulic purposes.*

#### 1. *Description of a Sluice Governor for regulating the Introduction of Water upon Water Wheels of all kinds.*

As there is a particular velocity at which water wheels produce a maximum effect, and as the work to be performed is often injured by an irregularity in the velocity of the machinery, it is of great importance to regulate the admission of the water so as to prevent any increase of velocity when there is too much water in the mill-course. In corn mills, the meal becomes heated and injured by too great a velocity, and in cotton mills, the threads are broken from the same cause.

The machine for this purpose, which is minutely represented in Plate CCCXXI. Figures, 5, 6, 7, and 8, was actually constructed by the late Mr Burns for Cartside cotton mill, who considered it of such advantage as to produce a saving of more than 100*l*. per annum. The motion of the water wheel is communicated by a belt or rope going round the pulley I to the axis EF, which carries the balls G, H, Fig. 5. This motion is conveyed to the upright shaft T by the wheels and pinions Q, R, S, T, and the wheel N at the bottom of the shaft drives the wheels O, P, Fig. 6 and 7, in opposite directions. When the velocity of the wheel is such as is required, the wheels O, P move loosely about the axis, and carry the motion no farther. But when the velocity of the wheel is too great, the balls G, H, separated by the increase of centrifugal force, raise the box *a* upon the shaft EF. An iron cross *b c*, see Fig. 8, is fitted into the box *a*. This cross works in the four prongs of the fork *e b c*, Fig. 6, at the end of the lever *d q f e*, which moves horizontally round *f* as its centre of motion. When the box *a* is stationary, which is when the wheel has its proper velocity, the iron cross works within two of the prongs so as not to affect the lever *d f c*, but to allow the clutch *q q*, fixed at the end of the lever, to be disengaged from the wheels. When the cross *b c* rises, it strikes in turning round the prong 3, see Fig. 8. which drives aside the lever *e f d*, and throws the clutch *q* into the arms of the wheel P, Figs. 6, 7. This causes it to drive round the shaft DC in one direction. When the iron cross *b c*, on the contrary, is depressed by any diminution in the velocity of the wheel, it strikes, in turning round, the prong 4, which pushes aside the lever *e f d*, and throws the clutch *q'* into the wheel O. This causes the wheel O to drive the shaft in an opposite direction to that in which it was driven by P. Now the shaft DC. which is thus put in motion, drives. by means of the pinion C and wheel B, the inclined shaft BW, which by an endless screw X working in the toothed quadrant Z, elevates or depresses the sluice KL, and admits a greater or a less quantity of water, according as the motion is given to the shaft by the wheel P or O. This change in the aperture is produced very gradually, as the train of wheelwork is made so as to reduce the motion at the sluice. The centre in which the sluice turns should be $\frac{1}{3}$ of its height from the bottom, in order that the pressure of the water on the part above the centre may balance the pressure on the part below the centre.

#### 2. *Description of Archimedes's Screw.*

The screw engine for raising water invented by Archimedes, was formerly constructed so as to consist of a cylinder with a flexible pipe, wrapped round its circumference like a screw; but it is now more frequently constructed in the manner shewn in Plate CCCXXII. Fig. 1. where AB is a cylindrical axis, having a flat plate of wood or thin iron, coiled as it were round it like the threads of a screw. The plane of this plate is perpendicular to the surface of the cylindrical axis AB, but inclined to this axis at an angle, which must always exceed the inclination of the cylindrical axis AB to the horizon. This last angle is commonly between 45° and 60°. This wooden screw, with a very deep thread, is fixed in a cylindrical box CDEF, so that we have a spiral hollow groove as it were running up the tube from B to A, which will have the same effect as if a pipe of lead or leather had been coiled round the cylindrical axis.

The lower end B of the screw is plunged in the water of the vessel E, which is to be raised to the upper vessel F, and when the screw is turned round its axis, either by a handle or winch placed at A, or by any other power acting upon the pinion at A, the water at E will fall into the hollow spiral groove, and as the screw turns round, the water will necessarily remain in the lower part of the spiral, and will at last reach the top of the spiral pipe, where it is discharged as seen at F. In this engine, therefore, the water rises by a constant descent in the spiral tube. The operation of this engine, which appears at first sight to be paradoxical, will be best understood by wrapping a cord spirally round a bottle containing a little water, and inclining the bottle at a less angle to the horizon than the inclination of the cord to the axis. It will then be seen, that if water falls into the lowest part of the spiral when it is at rest, the motion of the bottle about its axis will remove as it were the spiral out from below the water, which must therefore occupy the part of the spiral immediately above it, and so on till the water reaches the top of it. When the outer case CDEF is fixed, and the screw revolves within it, the engine is called a *water screw*, which should be inclined only about 30° to the horizon.

As we conceive this engine to be entitled to more notice than it has generally received from practical mechanics, we have given a drawing of a very excellent screw engine, which was erected in 1816 at the Hurlet Alum works, upon the Water of Levern, near Paisley; for which we have been indebted to the kindness of John Wilson, Esq. one of the proprietors. The water-wheel A, constructed of iron, with wooden buckets, (see Plate CCCXXII. Fig. 2.) is 12 feet diameter, and conveys its motion to the screw by the bevel wheels C, C, and the shafts B, B, 126 feet long, and $5\frac{1}{2}$ inches diameter. At the end of the shaft B is fixed another bevel wheel D, which works in a similar wheel D′, fixed on the circumference of the screw which rests upon an inclined plane of solid masonry, and is inclined 37° 30′ to the horizon. The axis KK of the screw, which is represented without its covering in Fig. 2. No. 2. is octagonal, and 8 inches in diameter. The diameter of the spiral is 22 inches, and the thickness of the covering 2 inches, so that the whole diameter is 26 inches. The distance of the threads is 9 inches, and their number 168. The thickness of the spiral is 2 inches, so that the spiral tube in which the fluid is to be raised is 7 inches wide, and 7 inches deep. The screw is supported on five sets of friction rollers, constructed as shewn at L in No. 3; two rollers having been found preferable to a greater number, which were at first employed. The well or stone cistern in which the foot of the screw is immersed, and from which the alum liquors are raised, is shewn at O; and at M there is an ingenious contrivance for supplying the pivot regularly with oil. The foot of the screw N is supported by a step of bell metal, inserted into a piece of wood, the socket for which is of cast iron wedged in the foot of the screw, and well lapped in woollen cloth dipped in rosin and tallow, to prevent the liquor from acting upon it. The fall of water which drives the wheel is 9 feet, and the water strikes the wheel 3 feet above the horizontal axle; the width of the mill course is $4\frac{1}{2}$ feet, the depth of water 14 inches, and the aperture of the sluice $2\frac{1}{2}$ inches. The water wheel revolves 12 times in a minute, and the screw performs two revolutions for one of the wheel, and consequently 24 revolutions in a minute. The quantity of liquor discharged is 70 wine gallons; but as the specific gravity of the fluid raised is 1.065, the weight of the quantity discharged in an hour is 17 tons. The pump is wholly built of timber, as the alum liquor acts upon the iron. Its total length is 127 feet, and the height to which the liquor is raised is $=$ sin. $37° 30' \times 127$ feet $=$ 76 feet 9 inches. The water wheel, besides driving the screw, moves two pumps for lifting liquor to the height of 30 feet. The pumps make each $2\frac{1}{2}$ strokes for one turn of the wheel, and the bore is $5\frac{1}{2}$ inches in diameter.

A very ingenious double screw engine has recently been invented by M. Pattu, engineer of roads and bridges in the department of Calvados. It is represented in section in Fig. 3, and consists of two ordinary and concentric screws, one of which, AB, is long and narrow, and serves for the nucleus of the other, CD, which is much wider and shorter. These two screws turn round the axis in opposite directions, so that when one of them appears to be moving upwards, the other appears to be moving downwards. The screw is inclined 35° to the horizon. The water from the stream MN is introduced into the larger screw, and puts the whole in motion, and the water, after its fall into OP, enters the smaller screw, in which it is raised to the cistern at B. When it is used for draining, and when the moving power of the water can be applied at A, the small screw serves to drive the larger one, which raises the water to a height sufficient to carry it off, as shewn in Fig. 4. Figures 5 and 6 shew other modes of applying this screw. Fig. 5 is the form used for raising water to irrigate high grounds, to fill the reservoirs of baths, gardens, and manufactories. The large screw is here the moving power. Fig. 6 is the form used for keeping dry those places where foundations are building. The large screw is here the mover.

M. Eytelwein has shewn that the screw should always be placed so that only one half a convolution may be filled at each turn. When the height of the water is so variable that this precaution is impracticable, he prefers the water screw, although nearly one-third of the water in this case generally runs back, and though it is easily clogged by accidental impurities in the water.

Fig. 7. shews the form of Archimedes's screw, as recommended by D. Bernoulli.

These machines are particularly useful when the water to be raised is not pure, but is mixed with gravel, weeds, or sand, which could not be elevated by ordinary pumps. For farther information on this subject, see *Vitruvius*. Pitot, *Mem. Acad. Par.* 1736, p. 173. Bernoulli, *Hydrodynamica*. Hennert, *Dissertation sur la vis d'Archimede*, Berl. 1767. Euler, *Nov. Comment. Petrop.* tom. v. p. 259. Ferguson's *Lectures*, vol. ii. p. 113. Pattu, *Journal des Mines*, Nov. 1815, vol. xxxviii. p. 321. Eytelwein's *Handbuch der Mechanik*, Berl. 1805. chap. xxi. Gregory's *Mechanics*, vol. ii. p. 348.

### 3. *On the Spiral Pump, or Zurich Machine.*

This machine, represented in Plate CCCXXIII. Fig. 1. was invented about 1746 by Andrew Wirtz, a pewterer in Zurich, who erected it for a dye-house on the river Limmat. It consists of a spiral pipe ABCDEF, either coiled round in one plane, as shewn in the Figure, or arranged round the circumference of a cone or a cylinder. The interior end of the spiral G, or the remote end of it, is connected by a water tight joint to an ascending pipe GH, in which the water is to be raised. When this spiral, immersed in the water MN, which is to be raised, is put in motion in the direction ABCD, the scoop BA, which begins to widen from C, takes in a portion of water. As the scoop emerges, this water passes along the spiral, driving the air before it into the pipe GH, where it escapes. Air is again admitted into the scoop after it emerges, and when the scoop has performed one revolution, it again takes up another portion of water, which is driven along the spiral as before, and is separated from the first portion by a column of air of nearly equal length. By continuing to turn the spiral, a second column of water and another of air will be introduced, and so on. Now, the water, on every turn of the spiral, will have both its ends horizontal, and the included air will have its natural density. But as the diameter of the spirals diminish towards the centre, the column of water, which occupied a semicircle in the outer spiral, will occupy more and more of the inner spirals as they approach to the centre G, till there will be a certain spiral, of which it will occupy a complete turn. Hence it will occupy more than the entire spiral within this spiral, and consequently the water will run back over the top of the succeeding spiral, as at No. 4. into the right hand side of spiral No. 3. The water in spiral No. 3. will consequently be pushed upwards till it runs over at 3 into the right hand side of spiral No. 2., and so on till some of the water escapes at the scoop A into the cistern MN. When the water enters the pipe GH at G, and rises a little in it, the escape of the air is prevented when the scoop AB takes in its next quantity of water. "Here then," as Dr Robison has remarked, "are two columns of water acting against each other by hydrostatic pressure, and the intervening column of air. They must compress the air between them, and the water and air columns will now be unequal. This will have a general tendency to keep the whole water back, and cause it to be higher on the left or rising side of each spire, than on the right descending side. The excess of height will be just such as produces the compression of the air between that and the preceding column of water. This will go on increasing as the water mounts in the rising pipe; for the air next to the rising pipe is compressed at its inner end with the weight of the whole column in the main. It must be as much compressed at its outer end. This must be done by the water column without it; and this column exerts this pressure, partly by reason that its outer end is higher than its inner end, and partly by the transmission of the pressure on its outer end by air, which is similarly compressed from without. And thus it will happen, that each column of water being higher at its outer than at its inner end, compresses the air on the water column beyond or within it, which transmits this pressure to the air beyond it, adding to it the pressure arising from its own want of level at the ends. Therefore, the greatest compression, viz. that of the air next the main, is produced by the sum of all the transmitted pressures, and these are the sum of all the differences between the elevation of the inner ends of the water columns above their outer ends; and the height to which the water will rise in the main will be just equal to this sum."

The spiral pumps seem to have remained long unnoticed. They were erected, however, at Florence, in 1778, with the improvement suggested by Bernoulli, of having the spiral coiled on the circumference of a cylinder, as represented in Fig. 2. In 1784, a spiral pump was erected at Archangelsky, near Moscow, which raised a hogshead of water in a minute to the height of 74 feet, and through a pipe 760 feet long. It has not yet been ascertained whether the plane, the cylindrical, or the conical spiral is best. The only practical difficulty consists in making the joint perfectly water-tight. The machine erected at Florence had its spiral cylindrical. Its diameter was ten feet, and that of the pipe six inches. The enlarged part occupied $\frac{3}{4}$ of the circumference, and was $7\frac{8}{10}$ inches wide at the outer end. The enlarged part contained 6844 English cubic inches. The spiral revolved six times in a minute, and raised 22 cubic feet of water 10 feet high in a minute. Eytelwein considers this as a very powerful machine, and well deserving the attention of the engineer. The length of the pipe becomes extremely cumbersome when the water is to be raised through a great height. Dr Young found that 100 feet of pipe $\frac{3}{4}$ of an inch in diameter was necessary for a height of 140 feet; and he considers that the machine would succeed better if the pipes were entirely of wood, or of tinned copper, or even of earthen-ware. See Sulzer's *Sammlungen Vermischten Schriften*, 1754; Daniel Bernoulli, *Nov. Comment. Petrop.* 1772, tom. xvii. p. 249: Bailey's *Machines approved of by the Society of Arts*, vol. i. p. 151; Dr Robison's *System of Mechanical Philosophy;* Eytelwein *Handbuch der Mechanik*, &c.; and Dr Thomas Young's *Natural Philosophy*, vol. i. p. 330, &c.

### 4. *Description of Pitot's Bent Tube for measuring the Velocity of Water.*

One of the most ingenious instruments for measuring the velocity of water is the *tube recourbé*, or bent tube, invented by M. Pitot, and described in the Memoirs of the Academy of Sciences for 1732. It is represented in Plate CCCXXIII. Fig. 3, and consists of a prism of wood ABCDEF, one of the angles of which is presented to the current. On the hinder face BCFE are fixed two tubes of glass parallel to each other, and having a graduated scale between them; one of them, viz. MNO, being bent into a right angle at O, so that the part MN may pass through the prism horizontally. When this instrument is plunged in a running stream, the general level of the current is shewn by the rise of the water in the straight tube PQ, while the height of the water in the bent tube MNO becomes a measure of the force of the stream. The difference between these heights will therefore be the height due to the velocity. In the practical use of this instrument, it is however difficult to fix it sufficiently steady, to prevent the water from oscillating in the tubes.

M. Du Buat having examined the instrument experimentally, found that it could be trusted no farther than to give the ratio of different velocities. He therefore suppressed the tube PQ altogether, and substituted, in place of the bent tube of glass MNO, a simple tube of white iron, sufficiently large to admit a float for pointing out the height of the water in the tube. The lower end of the white iron tube is bent back as at MN, and is terminated by a plane surface, perforated at its centre with a small orifice, which will greatly diminish the oscillations of the elevated column. If we then take *two-thirds* of the height of the water in the tube above the level of the stream, we shall have very exactly the height due to the velocity of the current for the depth to which the orifice is immersed. See Pitot. *Mem. Acad. Par.* 1730, 1772, p. 363; Du Buat's *Principes d'Hydraulique*, tom. ii. p. 332, edit. 1786; Bossut's *Traité d'Hydrodynamique*, tom. ii. p. 267, 268, edit. 1796.

### 5. *Description of the Hydraulic Quadrant for measuring the Velocity of Water.*

The hydraulic quadrant which has been recommended by several authors for measuring the velocity of water is shewn in Plate CCCXXIII. Fig. 4. It consists of a quadrant ABC, with a divided arch AB, and having two threads moving round its centre. One of these, CP is short, and carries a weight P, which always hangs in air, while the other CH or CM is longer, and carries a weight, whose specific gravity is greater than that of water, and which plunges more or less deep in the current as the thread is lengthened. The instrument is then held as in the figure, so that the plummet CP passes through 0°; and the angle ACD, or the angular distance of the other thread from a vertical line, will be a measure of the force, and consequently of the velocity of the current. Bossut has shewn that the force is as the tangent of the angle ACD, and that if $u$ be the velocity when the thread has the position CH, and V the velocity when it has the position CM, we shall have $u : V = \sqrt{\left(\frac{\sin. XCR}{\sin. XRC}\right)} : \sqrt{\left(\frac{\sin. XCS}{\sin. XSC}\right)}$. If we therefore know $u$, we also know V. We have therefore only to determine $u$, when H is at the surface, for any given angle ACD, and V will be had for any other velocity, either at the surface or at any depth below it. See Bossut's *Traité d'Hydrodynamique*, tom. ii. p. 265, 266. Eytelwein's experiments with the hydraulic quadrant will be found in the *Samml. zur Bauk.* 1799.

### 6. *Machines for discharging a uniform quantity of Water.*

In Plate CCCXXIII. Figs. 5, 6, 7 we have represented three ingenious contrivances for discharging equal quantities of water from a vessel which is constantly emptying itself, or where there is a variable head of water. The contrivance in Fig. 5. where MNOP is a vessel nearly full of water, consists of a tube BA moving round a joint at B, and having its upper end B connected with a hollow floating ball C. The velocity with which the water enters the extremity B is that which is due to the height BC, or the depth of B below the surface. As the surface MN descends the float C also descends, so that whatever be the height of the water in the vessel, it will always enter B with the same velocity. The discharge at the other end A will not be quite uniform, as the water will acquire greater velocity in descending the tube BA when it is much inclined than when it is nearly horizontal.

A floating syphon, which produces the same effect in a more correct manner, is shewn in Fig. 6, where ABD is a syphon with a hollow floating ball at its shorter end. This syphon is suspended by the chains EP, EP, which pass over two pulleys P, P, upon a horizontal axle PP, and suspend at their other extremities counterweights W, W. As the water in the vessel MNOP sinks by being discharged at D, the syphon descends and the counterweights rise, and an uniform stream is obtained till the end A reaches the bottom of the vessel.

Another very ingenious contrivance for the same purpose is shewn in Fig. 7. A cone AB attached to a lenticular float C, and fixed upon the axis *c f*, rises and falls in the aperture *m n*, by which the water of the vessel MNOP is to be discharged. It is kept in an upright position by the horizontal axes *o p*, *r s*. Now, when the vessel is full of water, and the head therefore great, the velocity at *m n* will also be great; but as the float C rises with the surface MN, the aperture *m n* will be partly filled by a thicker part of the cone AB; whereas, when the surface MN has descended, the float AB will also descend, and the aperture at *m n* will be widened, in consequence of a smaller part of the cone being included in it. In this way, the varying diameter of the cone always adjusts the aperture *m n* to the variable head of water, so that the quantity discharged through the tube *m n o p* is nearly always the same.

### 7. *Water-blowing Machine, or Shower-Bellows.*

The water-blowing machine, called *trombe* by the French, seems to have been first introduced in Italy about the year 1672, for the purpose of procuring a blast of air by the descent of water. It is represented in Figs. 8 and 9, where MN is a reservoir of water, in the bottom of which is inserted a long tube AB, consisting of a conical part *a b*, seen upon an enlarged scale in Fig. 9, communicating with a cylindrical tube *d* B, which enters the vessel CDEF. A number of openings *c*, *d*, &c. are made at the top of the tube *d* B, so that when the water is discharged at the conical aperture *b*, it drags along with it the adjacent air. This mixture of air and water falls upon a stone pedestal G, so as to separate the air from the water. The water descends to the bottom of the vessel, while the air escapes through the pipe CIK to supply the furnace. Another form of the machine is shewn in Fig. 9. where $\alpha\,\beta$ is the conical pipe, and the water is supplied with air from the pipes $\kappa\,\beta$, $\delta\,\beta$.

In the water-blowing machines used in Dauphiny, in the neighbourhood of the town of Alvar, the diameter of *a b* is 12 inches at *a*, and 5 at *b*; the diameter of *d* B is 10 inches. Only four holes are used at *c*, *d*, and the end B enters 1½ feet into the vessel CDEF, which is 4 feet high and 4 feet broad. The water is discharged at an aperture above F, a foot in diameter; and sometimes the admission of the water and its discharge are regulated by sluices *m* and *n*. A strong, equal, and continued blast is obtained by this machine; but it is thought to be too moist and too cold. We have seen in Switzerland one of these machines working with great effect at the lead works of M. Lenay, in the valley of Servoz near Chamouni.

Kircher appears to have been the first who explained the production of wind by a fall of water. Barthes long afterwards gave another theory, and Dietrich and Fabri ascribed the wind to the decomposition of the water. In 1791, the Academy of Tholouse invited philosophers to investigate this phenomenon, and it was probably in consequence of this that Venturi directed his attention to the subject. This ingenious philosopher has proved, that the air is dragged down upon the principle of the lateral communication of motion in fluids; and he has pointed out the best mode of constructing the machine, so as to produce the greatest quantity of air. The diameter of the tube *d* B should be at least double of the aperture at *b*. To a height about 1½ feet above C D, the tube should be completely air-tight, as well as the vessel CDEF, but above that part the tube *d* B may be perforated in every part with holes. M. Venturi has calculated, that the quantity of air which passes in one second into the tube is $= 6.1\,a^2\sqrt{(a+b-1.4)}-0.4a^2\sqrt{(a\times 0.1)}$, where *a* is the diameter of the aperture at *b*, and *b* the diameter of the tube *d* B. From this quantity about one-fourth should be deducted in practice, on account of the dashing of the scattered water against the lower part of the tubes. If the pipe CIK does not discharge all the air which is generated, the surface of the water in the vessel will descend, and part of the air will issue out of the lower apertures of the tube *d* B.

Phenomena similar to those produced by the water-blowing machine have been observed in nature. At the foot of the cascades which fall from the glacier of Roche Melon, on the naked rock of La Novalese towards Mount Cenis, Venturi found that the force of the wind arising from the air dragged down by the water could scarcely be withstood. The *ventaroli* or natural blasts, which are most frequently found to issue from volcanic mountains, arise from the air carried down the hollows by the falls of water; and what are called the *rain winds* have the same origin. ### 8. *Description of the Gaining and Losing Buckets.*

This very ingenious machine seems to have been first proposed by Schottus, but was afterwards greatly improved and actually constructed by George Gerves, for Sir John Chester, Bart. at his seat at Chichley in Buckinghamshire. The object of this machine is to raise water from a well or spring A, Fig. 10. to a reservoir R. In order to effect this, a wheel WW, 6 feet in diameter, is fixed above R, and on the same axis another wheel *w w*, 2 feet in diameter. To the circumference of W is fixed a chain W *x*, to which is hung a small bucket *b* with a valve in its bottom, and suspended as seen at *b* in Fig. A. To the circumference of *w w* is fixed another chain *w w y*, fastened to a rod *y z*, to which is suspended the large bucket B, with a valve in its bottom, as seen above B. This valve is fixed at the end of the arm *o* B, and is kept in its place by the weight *m*, acting at the end of the lever *m o*, whose fulcrum is at *n*; but is raised from its place by raising the arm *m o*, as shewn in Fig. B.

Let us now suppose that the small bucket *b* is filled with water, and that in consequence of water being poured into the large bucket B, this bucket descends. The bucket *b* will therefore ascend till it strikes the hook at *s*. This hook catching the edge of the bucket, turns it to a side, as shewn in Fig. A. and empties it into the reservoir R. By this time the descending bucket B has reached nearly the bottom of the cistern *z* Z. The arm *m o* of the lever falling upon the projection M is raised, as shewn in Fig. B. The valve in the bottom is consequently raised also, and the water is discharged at B into the cistern Z. The small bucket *b* is now an overmatch for B, in consequence of its acting at the end of a longer lever, and therefore *b* descends to the cistern A, while B ascends to the position it has in the figure. When *b* reaches the cistern A, the lower end of the valve strikes against a fixed obstacle; it is therefore raised out of its place, and admits the water of the cistern into the bucket. At the same instant the arm *o n* of the lever in the large bucket B striking against the bottom of a valve, seen below *a*, in a branch *a* of the cistern A, raises it, and allows the water from the cistern to run into the bucket B, till the weight of the bucket is sufficient to raise *b* out of the cistern A. As soon as it has received this weight of water it descends, the valve below *a* falls into its place, the valve in the bottom of *b* also falls into its place, when it rises above the fixed obstacle, and the bucket *b* ascends as before, to discharge its contents into the reservoir, while the large bucket descends to M to get rid of its load of waste water. It is obvious that the equilibrium of the chains and rods will be different in different positions of the buckets. When *b* is at R, and B at Z, B will be loaded with an additional quantity of chain. In order to regulate the weight of the chains in every position, a quadrant Q moves round C as a centre, and a chain *c d* attached to the point C of the rod *c z*, is fixed to the lower end *d* of the arch *d* Q. A weight X is also fixed at the end of the radius *d* C. Now when B is down at Z, X will have descended to *p*, and from acting at the end of a shorter lever, will be a less load upon the rod *c z* than when it had the position at X; that is, the additional weight which the bucket B has received from the increase of its chain is counterbalanced by the diminution of weight occasioned by the descent of CX into the position CP. Desaguliers remarks, that one hogshead falling 10 feet will raise very nearly one hogshead 10 feet, or one-fourth of a hogshead 40 feet.

### 9. *Description of the Scoop Wheel.*

The scoop wheel is intended to raise water through a height equal to its semidiameter. It is represented by WW in Fig. 1, and consists of a number of semicircular partitions, shewn in the Figure. These partitions are open at both ends, viz. at the circumference and at the centre of the machine. As the wheel is turned round in the direction WXW, either by the hand or by any other power, the scoops take up the water, which gradually descends during the rotation of the wheel, till it runs into its hollow axle, which again discharges it into a spout O. The scoop wheel is one of the forms in which the Persian wheel is generally described.

### 10. *Description of the Persian Wheel.*

The Persian wheel is a double water wheel, with floatboards on one side, and a series of buckets on the other, which are moveable about an axis above their centre of gravity. The wheel is placed in a stream, which puts it in motion, by acting upon its floatboards. As the wheel turns, the moveable buckets dip in the water, and ascend filled with fluid. But when they reach the highest point, their lower ends strike against a fixed obstacle, so as to make them empty themselves into a reservoir placed at the top of the wheel. See Ferguson's *Lectures*, vol. i. p. 180.

Another form of the Persian wheel is shewn in Fig. 2, where WW is a common bucket wheel, moving in the direction WOW. The buckets dipping in the water MN, rise filled with it, and discharge their contents into the reservoir O near the summit of the wheel. The wheel for draining the moss of Blair Drummond belongs to this class. It is driven by floatboards fixed on its periphery like the common undershot wheel, and a current of water is brought in at a side to fill buckets placed on the concave side of the rim.

### 11. *On Throwing Wheels, or Flash Wheels.*

A throwing wheel, which is commonly driven by a windmill, and used for draining fens, is nothing more than an undershot wheel, the floatboards of which push the water up a curvilineal plane, inclined from a lower to a higher level. One of these wheels is represented in Plate CCCXXIV. Fig. 3, where WW is the wheel, MN the inclined plane, N the water to be raised or pushed up the declivity MN, and M the drain which is to carry it off.

### 12. *On the Chain Pump.*

The chain pump, represented in Plate CCCXXV. Fig. 4, consists of an endless chain WWBA, passing round the wheel WW, and after entering the water to be raised, returning through the tube BA into the cistern MN. This chain carries a number of flat cylindrical pistons *a*, *b*, *c*, of nearly the same diameter as the tube AB, one half of each piston being received into openings in the circumference of the wheel. When the wheel is put in motion, the pistons enter the barrel BA, and pushing the water before them, raise it into the reservoir MN. When the wheel is turned with great velocity, the barrel is generally filled with water.

Pumps of this kind are frequently placed in an inclined position, and they raise the greatest quantity of water in this position, when the distance of the flat piston is equal to their breadth, and when the inclination of the barrel is about 24° 21′. The Spanish *noria* is the same as a chain pump, having a number of earthen pitchers placed between two ropes in place of a chain.

These machines are sometimes called *cellular pumps*, and when stuffed cushions are used in place of pistons, they are called *Paternoster pumps*.

Chain pumps are sometimes constructed without the piston *a*, *b*, *c*. In this case, the barrel AB is also removed, and they have the form shewn in Fig. 5, where W, W are two wheels with a set of buckets fixed to an endless chain, which passes round their circumference. By turning the upper wheel, the buckets dip into the water with their mouths downwards, and rising on the other side, convey the water into the reservoir at M.

### 13. *On the Hair Rope Machine of the Sieur Vera.*

The hair rope machine of the Sieur Vera is shewn in Fig. 6. It consists merely of a rope AB made of hair, passing round a wheel W, and kept stretched by going round a pulley P, fixed in the water. By turning the handle H, the rope rises loaded with the water that adheres to it, and when it reaches the top, it passes through a small tube which rubs the water from it, into a cistern. In a machine of this kind, where the wheel was three feet in diameter, the rope half an inch in diameter, and the well 95 feet deep, a labouring man could produce only 60 revolutions in a minute, and could not continue the exertion long. This raised 6 gallons in a minute. A great deal of water was raised when the wheel made 50 turns in a minute, but very little when it made only 30 turns. The rope soon decays if it is not made of hair. See Rozier's *Journal de Physique*, tom. xx. p. 132; and Cavallo's *Natural Philosophy*, vol. ii. p. 441.

### 14. *Description of Whitehurst's Engine.*

Mr Whitehurst, an ingenious watchmaker of Derby, appears to have been the first who entertained the ingenious idea of raising water by means of its momentum. A machine upon this principle was erected at Oulton in Cheshire, and was described in the Transactions of the Royal Society for 1775. This machine is represented in Plate CCCXXIV. Fig. 7, where AM is the reservoir of water, whose surface at M is on a level with B, the bottom of the reservoir BN. The main pipe AE is about 200 yards long, and $1\frac{1}{2}$ inches in diameter, and the branch pipe EF is of such a size that the cock F is about 16 feet below the surface of the water at M. A valve box with its valve *a* is shewn at D, and C is an air vessel into which are inserted the extremities *m n* of the main pipe, which are bent downwards for the purpose of preventing the air from being driven out when the water is forced into it. Now, when the cock F is opened, the water will rush out with a velocity of nearly 30 feet per second. A column of water, therefore, two hundred yards long and $1\frac{1}{2}$ inch diameter, is now put in motion, and must have a considerable momentum. Hence, if the cock F is suddenly shut, the water will rush through the valve *a* into the air vessel C, and condense the included air. This condensation will take place every time that the cock is opened, so that the included air being compressed, will press upon the water in the air vessel, and raise it into the reservoir BN. This simple and ingenious machine is obviously the same in principle as the hydraulic ram invented by Montgolfier, and which differs from it only in this, that the operation analogous to that of opening the cock F is produced by the motion of the water itself, as will be seen in the following description of this ingenious contrivance.

### 15. *Description of Montgolfier's Hydraulic Ram.*

This interesting machine was first constructed by Montgolfier about the year 1797, and has been brought to a very perfect state by a series of improvements which he has successively made upon it. The rams which we have represented in Plate CCCXXIV. Figs. 8, 9, 10, and 11, contain the improvements which have been made so late as 1816. The large pipe AB, called the body of the ram, passes through the side of the reservoir PQ, from which the fall of water is obtained. It has a trumpet mouth at one end A, and at the other end an opening HH, which can be closed by valves C or D. When these valves are open, the water will issue at HH with a velocity due to the height AP; but when the internal valve C is closed, as in the figure, the water is prevented from issuing. When the valve C opens, it descends into the position shewn by the dotted lines GG, being guided between three or four stems *g g*, which have hooks at the lower ends for supporting the valves. In this case the water has a free passage between these stems, and the width of the passage can be increased or diminished by the screws with which the stems are fixed. The valve C is made of metal, and has a hollow cup or dish of metal attached to its lower surface. The seat HH of the valve is wider than the diameter of the pipe AB. It consists of a short cylinder or pipe screwed by its flanch *h h* into the opening of the upper surface of the head R of the ram; and the cylinder is so formed as to have an inverted cup or annular space *i i* round the upper part of it for containing air, which cannot escape when it is compressed by the water. A small pipe *k l*, leading from this annular space to the open air, is furnished with small valves, *k*, *l*, one of which, *k*, opens inwards to admit the air into *i*, *i*, but to prevent its return, while the other valve, *l*, admits a certain quantity of air, and then shuts and prevents any farther entrance. The valve D is exactly the same as C, only it descends as in the figure when it shuts, and rises when it opens.

The upper part of the head of the ram at E is made flat, and has several valves which allow the water to pass freely from the pipe AB, but prevent its return. On each side of the head of the ram, at the part opposite to these valves, is a hollow enlargement, shewn by the dotted lines K, forming a circular basin, through the centre of which the pipe ABR passes. This part of the construction is shewn more distinctly in Fig. 9. which is a transverse section through LEZ in a plane perpendicular to that of the paper. The pipe is here made flat instead of circular, as seen at E, Fig. 9. for forming the seats of the valves, and the basin KK is covered with an air vessel FF. This air vessel communicates all round the pipe B, with the basin KK, and with the vertical pipe M.

The machine being thus constructed, let us suppose the pipe ABR full of water, and the valve C to be opened, the water will lift the valve D, and escape with a velocity due to the height of the reservoir. In a short time, the water having acquired an additional velocity, raises the valve G, which shuts the passage, and prevents the escape of the water. The consequence of this is, that all the included water exerts suddenly a hydrostatical pressure on every part of the pipe, compressing at the same time the air in the annular space *i i*, which by its elasticity diminishes the violence of the shock. This hydrostatical pressure opens the valves at E, and a portion of the water flows into the air vessel F, and condenses the air which it contains. The valves at E now close, preventing the return of the water into the pipe, and the water recoils a little in the tube with a slight motion from B to A, in consequence of the reaction or elasticity of the compressed air in *i i*, and also of the metal of the pipe, which must have yielded a little to the force exerted upon it in every direction. The recoil of the water towards A produces a slight aspiration within the head R of the ram, which causes the valve D to descend by its own weight, and prevents the water X which covers it from descending into the tube. The air, however, passes through the pipe *l k*, opens the valve *k*, and a small quantity is sucked into the annular space *i i*; but the quantity is very small, as the valve *k* closes as soon as the current of air becomes rapid. During the recoil towards A, the valve C, being unsupported, falls by its own weight; and when the force of recoil is expended by acting on the water in the reservoir PQ, the water begins again to flow along ABR, and the very same operation which we have described is repeated without end, a portion of water being driven into the air vessel F at every ascent of the valve C. The air in this vessel being thus highly compressed, will exert a force due to its elasticity upon the surface of the water in the vessel F, and will force it up through the pipe M to a height which is sufficient to balance the elasticity of the included air.

The small quantity of air which is drawn into the annular space *i i* through the air tube *l k* at each aspiration, causes an accumulation of air in the space *i i*: and when the aspiration of recoil takes place, a small quantity of air passes from *i i*, and proceeds along the pipe till it arrives beneath the valves at E, and lodging in the small space beneath the valves, it is forced into the air vessel at the next stroke, and thus affords a constant supply of air to the vessel. The valves make in general from 50 to 70 pulsations in a minute.

When the fall of water, or PQ, is five feet, and the pipe AB six inches in diameter and 14 feet long, a machine with its parts proportioned as in the figure will raise water to the height of 100 feet. It will expend about 70 cubic feet per minute in working it, and will raise about $2\frac{1}{3}$ cubic feet per minute to the height of 100 feet. Mr Millington observes, that one of these machines is said to have raised 100 hogsheads of water in 24 hours to the height of 134 feet by a fall of $4\frac{1}{2}$ feet.

The form of the ram represented in Fig. 10, is suited to the case where a current of foul water AB is employed to raise clean water from the well WW. This effect is produced by a bent pipe OPQ, containing a column of air from O to Q, and by another pipe T, with a suction valve *t*: The mode of action is precisely the same as in Fig. 8. When the valve C shuts, the sudden hydrostatical pressure forces the water up the bent tube at O, compresses the column of air OQ, which again presses, by its elasticity, on the surface of water at Q, and forces the clean water up through the valves into the air-vessel FF. The recoil of the water from B to A will produce a rarefaction in the column of air QO, in consequence of which the atmospherical pressure upon the water in the well will raise the valve *t*, till as much water is admitted as was driven into the air-vessel. Montgolfier proposes to substitute a straight pipe in place of OQ, and to place a piston, moving freely in the pipe, which will transmit the pressure from the foul water to the clean water, without allowing them to mix. We conceive that the same effect might be obtained more simply and with much less friction, by a very loose diaphragm fixed in the tube.

When the ram is employed to produce a current of air, it has the form shewn in Fig. 11. The air is expelled through the air-pipe *w m*, in consequence of the mass of water rushing into the air-chamber W, by the shutting of the valve C. The water in W is prevented from following the air by a hollow ball of copper *n*, which floats on the water, and shuts up the lower end of the pipe, when the water dashes into W. When things are in the state shewn in the figure, and all the air expelled from the chamber W, the air compressed in the annular space *p p*, (which serves the same purpose as *i i* in Fig. 8) produces a recoil of the water. The valve D shuts, C opens, the water quits the chamber W, and the valve *w* shuts, and prevents the admission of air. At the same time the valve *r* opens, and admits a fresh supply of air into the chamber; but when the water has descended below the float *e*, this float descends, and by its rod *e d* shuts the air-valve *d*. When the force of recoil is spent, the water flows again from A to B, and the operation which we have described is again repeated, so that there is a constant current of air in the pipe *w m*, which may be equalized by a water regulator, or any other contrivance. See the *Repertory of Arts*, Dec. 1816; Ferguson's *Lectures*, vol. ii. App.; and Brande's *Journal*, vol. i. p. 211. Lond. 1816.

16. *Description of the Chemnitz Fountain, or Hungarian Machine.*

The Chemnitz fountain is represented in Plate CCCXXIV. Fig. 12, where C is a collection of water, either in a mine or in a well, which it is required to raise to the reservoir B by means of a small head of water at A. In order to effect this, a pipe AFT, 4 inches in diameter, having a cock at M, enters the top of the copper vessel TD, $8\frac{1}{2}$ feet high, 5 feet in diameter, and 2 inches thick, containing about 170 cubic feet, and extends to D within 4 inches of the bottom. The vessel TD has a cock at N, and a very large one at P, and from its top proceeds a pipe TOG, 2 inches in diameter, with a cock at O, entering the top of the vessel KE, which is $6\frac{1}{2}$ feet high, 4 feet in diameter, 2 inches thick, and containing about 83 cubic feet. Another pipe EKHB, 4 inches in diameter, rises from E, within 4 inches of the bottom of the vessel KE, is soldered into its top at K, and rises into the reservoir B. The cylinder KE communicates by a tube with a cock at R, with the water C to be raised, and has a cock Q at its top. Let us now suppose that the cock M is shut, and all the other cocks open. The cylinder TD will contain air, and KE will contain water standing as high as the level of the water in the cistern C. Shut the cocks N, P, Q, and R, and open the cock M. The water from A will descend into the vessel TD, and after it rises above the mouth D of the pipe, it will compress the air in the vessel TD, in the pipe TOG, and in the upper part of the vessel KE. The action of this air upon the water in KE will force it up the pipe KH, till it is discharged into the reservoir B. This discharge into B goes on till the upper vessel TD is filled with water. As soon as this happens, the water is prevented from running into the pipe TO by a cork ball, or double cone, which hangs in the pipe TO by a brass wire, which is guided by holes into two cross pieces in the pipe. The ascent of the water into the mouth of the pipe at T pushes in this plug, and closes the pipe. The influx of water now stops; but the water still flows into B till the elasticity of the air in the lower vessel KE is no longer able to balance a column which reaches to H in the pipe KH. This cessation of the efflux into B generally ceases when KE is half full of water. When this takes place, the workman shuts the cock M, and opens the cock P, from which the water rushes with great velocity. Whenever $\frac{2}{3}$ths of the water in the vessel TD is discharged at P, which is measured in the vessel which receives it, the workman opens the cock R with a long rod, so as to fill the vessel KE with water. This drives the air out of KE through the pipe GO into the vessel TD, and consequently drives out all the remaining water. Every thing is now in the state in which it was at first, which is known to be the case when no more water flows out at P. The workman, therefore, shuts the cocks P and Q, and opens M, and the same operation is repeated. If the cock N be opened when the efflux has ceased at B, the water and air rush out together with prodigious violence, accompanied with hail and pieces of ice produced by the cold which attends the sudden expansion of air. It is usual to shew this sight to strangers, whose hats, when held opposite N, are sometimes pierced with the pieces of ice which are projected from it.

A considerable improvement upon this engine has been made by Mr John Whitley Boswell, who has added to it an apparatus which enables it to operate without any attending workmen. An account of this improvement will be found in Nicholson's *Journal*, 4to. vol. i. and 8vo. No. 5.

17. *Description of the Danaide invented by M. Mannoury Dectot.*

This machine consists of a cylindrical trough of tin-plate, nearly as high as it is broad, and having a hole in the centre of its bottom. It is fixed to a vertical axis of iron, which passes through the middle of the hole in the bottom, a vacant space being left all round to permit the water to escape. The axis turns with the trough upon a pivot, and is fixed above to a collar.

A drum of tin-plate, close above and below, is fixed upon the axis of the trough, and placed within the trough, so as to be concentric with it, and to leave only between the outer circumference of the drum and the inner circumference of the trough, an annular space not exceeding $1\frac{1}{2}$ inches. This annular space communicates with a space less than $1\frac{1}{2}$ inches, left between the bottom of the drum and the bottom of the trough, and divided into compartments by diaphragms fixed upon the bottom of the trough, and proceeding from the circumference to the central hole in the bottom of the trough.

The water comes from a reservoir above by one or two pipes, and makes its way into this annular space between the trough and drum. The bottom of these pipes corresponds with the level of the water in the trough, and they are directed horizontally, and as tangents to the mean circumference between that of the trough and of the drum. The velocity which the water has acquired by its fall along these pipes, makes the machine move round its axis, and this motion accelerates by degrees, till the velocity of the water in the space between the trough and drum equals that of the water from the reservoir; so that no sensible shock is perceived of the affluent water upon that which is contained in the machine.

This circular motion communicates to the water between the trough and drum a centrifugal force, in consequence of which it presses against the sides of the trough. This centrifugal force acts equally upon the water contained in the compartments at the bottom of the trough, but it acts less and less as this water approaches the centre.

The whole water then is animated by two opposite forces, viz. gravity, and the centrifugal force. The first tends to make the water run out at the hole at the bottom of the trough; the second, to drive the water from that hole.

To these two forces are joined a third, viz. *friction*, which acts here an important and singular part, as it promotes the efficacy of the machine, while in other machines it always diminishes that efficacy. Here, on the contrary, the effect would be nothing were it not for the friction, which acts as a tangent to the sides of the trough and drum.

By the combination of these three forces, there ought to result a more or less rapid flow from the hole at the bottom of the trough: and the less force the water has as it issues out, the more it will have employed in moving the machine, and of course in producing the useful effect for which it is destined.

The moving power is the weight of the water running in, multiplied by the height of the reservoir from which it flows above the bottom of the trough; and the useful effect is the same product diminished by half the force which the water retains when it issues out of the orifice below.

In order to ascertain, by direct experiment, the magnitude of this effect, MM. Prony and Carnot fixed a cord to the axis of the machine, which, passing over a pulley, raised a weight by the motion of the machine. By this means, the effect was found to be $\frac{7}{10}$ of the power, and often approached $\frac{75}{100}$ without reckoning the friction of the pullies, which has nothing to do with the machine. This effect exceeds that of the best overshot wheels. See the *Report of the Institute*, 23d August 1813; or Thomson's *Annals of Philosophy*, vol. ii. p. 412.

### PLATE CCLXXXIV.

Figs. 1, 2. Represent Mr Tappen's Method of constructing Groined Vaults.

Figs. 3, 4, 5, 6. Shew the Instruments used for forming Gun Flints.

Figs. 7, 8, 9. Represent the Masses of Flint in their different States.

Fig. 10. Represents the Eprouvette invented by Dr Hutton, for measuring the strength of Gun-powder.

Fig. 11. Represents the Ballistic Pendulum, invented by Mr Robins, for measuring the initial velocity of Projectiles.

### PLATE CCLXXXV.

Fig. 1. Represents Mr Forsyth's new Lock in the Priming Position.

Fig. 2. Represents the same Lock in the firing Position.

Fig. 3. Is a Section of the Magazine for containing the priming powder, and the Mechanism for inflaming it by Percussion.

Fig. 4. Is a Section of the Breach of the Gun, with the Roller screwed into it. See GUNMAKING.

Fig. 5. Represents the Indian Matchlock.

Fig. 6. Represents the European Matchlock or Harquebuss.

Fig. 7. Represents the Rest for the European Matchlock.

Fig. 8. Represents the Wheel Lock.

Fig. 9. Represents a modern Fowling Piece.

Fig. 10. Represents a Modern Spanish Lock.

### PLATE CCLXXXVI.

Figs. 1, 2, 3, 4. Are Diagrams for illustrating the mathematical principles of Gunnery.

Fig. 5. Is a Diagram for explaining Robins' theory of the explosive force of Gunpowder.

Fig. 6. Represents the Instrument invented by Mattei, for measuring the initial velocity of Projectiles. AB is a horizontal wheel, with a vertical axis CD turned by the weight Q, suspended to the rope GG, and raised by the winch N. AE, BF, is a circular drum about six inches high, formed of writing paper, fixed round the circumference of the wheel. The gun is fired at the distance of 20 feet, and pointed so, that the axis of the gun produced would pass along a diameter of the drum perpendicular to GG. A block of wood is placed two or three feet from the drum, to receive the balls. When the Machine was used at Turin, a little eccentric wheel IL was fitted to the axis CD, which with each revolution gave a vibrating horizontal motion to a tongue of wood, suspending a common pendulum, that was shortened or lengthened till its vibrations were isochronous to those of the tongue. The length of the pendulum will then shew how long the wheel is in making each revolution.

Fig. 7. Is a Diagram explaining one of Antoni's Methods of measuring the initial velocities of Projectiles.

Fig. 8. Is a Diagram for explaining Antoni's Method of determining the curve described by Projectiles, by firing the Guns from different heights.

### PLATE CCLXXXVII.

Fig. 1. Represents the Halo observed by Scheiner at Rome on the 20th March 1629.

Fig. 2. Is the Halo observed by Hevelius at Dantzic, on the 20th February 1661.

Fig. 3. Shews the Halo observed by Scheiner at Rome, in 1630.

Fig. 4. Represents the Paraselenæ seen by Hevelius at Dantzic, on the 30th March 1660.

Fig. 5. Shews the Parhelia seen by Hevelius, on the 6th April 1660.

Fig. 6. Shews the Paraselenæ seen by Hevelius, on the 17th December 1660.

Fig. 7. Represents the Halo seen in England, on the 8th April 1233.

Fig. 8. Is the Halo seen at Leyden, on the 14th January 1653, by Kechelius.

Fig. 9. Is the Halo seen by Dr Halley, on the 8th April 1702.

Fig. 10. Represents a very complicated system of Halos, which was seen at St Petersburg by M. Lowiz, on the 18th June 1790.

Fig. 11. Shews a Halo seen in Scotland, on the 18th February 1796, by Mr Hall.

Fig. 12. Is the Halo seen by Sir Henry Englefield at Richmond, on the 20th November 1812.

## PLATE CCLXXXVIII.

Figs. 1, 2, 3, 4, 5, 6. Represent the Harmonic Sliders invented by Dr Thomas Young.

Fig 7. Is an elevation of the Machine invented by Mr Thomas, for weaving Chip Hats.

Fig. 8. Is a Section of the same Machine.

Fig. 9. Represents the Apparatus used by M. Pictet, to illustrate the reflection of Heat. A and B represent the Concave Mirrors, C the heated Iron Ball, and D the Bulb of the Thermometer. The dotted lines mark the progress of the rays of heat which are emitted from the heated iron, impinge upon the Mirror A, then pass in straight lines to the Mirror B, and from this are reflected to the Focus D.

Fig. 10. Represents an Instrument invented by Dr Wollaston, and called the *Cryophorus*, for freezing at a distance.

## PLATE CCLXXXIX.

Figs. 1, 2, 3, 4, 5, 6, 7, 8, 9. Are Diagrams for explaining the new properties of heat discovered by Dr Brewster.

Fig. 10. Represents the Apparatus employed by Dr Brewster, in rendering visible the propagation of Heat downwards through Fluids.

Fig. 11. Represents the Apparatus employed by Professor Leslie in his experiments on Heat. A, is the concave elliptical Reflector; B, the differential Thermometer placed in one of its foci; C, the cubical Canister of block tin, placed on the other focus, and filled with hot water, whose temperature is ascertained by the Thermometer D, passing through an orifice in the upper side of the Canister, and having its Bulb in the centre of the Cubical Canister; E, is a Screen consisting of a light frame of wood, wider than the diameter of the largest reflector used. It has occasionally different thin substances attached to it.

Figs. 12, 13, 14, 15, 16, 17, 18, 19, 20. Represent the Apparatus used by MM. Delaroche and Berard, in their experiments for determining the specific heat of the Gases.

Fig. 12. Is a thin copper Cylinder, (called the *Calorimeter*,) 6 inches long and 3 inches in diameter, filled with distilled water, and traversed by a worm about 5 feet long, having 8 spiral turnings, the two ends of which open without the vessel. A regular current of gas, at a high and constant temperature, was made to pass through the worm, and the intensity of this heat was considered as proportioned to the excess of the temperature of the Cylinder AB (when it had become stationary) above that of the surrounding air. Hence, by repeating this experiment on each of the gases, each current will raise the temperature of the Cylinder AB above that of the ambient air, to a fixed point where it will be stationary; and, therefore, we obtain the quantity of heat given out by each current of gas. The relative specific heats consequently of the gases are obtained with great exactness.

Figs. 13, 14, 15, 16. Represent the Apparatus employed by Messrs Delaroche and Berard, to make a regular current of hot gas pass through the Calorimeter. In order to understand this, suppose a globular glass vessel A, Fig. 3. filled with water, and placed above a reservoir of glass or metal B, filled with any gas insoluble in water. Let these two vessels communicate by a vertical tube CD, which may be shut by a stop-cock E. Suppose, likewise, that the upper surface of the water contained in A is GH. It is evident, that if the stop-cock E is opened, the water will fall into the vessel B, and drive out the gas, which will make its escape by the mouth L, (the stop-cock M being open.) It is equally obvious that the force with which the water of the vessel A will run down, at first equal to the column of water HK, will diminish in proportion as the surface of the water GA sinks. But then, if the mouth F is shut exactly, and the communication of the vessel A established with the external air by the tube NO, open at its two ends, the air, in order to introduce itself into the vessel A, and fill up the place of the water that has run out, must overcome the pressure of the column of water HI. Of course, the water will only run into the vessel B, with a force equal to the column HK, minus HI, that is to say, the column IK, which is a constant quantity, as long as the surface of the water continues higher than OI. Now suppose the reservoir B be totally emptied of gas, and filled with water from the vessel A. Shut the stop-cocks EM, and introduce by the tube QR, which goes to the bottom of the vessel, a constant current of gas, coming from a similar gazometer. In these circumstances, if the stop-cock P is opened, to let out the water from the reservoir B, it is clear that this gas, in order to get into the reservoir B, is obliged to overcome a resistance represented by the column of water which this reservoir contains. On the other hand, it is attracted by an equal force, namely, the force with which this water tends to run out by the stop-cock P, and which is represented by the same column. These two forces being equal, and opposite, it follows that the regularity of the gas entering by the tube QR, will not be disturbed, and that the reservoir B will be filled with gas coming from the other gazometer, without having any effort to overcome. The stop-cock E remaining shut during the whole of this operation, there will be time to open the mouth F, and to fill the vessel A with water, in order to recommence the operation. It is easy to see that with two similar gazometers, we may make a certain quantity of gas pass from the one to the other as often as we please, without interruption.

When the gas which fills the reservoir B is not atmospherical air, when it is hydrogen gas, for example, if we pass it often from one gazometer to another, it will disengage the air contained in the water, and take its place, so that the purity of the gas will be injured. It would have been impossible to have produced a current of carbonic acid gas, nitrous oxide gas, or olefiant gas, in this manner, though they are but imperfectly soluble in water. This difficulty would have obliged them to renounce this kind of gazometer, if they had not found a method of obviating it. This method consists in putting only atmospherical air into the reservoir B, and in introducing the gas which is to circulate into a bladder V, Fig. 14. inclosed in a globular vessel M, communicating by the tube C with the reservoir B. If in this state of things we suppose a regular current of atmospherical air proceeding from the reservoir B to the vessel M through the tube C, as the vessel M is accurately shut, the air will press uniformly on the bladder, and there will issue out through the tube D a regular current of the gas contained in the bladder.

If, on the other hand, we suppose that the constant current issuing from the bladder V enters into another bladder V′, (Fig. 15.) which is empty, and placed, in the same manner as the first, in another globular vessel M′, which is full of air, and communicates with the reservoir B′ of the other gazometer, by the tube C′, which reaches down to its bottom. The reservoir B′ being full of water, and its stop-cock P′ open, the bladder V′ will become gradually filled with gas, and will drive the air of the globular vessel M′ into the reservoir B′, in an uniform current. It is now easy to form an idea of the apparatus which we employed, and of which we have given a vertical projection in Fig. 15.

B and B′ are the two lower reservoirs of the two gazometers. The reservoir B is supposed full of air, and B′ full of water. V is a bladder filled with gas, hydrogen gas for example, whose specific heat is to be determined. The corresponding bladder V′ is empty; *a*, *b*, *c*, *d*, *e*, *f*, *g*, *h*, are the stop-cocks. Let us suppose *a*, *c*, *f*, *h*, alone open, if we make the gazometer B act, a regular current of common air will flow out of B, and pass into the globular vessel M. It will compress the bladder V, and force out a current of hydrogen gas. This gas will pass through the tube CDE, about forty inches in length, and which is surrounded by a larger tube FG. This last tube is kept filled with the steam of boiling water by means of a small boiler K, filled with water, and kept constantly boiling. The steam passes through the tube KF, into the tube FG, traverses the whole of it, and makes its escape by the tube GI. The part DE of the tube through which the gas passes is long enough to enable the gas during its passage to acquire very nearly the temperature of boiling water. The gas, when it leaves this tube, passes into the calorimeter L, where it gives out its heat, and then issues out by the tube NO, which conducts it to the bladder V′. It fills this bladder, driving the air of the vessel M′ into the reservoir B′, by a tube which plunges to the bottom of the reservoir.

When all the air has been driven out of the reservoir B, and water has been substituted in its place, then the bladder V is empty, and the vessel M full of air from the reservoir B. The bladder V′ is full of hydrogen, and the reservoir B′ full of air from the vessel M′. If we now shut at once the stop-cock *a*, *c*, *f*, *h*, and open *g*, *e*, *d*, *b*, and put the gazometer B′ into action; then the air issuing from the gazometer by the stop-cock *g*, will fill the vessel M′, press upon the bladder V′, and cause an uniform current of hydrogen gas to pass through the stop-cock *e* into the tube DE, where it will be heated. It will then pass through the calorimeter, and issuing out by the tube NO, it will pass through the stop-cock *d* into the bladder V, will fill it, and drive the air of the vessel M into the reservoir B. Thus matters will be brought to their primitive state, and we may commence the process as at first. With a bladder filled with hydrogen gas we may pass an uniform current as long as we please through the calorimeter; and we know, from experience, that notwithstanding the continual agitation given to this gas, by making it move so frequently through so long a circuit, it does not contain, after having circulated for six hours, three per cent. of impurities.

The greatest part of the apparatus which has been described is contained in the same room; but the calorimeter, the ends of the tubes DE, FG, and a part of the tubes GI, NO, are in another room, separated from the first by the door PQ, which has proper holes in it to allow the tubes to pass. This second room being but seldom opened, the air which it contains, and which surrounds the calorimeter, is seldom agitated, and its temperature scarcely varies.

Fig. 17. Represents a Horizontal Section of the Calorimeter AB, Fig. 12, through its lower part. This plate has fixed to its two extremities two rods, *b b*, *b′ b′*, six inches long, and cut half their length into the threads of a screw, upon which are fixed the nuts C, C′. The middle of this plate is pierced with a hole *d d*, which coincides with the orifice by which the inferior part of the serpentine opens outwards. Round the hole is a flat place *f f*, destined to receive a piece of leather.

Fig. 18. Represents the extremity of the Tube filled with vapour, which serves to heat the gases. This extremity is of copper. The plate EE, which terminates it, is pretty thick, and pierced in its middle with an opening II, communicating only with the interior tube, which contains the gas. This opening is surrounded externally with a flat place LL, which receives a round piece of leather. Immediately in the neighbourhood of the terminal plate is the tube RS, which opening into the inside of the vapour tube, allows the vapour and the condensed water to escape, and carries them to a distance from the calorimeter. It is the same tube that is represented by GI in the horizontal section of the apparatus, Fig. 16.

MM, NN, are two oval plates, pierced in their centre by a circular opening, which receives the vapour tube, to which they are firmly fixed. At each of their extremities is a hole, sufficiently large to give passage to the rods *b b*, *b′ b′*, fixed to the calorimeter, and represented in Fig. 17.

It is easy to see that when the extremity of the vapour tube is presented to the calorimeter, and the metallic rods are made to pass through corresponding openings in the wooden disks MM, NN, the opening II of the gas tube will be exactly opposite to the opening *d d* of the serpentine. If we interpose between the two openings a tube of glass of the requisite size, and such that its extremities, ground with care, press against the disks of leather which cover the flat faces *f f*, L L; and if, by means of the nuts C, C′ we force the extremities of the vapour tube to approach as near as possible to the calorimeter, then the tube of glass firmly fixed between the two disks of leather will establish a communication between the gas tube and the calorimeter, and will prevent all gas from escaping in any other direction.

Fig. 19. Represents the modification of the Apparatus for determining the specific heat of air subjected to different degrees of pressure. To the stop-cocks P and P′ was soldered a tube in the form of a Y reversed. The two branches of the Y united in a common tube HH, which, rising vertically, and passing through an opening in the roof of the room, opened above a tub X, placed in the room above. We carried to this room the cylindrical glass vessels A, A′, and formed the communication between them and the reservoirs B, B′, by the long tubes which passed down through the floor. In this apparatus the height HH, of the upper extremity of the tube H, above the mouth of the stop-cocks P, P′, determined the pressure to which the gas was subjected.

Fig. 20. Represents the Apparatus employed by the same Chemists for comparing the specific heats of the gases with that of water taken as unity.

In order to get a constant and regular current of water, they made use of a syphon of glass C, one of the branches of which passed through one of the mouths of a flaggon, with two mouths almost filled with water. On the other mouth was placed a globular vessel turned upside down, and full of water. The neck of this vessel was of such a length as just to reach the surface of the water in the flaggon. Hence it is evident, that whenever the water ran out through the syphon so as to sink its surface below the mouth of the globular vessel, the water which filled that vessel would fall down and supply its place; so that the height of the water in the flaggon would remain always nearly the same, and of course the water would flow through the syphon pretty equably. The bore of the syphon was capillary, in order to make the current of water very slow.

This current of water was heated in the same manner as the current of the different gases in the preceding experiments: but when a current of hot water circulates slowly in a horizontal tube, it is impossible to determine its temperature exactly by means of a thermometer placed in the centre of the tube, on account of the unequal temperature of the different strata of fluid which constitute the current. It was then ascertained, by experiment, that a thermometer, thus placed, indicated a temperature much lower than the true temperature of the current. To get rid of this uncertainty, the apparatus was disposed in the manner represented in Fig. 20.

The current of water which flows from the syphon C is received into the tube DD, which passes through a larger tube EE, kept continually filled with steam, by means of the small boiler R. The tube DD is soldered to another tube FF, about 0.3 inch in diameter. In this tube, placed, as will be seen, almost vertical, are disposed three thermometers, Nos. 1, 2, 3, in such a manner that the small spherical bulb of each is in the centre of the tube, and at the distance of 1.083 inch from each other. These thermometers served to determine the temperature of the current of water at its entrance into the calorimeter. The tube FF is cemented to the horizontal tube of glass GG, which is cut at its end G, very near the junction, so that the bulb of the thermometer No. 1, which must necessarily be in the vertical tube, that it may acquire the temperature of the current of water, is, notwithstanding, no farther distant from the calorimeter than the first thermometer is from the third. The tube GG is shut by a stopper H, that no water may escape, and it is ground at its extremity G, so that by pressing it, by means of two screws, against a piece of leather placed on the calorimeter, it is sufficiently tight to prevent any water from escaping in that direction. The water comes out of the calorimeter by the tube OOO, which is capillary at the extremity P, from which it falls, drop by drop, into a graduated tube, which serves to measure the rapidity of the current. The calorimeter was placed, as in the preceding experiments, in a separate room, that the temperature of the ambient air might be less variable.

## PLATE CCXC.

Fig. 10. Is a Jack constructed by Bramah on the hydrostatic principle discovered by Pascal.

## PLATE CCC.

Fig. 1. Represents a side view or profile of the going part *only* of the ancient striking Clock made by Vick. A is a heavy weight suspended at the end of a long cord, coiled or wrapped round a cylinder or barrel B, which is fixed on the arbor or axis, *a*, *a*, the small ends of which, called pivots, *b*, *b*, *b*, turn in holes made in the frame plates C, DD. These plates, in the early clocks, were of iron, and connected or put together by means of upright iron kneed pieces or pillars E, E, formed from one of the plates standing at right angles to them. The ends of these pillars being tapped, and having a shoulder, went through holes in the other plate, and the whole was kept together by screwed nuts, one of which is seen near D, and the other at upper D, thus forming what is called the *frame*. The action of the weight A tends necessarily to turn the cylinder or barrel B, and if it was not restrained, it would fall with an accelerated motion; but one of the ends of the cylinder carries a wheel F, having

teeth of the ratchet form, against the faces of which the end of a click is opposed, to prevent the barrel turning without bringing the great wheel GG along with it. The *click* is attached to the great wheel by a screw, and having a hole in it, it has liberty to move on a plane or cylindrical part of the screw; and when the weight A is winding up, the click is pressed down by a spring into the teeth of the ratchet wheel, in order to prevent any returning. The ratchet, with the click and its spring, are called the *click-work*, and without them there could be no security after winding up the weight. It may then be easily conceived that the action of the weight is transmitted to the toothed or great wheel GG, the teeth of which enter into the spaces or openings of the teeth, which are formed on the small wheel or lantern pinion *e*, and in such a manner that they compel it to turn on its pivots *f*, *f*. This kind of communication by the teeth of one wheel with those of another, or with a pinion, is called *pitching*. The wheel H H is fixed on the axis of the lantern pinion *e*; so that the motion communicated by the weight A to the wheel G G is transmitted to the pinion *e*, and consequently to the wheel H H, which pitches into the lantern pinion *g*, whose axis carries the crown wheel I I, which is by foreign artists called the *wheel of rencounter*, or of the 'scapement; and the action of the weight A is transmitted by the crown wheel I I to the levers or pallets *h*, *i*, formed on the vertical axis K K, which turns on its pivots the upper pivot at *l*; the lower one near to K turns in a stud fixed to the plate DD. It is on this axis that the regulator or balance LL is fixed: this regulator is suspended by a small cord M, and it can describe arcs of a circle round its pivots, going and returning alternately on itself, or vibrating. The alternate motion, or vibration of the balance, is produced here by the action of the wheel I I upon the pallets of the axis K K of the balance, whose planes may stand at an angle of 90 degrees or so, and with the axis form what is called, in technical language, the *verge*;* so that when a tooth of the wheel has drawn aside the pallet *h*, and has escaped, the other pallet *i* presents itself to a tooth of the wheel on that side which is diametrically opposite, and is in its turn drawn aside also; so that, by the wheel turning always in the same way, the balance going and returning on itself, forms vibrations which moderate and regulate the velocity of the wheel I, and consequently of the wheels H and G, whose revolutions serve to measure the time. The reciprocal action of the teeth of the wheel I, on the pallets *h*, *i*, carried by the axis of the balance, and of the pallets themselves on the teeth of the wheel serving to regulate as well as to restrain the motion of it, is what is called the *'scapement*. The wheel GG makes a revolution in an hour; the pivot *b b* of this wheel is lengthened a little beyond the outside of the fore plate, and carries a pinion *n*, which pitches into or leads the wheel N N, causing it to make one turn in 12 hours. The axis of this wheel carries the index or hand O, which marks or points to the hours on the dial-plate. We must now explain how a revolution of the wheel G is determined, so as to be made in an hour precisely. To produce this effect, it is necessary to know that the vibrations of the regulator or balance become slower if it is made heavier, or if its diameter is increased. We suppose here, that the regulator LL must make vibrations whose duration is exactly equal to one second, which is obtained by bringing nearer or farther from the centre the weights *m*, *m*, which hang upon it. We shall now proceed to show how, by means of the number of the teeth of the wheels and leaves of the pinions, we determine that the wheel G is to make its revolution exactly in an hour. In giving 30 teeth to the crown wheel I, I, it will make one turn in the time that the regulator shall make 60 vibrations; for at each turn of the wheel, the same tooth acts once on the pallet *h*, and once on *i*, which gives two vibrations for each tooth; thus, the wheel having 30 teeth, it will cause twice 30 vibrations to be made, and will consequently make a revolution in a minute of time: it is requisite, then, that the crown wheel I, I should make 60 revolutions in the same time that the wheel G makes one. Moreover, to determine the number of the teeth of the wheels G, H, and of their pinions, it must be observed, that a wheel gives as many more turns to its pinion, during the time it makes one turn, according as the number of the leaves of the pinion is contained a greater number of times in that of the teeth of the wheel: For example, the wheel G having 64 teeth, and the lantern pinion *e* 8, this pinion will make eight turns during the time that the wheel makes one. In like manner, the wheel H having 60 teeth, and the pinion *g* 8, it will cause this pinion to make $7\frac{1}{2}$ turns; but the wheel H, carried by the pinion *e*, makes 8 turns for one of the wheel G, the pinion *g* makes then 8 times 7 turns and a half, that is to say 60, during the time that the wheel G makes a turn; and we have seen that the wheel I, I, carried by the pinion *g*, makes a revolution in a minute; the wheel G makes then a turn in an hour. We see, from the same principle, that the pinion *n* carried by the axis of the wheel G, must make 12 turns during the time that the wheel NN makes one. When the cord which suspends the weight A is wholly uncoiled from the barrel, or when the weight A is run down, a handle or winding up key, is put upon the square part formed on the arbor of the lantern pinion *n'*, which pitches with the teeth of the wheel *n'*, fixed on the arbor of the cylinder or barrel B; and in turning the winding up key, the weight ascends. This wheel, and the ratchet wheel F, can turn separately from the wheel G, which remains immoveable during the time of winding. The retrograde motion of the barrel is obtained by means of the ratchet and click-work. The teeth of the ratchet are inclined on one side, which serves to raise up the click, so that during the whole time of winding up the weight, the ratchet F and barrel B turn along with the wheel, which are forced about by turning the pinion *n'*, and all turn independently of the wheel G; but as soon as the weight, after being wound up, is left to itself, it acts on the cylinder and on the ratchet, the faces or right side of whose teeth butt against the end of the click, which obliges the wheel G to turn with the cylinder; the click spring, as has already been mentioned, serving to push the click down among the teeth of the ratchet. In a plate wheel which is attached to the wheel NN, twelve

* In clock verges the angle of the pallets is considerably less than 90 degrees, and in Vick's clock it would be so too.

pins are fixed equally distant from one another, whose use is to raise an arm up, by the lifting of which another arm is raised; the fly pinion of the striking part is then discharged, and the hour is struck by the force of the striking weight acting on its barrel and train of wheels contained in the clock frame: By these the hammer is raised, and gives a blow on the bell, either by its falling from the force of gravity, or by its being impelled by the force of a hammer spring.

Fig. 2. Is the Crown Wheel and Verge 'Scapement, as mentioned in HOROLOGY, Chap. I. p. 473, the principle and mechanism of which is the same as that which has been described in Vick's clock. It was long applied to clocks and watches before the application of a pendulum to the former, or before the invention and application of the spiral or balance spring to the latter. This spring had originally been called the *pendulum spring*, which it still improperly retains, no difference being made here in the name, whether it is the spring which suspends the pendulum of a clock, or moves the balance of a watch: when applied to it, the *balance spring* appears to be the proper term. The crown wheel and verge 'scapement is still used in common pocket watches.

Fig. 3. Is a side view of an Alarm Clock, the alarm part of which is nearly the same as the going part in Vick's clock. The iron frame of the alarm clock is formed much in the same manner as Vick's clock, only it has a bar or plate in the middle of the frame which serves to make it a double frame; one division of which, CD contains the going part, while the other, NO, contains the alarm part. H is the great wheel of the going part, carrying on its arbor a pulley, in the groove of which is fixed a few short steel points, serving to enter a little way into the texture of a cord wove either of silk or cotton. At one end of the cord is hung the going weight F; and at the other the counter weight G. This pulley with its socket and ratchet are fixed together, and turn freely on the arbor of the great wheel H. The ratchet click and click spring are upon the wheel H, so that, on pulling down the counter weight G, the weight F ascends. The old click and ratchet work consisted of a circular kind of steel spring, pinned down by one side against the bottom of the jagged and moveable pulley. The spring having a step made on it, acted both as click and spring, the arms or crosses of the wheel serving as a ratchet, the step of the spring stopping against them. The weight when wound up was kept there, and exerting its force on the pulley and wheel H, put the going part in motion. The first wheel H makes its revolution in an hour; its axis, which is also that of the pulley, has the fore pivot *b* prolonged outside of the fore plate C. This pivot carries a socket, on the end of which is the minute hand fitted by means of a square. On the lower end is fixed a wheel *c*, which pitches with the wheel *d* of the same diameter and number of teeth; the axis of the wheel *d* carries the pinion *e*, which leads the wheel *f*; this makes a revolution in 12 hours, and on its socket the hour hand is fitted spring tight.—The wheel H, which has 64 teeth, pitches into the pinion *g*, which has eight. The arbor of this pinion carries the wheel I, of 60 teeth. This again pitches into the pinion *h*, which makes 60 turns for one of the wheel H; it makes then a turn in a minute, and the hand *i*, carried by the long pivot from the axis of the pinion *h*, marks the seconds on the seconds circle of the dial. The axis of the seconds pinion *h* carries also the contrate wheel K, which has 48 teeth; it pitches into the pinion *k* of 12 teeth or leaves. The axis of this pinion carries the crown wheel, or wheel of rencounter L, of 15 teeth. This wheel makes 'scapement with the pallets *i*, *r*, carried by the axis of the balance MM, which is the regulator of this machine. At each revolution of the crown-wheel L the balance makes twice 15 or 30 vibrations, and this wheel makes four turns for one of the contrate or seconds wheel. Thus the balance makes 120 vibrations in a minute, and 7200 in an hour. Each of the vibrations is then equal to half a second of time; the seconds hand consequently gives half a second on the seconds circle. The mechanism of the alarm part, which is very simple, is contained in NO, the second division of the frame connected with that which contains the wheel-work of the going part of the clock. The crown-wheel P carries on its axis the jagged pulley Q, over which is laid the cord which supports the weight R, which puts the alarm part in motion, the counter-weight S being on the other end of the cord. The teeth of the crown-wheel P makes 'scapement with the pallets *n*, *o*, formed on the vertical axis or verge TV, the kneed or bent arm of which *p p*, *q q*, at the top of the figure, forms with *g x* the alarm hammer. This hammer has the form of a small cylinder, and carries two ends or buttons *x*, which strike alternately on the inner edges of a bell, which is not represented here. The alarm or crown-wheel P carries on its circumference a pin, which serves to stop the alarm, after having drawn up the alarm weight. This stopping is made by means of a detent at *p*, fixed into an arbor *p*, *q*, whose pivots run, one in the dial, the other in the back frame plate O of the alarm part. To discharge or set off the alarm, there is placed on the socket of the hour wheel another socket, which carries the small dial *t* for the hours of the alarm, and a counter spring *s*, in which is fixed a pin, which serves to raise the arm *r*, fixed on the same arbor *p*, *q* in which the detent is fixed, so that when the pin in the counterspring *s* raises up the arm *r*, the detent is raised up at the same time from the wheel P, and the pin which it carries getting disengaged, the alarm part immediately sets off, and the hammer strikes the bell with force and precipitation. In order that the alarm should set off at the precise hour that is required, or at which we wish to be awakened, it is only necessary to turn the small dial *t*, so as the number of the hour required is placed under the tail of the hour hand. If it is required that it sets off at four hours and a half, the tail of the hour hand will stand between the figures 4 and 5.

Fig. 4. Represents a Side View of Huygens's Clock, with the cycloidal cheek-pieces, which were put for the purpose of causing the long and short vibrations of the pendulum to be performed in equal times, a double and flexible silk thread, by which the pendulum was suspended, applying itself on the inner sides of these checks more or less, according to the extent of the arc described by the pendulum. A perspective view of the cheeks and of the double thread is seen in Fig. A. The brass frame plates of this clock as seen at AA, BB, placed vertically, 6 inches in height, and 2 inches and a half broad, are

connected by four brass pillars, turned and placed near the angles of the plates, their height being about one inch and a half: The pivots of the arbors of the principal wheels run in holes made for them in the plates. The first wheel marked CC has eighty teeth, and is two inches and a half in diameter. It carries on its arbor a pulley D; the bottom of the groove, being a very little convex, is furnished with steel points, to prevent the cord which goes over it from slipping, to which cord two weights are attached, as will be afterwards explained. The wheel CC deriving its motion from a weight, communicates it to the pinion E of eight leaves, and of consequence also to the wheel F of forty-eight teeth, having the same axis as the pinion. The wheel F conducts the pinion G and the contrate wheel H both upon the same axis. The contrate wheel has 48 teeth. It is from this last wheel that the pinion I, and the crown wheel K on the same vertical axis, receive their motion. The pinion I has 24 teeth or leaves. The crown wheel K carries 15 teeth, inclined as the figure represents. Two bridges are fixed on the top of the plate BB, the extremities of which carry the pivots of the axis LM, and the jutting out part Q of the bridge NQ has two holes pierced in it, through one of which the axis LM goes, and in the other, the upper pivot of the arbor of the crown wheel K runs. The same axis LM (which passes also through the plate BB) carries two pallets, which must be raised up alternately and in a contrary direction by the teeth of the wheel K. The part M of the axis LM, which goes beyond the frame plate, carries the fork MS, between two branches of which passes the rod VV of the pendulum VX, suspended by means of two threads between the two cycloidal cheeks, which are distinctly seen in Fig. A. With regard to the curve formed on the cheeks, we will speak of it more at length afterwards; at present let us attend to the movement of the clock. It is evident at first, that the pendulum having been drawn aside from the perpendicular and then left to itself, this will not only allow the teeth of the wheel K to pass successively, but the motion impressed by the force of the weight will cause the teeth of the wheel K to act on the pallets of the verge LM, and by this means and that of the fork restore to the pendulum that motion, which friction, or the resistance of the air, would insensibly take away from it; and although in ordinary clocks the wheel K does not always act with the same force, the curve that has been given to the cheeks, on which the threads of the pendulum must apply themselves, subjects the pendulum to make its oscillations all in the same length of time so long as its length remains the same, determines the teeth of the wheel K to pass only in equal times, and consequently gives uniformity to all the other parts of the clock, since their motions are proportional: So that, whatever fault there might be in the construction, whatever difficulties in the motion of the wheel-work, occasioned by change of temperature in the air, provided that the motion of the clock is not wholly interrupted, there will no inequality result from it; the clock will always measure time exactly, or it will not measure it at all. *g g* is a third plate, parallel to the two former, and distant about a quarter of an inch from the plate AA. In the centre of the dial which is traced on this plate, the arbor of the wheel CC prolonged comes through. On this dial are traced two concentric circles, the one divided into twelve, the other into sixty parts. On the arbor of the wheel CC, and outside of the plate AA, is put spring-tight the cannon or socket of the wheel *a*. This cannon is prolonged or carried out near to *e* through the plate *g g*, and turns with the wheel CC, and can also be made to turn independently of it when it is necessary; this is when setting the hands. It is at the point *e* that the minute hand is placed. With regard to the wheel *a*, it conducts a wheel *b* of the same number of teeth with itself, and whose axis carries a pinion of six leaves, whose pivots on the one part run in the plate AA, on the other in the cock or bridge *c* fixed to the same plate. Finally, this latter pinion conducts or leads the wheel *d* of 72 teeth, the socket of which goes on that of the wheel *a*, terminates under *e*, and passes like it through the plate *g g*. The extremity of this socket carries the hour hand, which is made a little shorter than that of the minute hand. With regard to the seconds, to avoid confusion, the axis of the wheel H, which is prolonged nearly as far as the plate *g g*, carries a small dial *f f* divided into 60 parts, which turns in the same time as the wheel H, and an index *g*, fixed to the upper part of an opening made in the plate *g g*, marks the seconds, according as the divisions pass the index. Let us examine now, if the number of teeth that we have assigned to the wheels agrees with the revolutions which we require of them. There results from these numbers, that at each turn of the wheel C, the wheel F will make 10 turns, the wheel H 60, the wheel K 120; and as this last has 15 teeth which raise up alternately the pallets LL, that is to say, that during one revolution of the wheel K, each tooth will raise up the two pallets during the time of this same revolution, the pendulum will make 30 vibrations, and consequently it will make 3600 during one turn of the wheel C, each being equal to one second. The wheel C will then make its turn in an hour. The same will be done by the wheels *a* and *b*; and as the pinion of the last conducts the hour wheel* *d* twelve times more in number than itself, it will then cause it to make, as well as the hand placed on its socket near to *e*, a revolution in twelve hours. Then as the wheel H makes, as we have said, 60 turns for one turn of the wheel C, which it does in an hour, the small dial *f f* will make a turn in a minute. The weight of the pendulum is three pounds, and is made wholly of lead, covered over with very thin brass. But to avoid the effects of the resistance of the air, it is not enough to use too heavy a pendulum; some attention must be paid to its outward form. It is for this reason that we have given it the figure of a cylinder standing the wrong way, the ends of which are finished off to a point. However, if this clock were to be employed at sea, a lenticular form would be preferable.

We see in Plate CCCIV. Fig. 6. the manner by which the going weight of Huygen's clock is suspended, so that the motion of the clock shall con-

* This wheel has, in the language of workmen, been always called the *hour wheel,* although it takes twelve hours to make one revolution.

tinue even at the time while this going weight is winding up; a thing which had not hitherto been thought of, and which deserves some consideration. The cord which is used here is continuous, that is to say, the two ends of it are joined together in such a way as to have no appearance of being joined. This cord being passed over the pulley D of the clock, Fig. 4. Plate CCC. represented here by A, from whence it descends and takes in the pulley by which the main weight P is suspended. From this pulley it is carried up and passed over the pulley H, moveable on a stud fixed to one of the frame plates. This pulley, like that of D in Fig. 4 is furnished with points in the bottom of the groove to prevent the cord from slipping, and has also teeth cut in the ratchet form, in such a way, that it can turn when we draw down one of the cords from H, and cannot turn the contrary way by action of the weight P, being kept back or restrained by the end of a click which comes against the right side or face of the ratchet wheel teeth. From this ratchet pulley the cord comes down, and takes in the pully to which the small counter weight $p$ is hung, whose purpose, along with that of the ratchet, is to prevent the main weight P from descending in any other way than by making the pulley D of the clock turn, carried by the first wheel C, and represented by A, Fig. 6. It is obvious, that by this arrangement the main weight P employs always the half of its force to turn the wheel work, and the effort of this force is not suspended during the time of the weight being wound up, so that no time is lost, the clock continuing to go during the time of winding up the main weight P. Certain rules cannot well be given to determine the quantity that the main weight P should have; but it may be said in general, that a clock has been so much the better contrived and executed, the less the weight shall be that is required to keep it going. In the best that has been made, according to the principles which we have given, this weight was about six pounds; that of the pendulum ball being three. These clocks, suspended or placed about the height of a man, would go for about thirty hours.

Fig. 5. of Plate CCC. Represents the Anchor 'Scapement, an invention claimed by Dr Hooke, as well as by W. Clement, a clockmaker in London. The 'scapement wheel SW being flat, and having saw or ratchet-like teeth, has a different appearance from that of the ancient crown wheel; the pallets P, P supply the place of the pallets or verge used with the crown wheel. The properties of the anchor 'scapement are taken notice of in p. 476. of our article Horology. The crown wheel and verge 'scapement gave a considerable recoil to the wheels, which was lessened in a small degree in the anchor one. From what has been said respecting the number of vibrations given by the crown wheel of 15 teeth and its verge, it will be seen, that since the ratchet kind of wheel in the anchor 'scapement has 30 teeth, and since each tooth acts on both pallets, then, as the motion of one pallet is equal to one vibration, one revolution of the wheel will be equal to 60 vibrations, and with a pendulum of the proper length will be equal to one minute. Objections having been made to the principle of the recoiling 'scapement, one of a contrary nature was contrived by the celebrated George Graham, and got the name of the *dead beat 'scapement*.

Fig. 6. Is a representation of Graham's *Dead Beat 'Scapement*. SW is the 'scapement wheel, or swing wheel, being so called from the swinging of the pendulum by the motion communicated to it by the wheel. P, P are the pallets, which have a small portion made circular, by taking their length as a *radius* from the centre of the arbor on which they are fixed, to the place where the teeth of the wheel rest on them, and describing small portions of circles on the piece of steel from which the pallets are to be formed. It is by the wheel teeth resting on the circular parts of the pallets during a part of the motion of the pendulum, and however more or less this may be, yet no motion can be given to the wheel teeth either forward or backward; at this time the seconds hand appears still or *dead*. The time of rest is on the inside circular part of the right hand pallet, and on the outside circular part of the left one, in the figure a tooth here seen on this side, after giving, by means of the left hand flanch, impulse to the pendulum, is just escaped from the pallet, another tooth at this instant gets on the right hand pallet, where, after resting on the inside circular part, it gets on the flanch, and in its turn gives impulse, and so on.

Fig. 7. Represents an improvement on Graham's Dead Beat 'Scapement, made by Lepaute. The first piece of this 'scapement is an arbor, placed horizontally in F, and bearing in the two plates of the clock frame to which it is perpendicular. The ends of this arbor terminate with pivots. On this arbor are two levers, bent in or crooked at one end FA $e$, HB $d$, and are twisted pretty firmly on the arbor, in such a way that they can be opened from one another more or less, so as to put them at pleasure to the angle necessary for the effects which they are required to produce when 'scaping. The parts RI, LS of the levers are arcs of the circle, whose centre is in the same plane with the wheel and at the axis F, but they are finished by the inclined planes I $e$, L $d$. The lever F A $e$ passes behind the wheel, whilst the lever HB $d$ is on the front side of it. On the surface or flat sides of the wheel, pins are placed perpendicular to the flat sides. The pins $x$ and $y$ (left white) are on the front side of the wheel. The pins $m$, $n$ placed alternately with the others, are on the opposite side. The wheel advancing by the motive force from $u$ towards $x$, the pins of the front side meet the inclined plane L $d$, and push it towards B. By this motion, the lever FA $e$, which is on the opposite side of the wheel, advances under the next following pin. At the time when the pin V has escaped from the point $d$, and the lever or pallet continuing to recede by the force of the impulsion impressed on the pendulum, the following pin $u$ finds itself on the concave circular part RI, which is the arc of repose or rest. The levers being returned or brought back from the side A by the descending oscillation of the pendulum, the pin which was resting or sliding on the arc RI, immediately meets with the flanch or inclined plane I $e$, on which it acts as the former did, but in a contrary direction, in pushing the levers from $e$ to A, until the following pin comes to find itself on the constant arc LS, to fall from it again on the inclined plane L $d$, and so on. The pin teeth of this wheel are thirty in number on each side, and are placed in such a manner that the inside diameter of the pins on the hinder side shall

coincide with the outside diameter of those on the front which impel the front pallet; the other set impel the pallet behind the wheel: the pins are cut one half away on the side length, in order to allow the pallets to drop off when at the extremity of the diameter of the pin. Lepaute's 'scapement has been made for pocket watches, and in place of such length of levers as are at the pallets of a clock 'scapement of this kind, those in a watch are formed into a short kind of crank which connects the pallets together.

Fig. 8. Represents the wheel and pallets of the recoiling 'scapement, nearly such as it is made at the present day. P, P, are the pallets; S, W, the swing wheel; the front or right side of the teeth follow the curved part. In the dead beat 'scapement wheel of Graham's, the right side of the tooth leads or goes first; this difference is to give the pallets in each way freedom to come down between their corresponding teeth.

Fig. 9. Is a side view of the 'Scapement contrived by Mudge for his marine time-keepers. BB represents the balance seen edgewise. AA, the balance wheel, formed somewhat in the manner of the ancient crown wheel, only the space between the teeth are more enlarged, to give room for the falling in of the pallets. F, the pendulum or balance spiral spring, the inner end of which is attached to the axis of the balance; the outer end to the stud G, which is screwed on the cock: it is by this spring that the time keeper is regulated. H, the pendulum or spiral spring which is acted upon by the compensation pieces: The inner end of this spiral is attached also to the axis of the balance; the outer end is fixed in the stud I, which is screwed to the upper plate. CC is a double kneed piece or crank, which connects the balance and its upper pivot with the lower one, or foot pivot as it is commonly called. D and E are two separate arbors, whose pivots run into cocks which are not represented here, neither are those which support the crown wheel pinion. Each of these arbors have a curved kind of pallet made of some fine hard stone, having a nib or detent at the edge on which the crown wheel teeth stop, after having so far raised up the pallets. *i* and *k* are screws which fix the pallets to their arbors. It is easy to conceive that the force of the crown wheel is derived from the main spring through the intervention of the wheels in the movement. From each of the arbors D, E, small arms *a*, *b* proceed or project; the upper one *a* takes hold of a pin *c* on the outside, which is fixed to the upper knee of the crank; the lower arm *b* takes hold likewise on the outside of the pin *d*, which is fixed on the inside of the lower knee of the crank; *e* and *f* are small spiral springs, whose inner ends are fixed to the arbors D and E, and the outer ends to the studs *g* and *h*. The pallets are not seen in the Figure; for if they had been represented, it would have given obscurity to the other parts. From what has been said, it is however expected, that all the parts of the 'scapement may easily be comprehended, and we shall now describe the way in which they act. For example, let a tooth of the wheel be at liberty to raise up the upper pallet which is on the arbor D; in doing which, the course of the wheel, when acting in its proper direction on the pallet, tends to carry away or turn the arm *a* from beyond the crank pin *c*; when the pallet is raised up, the tooth of the wheel stops on the nib, and gets no farther for the present; the pallet on the lower arbor E is allowed at this time to come down, and falls between the teeth. In its course this way, the balance being on the return from one of its vibrations, it makes the crank pin *c* come against the side or near the end of the arm *a*, carrying it on a little way; at the instant of the pin *c* meeting with the arm *a*, the crown wheel teeth get disengaged from the nib or detent of the pallet, and at the same instant the pallet on the arbor E is raised up, and the wheel stops; in the mean time the balance, making its excursion, carries the arm *a* with it, and consequently bends up a little more the small spiral *e*. After the force of the balance is spent, it returns again by means of the action of the small spiral spring, which makes the arm *a* press against the pin *c*, and in this way the motion of the balance is kept up. Near the end of this return, the crank pin *d* carries away the arm *b*, the wheel gets unlocked and raises the upper pallet, and so on. There is certainly great ingenuity displayed in the contrivance and principle of this 'scapement, so far as regards the keeping up the balance to a constant arc of vibration, and making it, as it were, totally independent of any inequality or irregularity that might arise from the mainspring and pitching of the wheels. Those time-keepers, with this 'scapement, which were executed by Mudge himself, seem to have performed well; but notwithstanding this, they failed in the hands of others; and it must be allowed, that the 'scapement is too complex and operose for the execution of any artist.

## PLATE CCCI.

Figs. 1, 2. Represent a Clock 'Scapement by Mr Thomas Reid.

Figs. 3, 4, 5. Represent another Clock 'Scapement by Mr Reid.

Figs. 6, 7, 8. Represent Harrison's Clock 'Scapement without oil.

These Figures are fully described in Horology, p. 477, 478, 479.

## PLATE CCCII.

Fig. 1. Represents a general view of a Watch Movement, which is fully described in Horology, p. 482.

Fig. 2. Represents a Frame, containing a 'Scapement contrived by Huygens. The object of the inventor was to give great arcs of vibration to the balance, or rather to make it have a few revolutions. AB is the frame; CC, the balance, and *a a* its spiral spring. EE is the crown wheel, with its pinion placed in the frame where the contrate wheel is usually put, the teeth 'scaping with the verge *f e*. On the verge, as an axis, is put a contrate wheel DD, which is placed where the crown wheel and pinion are commonly put, the teeth of the wheel DD acting on a pinion *d*, whose arbor carries the balance CC. The action of the pallets *f*, *e* upon the crown wheel EE, will cause a considerable portion of the wheel DD to turn, and consequently to give a few revolutions to the pinion, which will depend in some degree on the number of its leaves. This

sort of 'scapement is called by the French artists, *échappement à pirouette*.

Fig. 3. Is a perspective view of the Horizontal or Cylinder 'Scapement of Graham, which has been long and successfully used in pocket watches. F with its pinion is the 'scapement or balance wheel, the teeth of which are shaped like a wedge or inclined plane, as seen at *a*, *b*, *c*, and act on the edges of an opening made in a cannon A of steel well hardened, which is called the cylinder. Copper plugs are put in at each end of the cannon, and in these are inserted pieces of well tempered steel, from the ends of which the pivots 1, 2, of the balance B are formed. The balance is rivetted on the upper copper plug. The inclined planes of the teeth in the cylinder 'scapement are made on the wheel to facilitate the extent of the vibrations of the balance, which can describe a whole revolution nearly. Therefore, the inner diameter of the cylinder being equal to the length of a tooth, can be made to turn round the tooth nearly a whole turn; and as the cylinder is concentric with its pivots, the wheel, remains at rest during the time that the point of a tooth is stayed, or dwells on the cylinder, whether it is on the inside or outside of it.

Fig. 4. Contains two views of Debaufre's 'Scapement. WW is a front view of the balance wheels, which are seen edgewise in the other view. AB is the balance, on the verge or axis of which, CD, is put the pallet E; the flat end or base of which is uppermost, and is a little more than a semicircle, having a flanch made below and opposite to it. The body of the pallet behind the flanch is rounded down, and narrowed conically towards the lowest end of the flanch, which is here not a point, but in form a little round, somewhat resembling the curve of an inverted parabola. When a tooth of any of the two wheels passes down on the flanch, this gives impulse to the balance, causing it to turn or give a vibration. The tooth having escaped the flanch, a tooth of the other wheel falls on the semicircular base of the pallet, where it remains at rest during the going and returning of the balance, when this tooth in its turn gets on the flanch, and gives impulse to the balance in a direction opposite to that given by the teeth of the other wheel, and so on.

Fig. 5. Represents a 'Scapement by the Abbé Houtefeuille. The teeth of the wheel A are made to 'scape with the pallets B, which have somewhat of the anchor or recoiling form. On the same arbor with the pallets is fixed a rack or small portion of a toothed circle *b*, the teeth of which work or pitch into a small pinion *a*, not properly seen in the Figure. On the arbor of this pinion the balance CD is rivetted; the teeth of the 'scapement wheel urging the pallets, first on one side and then on the other, gives a small circular motion to the rack backward and forward, which makes the pinion and balance to have one, two or more turns likewise backward and forward; the turns are according to the radius of the rack and number of leaves in the pinion. In the drawing, the balance wheel and balance seem as if they were on the same arbor and centre, with the design of having the figure more compact. The middle of the small dark circular space near E may be considered as the place for the pinion or balance arbor; and the dark arm from the pallets that of the rack whose teeth work into the pinion. The faces, or acting parts of the pallets, are in general set with some fine hard stone, such as ruby or sapphire.

Fig. 6. Represents Dutertre's 'Scapement for a Watch. The toothed wheels, or balances A and B, are of equal diameter and pitch with one another. They are placed outside of the upper plate, as well as the double ratchet, consisting each of five teeth; the arbors on which these are fixed are supported each by a cock. The pallets D and E are fixed on an arm of their respective balances, and the arbors of the balances have each a notch in them to allow the teeth of the great ratchet to pass through them. They act in this way. When the point of a tooth of the great ratchet meets with the notch in the arbor of the balance B, it passes. The tooth 3 of the small ratchet strikes the pallet D, and makes the balances to vibrate. On the tooth 3 escaping, the tooth 4 of the great ratchet is detained by the arbor of the balance A; the return of the balance causes the notch to present itself to the tooth 4; it then passes, and the tooth 3 comes and strikes on the pallet E. After having escaped the point 5 is detained by the arbor of the balance B, and so on successively. Under one of the balances B is placed the spiral. These balances cannot vibrate without the spiral spring.

Fig. 7. Represents Dutertre's clock 'scapement. AB is the wheel of *arréte*, or repose; CD the wheel of impulse; both having the same number of teeth, but differing greatly in their diameters. E is the pallet seen on its arbor, in which is a notch to allow the teeth of the wheel of *arréte* to pass; at the instant of this taking place, the teeth of the lesser wheel give impulse to the pallet, and having escaped it, a tooth of the larger wheel falls on the circular part of the pallet arbor. See Horology, p. 487.

Fig. 8. Is the Duplex 'Scapement, of late much used in watches, the principle of which is obviously the same as that of Fig. 7. as a slight inspection of the Figures will show. WW is the balance-wheel, the long teeth of which serve as a wheel of repose, or *arréte*, which takes place at the time of their coming on to a very small ruby cylinder, fixed on the lower part of the pallet arbor. On this wheel, the teeth of impulse are formed, and stand a little up from the plane of it. A section of them is seen at the letters *a*, *b*, *c*. That of *a* may be supposed impelling the pallet AB, one of the teeth of the wheel of *arréte* having previously left the small ruby cylinder, which is represented by the dotted broken circle under the pallet AB, both of which as well as the balance, are on the same arbor. For a farther description of this 'scapement, see Horology, p. 488.

Fig. 9. Is a kind of perspective view of the 'Scapement known to workmen *formerly* by the name of that with the tumbling pallets. WW is the common crown wheel, and A, B, two semi-cylindrical pallets, formed on the verge or axis of the balance. For other particulars regarding it, see Horology, p. 488.

## PLATE CCCIII.

Fig. 1. Contains two views of what has been called Kendal's 'Scapement; one of which may be properly so called, as being an alteration of that of the crown-wheel and verge with semi-cylindrical pallets. The crown-wheel of the first is represented at AB, and a plan of it is seen at CD. *t* may be supposed to give a view of both the pallets; the light part be-

ing the upper pallet ; and the shaded, or dark part, the lower one. The action of the teeth and pallets of this 'scapement is the same as that of the tumbling pallets, or semi-cylindrical verge. When a tooth has escaped from the upper pallet, that on the opposite side of the wheel falls on the cylindrical part of the pallet below, and does not get on the face or flat part of it until the going and returning of the vibration of the balance; at the instant when the tooth gets on the face, it gives impulse to the lower pallet ; and so on. Mr Kendal, as has been formerly mentioned, put two crown-wheels on the same pinion arbor, and used one pallet only. A part of the wheels *w*, *w*, and the pallet *p p*, are seen at Fig. 1. The wheel on the right side of the pallet is represented as just on the escape from the flat part of the pallet. This being made, the other wheel has a tooth which falls on the circular part, where it rests until the return of the balance from that side, to which the tooth of the right hand wheel gave impulse ; then the wheel on the left will give impulse in its turn on the face of the same pallet ; and so on.

Fig. 2. Represents the Detached 'Scapement as made by the late Mr Arnold, and by his son the present Mr Arnold, for box chronometers. The 'scapement or balance-wheel A having 12 teeth, is calculated to have a train of 14,400; and by the seconds hand, half of a second will be marked at every step by it on the seconds circle on the dial. The acting part, or face of the tooth, is partly in the form of a cycloidal curve, and stands above the plane of the wheel, as represented in the edge view given of it; in the plan, the shaded or dark part of the tooth may be supposed either the upper end or top, or a section of it; the other two sides are flat, or bounded by right lines, the longest of which, with the cycloidal curve, form an angle ; and on this angle the wheel is locked by the spring detent CD, in which is set a small bit of fine stone, either of ruby or sapphire, for the purpose of the wheel being locked on it. This bit of stone may be supposed to be put into the spring detent, so as to stand near the point of the adjusting screw *b*, or nearly where the letter *a* is. It is by the screw *b* that the detent piece can be made to have more or less hold of the angle on the tooth. The end of the detent stone piece must be of such a length or height as to be quite free from the inside bottom of the wheel. R, is the main pallet or roller, having an opening or notch in it, the lower end of which being what is called the face of the pallet, in which is set a piece of precious stone, as seen at *c*. It is on it that the curved part of the tooth acts. As represented in the Figure, the tooth 1 has carried the pallet so far on, by a distance equal to that between tooth 2 and the point of the adjusting screw. Concentric with the main pallet R is a small lifting pallet *d*, whose use is to unlock the wheel, by pressing on the side end of the lifting spring D, and carrying it so far inwards, takes the detent and its spring along with it; the detent piece of stone by this means getting free of the angle of the tooth at *a*, the wheel gets forward, and the tooth 1 gives impulse to the main pallet R. During the first part of the impulse, and before the impelling tooth gets so far on as is here represented, or it may not take place till the tooth gets a little farther on, the end of the lifting spring parts with the lifting pallet *d*, leaving the detent and its spring at liberty; the detent then, by means of its spring, comes quickly to its place at *a*, and before tooth 1 has escaped, is ready to receive tooth 3, and lock it. On the balance returning from the vibration given by this impulse, the pallet *d*, meeting with the end of the delicate lifting spring, carries it so far outwards, and then parts with it, to complete its vibration on this side. It is evident that the point of the adjusting screw opposes the detent being carried that way, although the lifting spring is, and is at the same time connected with the detent spring, but extends so far beyond the end of the detent spring, that the lifting pallet *d*, whether going or returning, cannot touch it, but cannot pass either way without meeting with the side ends of the lifting spring, and working on it. The detent spring is screwed to one of the frame plates by the paume or sole, near to which it is made very thin and weak ; and at this place the centre of motion of the detent piece may be supposed to lie. The lifting spring is pinned by one end to the side of the detent spring, which may be called the outside of it. It is easy to perceive that the unlocking is made by carrying the detent spring inwards, or towards the centre of the wheel. When this takes place, the cycloidal part of the tooth falls (not on the point, but a little within it,) on the blunted edge, or nearly so, of the face of the pallet; having given impulse, and escaping, the wheel is again locked ; and so on. The wheel is unlocked at every alternate vibration of the balance, or 7200 times in an hour, or 120 times in a minute; hence half seconds are marked out on the dial by the seconds hand. The diameter of the main pallet R may be made at the option of the 'scapement maker, in any proportion to that of the wheel, but it must always stand, when the wheel is locked, free between the teeth; and the impulse given by the wheel to it will be so much more direct, the less the difference of the diameters. And in this experience is the best test; but it requires long and reiterated trials.

Fig. 3. Shews the Detached 'Scapement made by Mr Earnshaw for his box chronometers. The balance wheel ABCD is plain or flat, made of steel and sometimes of brass, the teeth have somewhat of the ratchet form, and are considerably undercut on the face, the number of teeth in it being 12, and calculated so as to give half seconds by the steps of the seconds hand on the seconds circle, in the same way as we have mentioned in Arnold's. The steel roller or main pallet MSK has an opening in it, the face of which is also much undercut, having a piece of some fine stone, such as hard ruby or sapphire set into it, as seen at *l h*, for the purpose of making the points of the teeth work smoothly on it, and preventing any wearing from their constant action. A stud G is fixed to the potence plate ; and to this stud the detent spring FF is screwed, and made very slender and weak near the stud. It is by the yielding at this place that any motion can be given to the detent on which the wheel is locked ; and here is its centre of motion. The tooth D of the wheel is supposed to be locked on a flat side of the stone detent, which is fixed in a thick part of the detent spring, by means of which it presses against the inside of the head of the adjusting screw *m*, which works in a fixed stud *a* P, so that when it is screwed into this stud the detent will have less hold of the tooth, and *vice versa*. Y is a delicate spring attached to the

inner side of the detent spring, and which is called the lifting spring. The end of the detent spring is bent a very little, so that the free end of the lifting spring may bear only on the inward bent point at *o*. Concentric with the main pallet is the small lifting pallet *u*, which is flat on the face or lifting side, and tapered or rounded off on the opposite side. Its position in the Figure represents it coming with its face against the lifting spring, which it would carry away with it; but this cannot have place without taking along with it the detent spring, and consequently the detent is carried out from locking a tooth of the wheel at D. By this time the main pallet has got so far forward as to be in the way of receiving impulse from the tooth B, and before it can escape, the lifting pallet parts with the end of the lifting spring, and leaves the detent and detent spring immediately to resume their place. The detent will then be ready to receive the tooth C, by which the wheel is again locked. The balance having performed this vibration by the impulse given, returns, and with it the lifting pallet *u*, the tapered side of which will press the lifting spring inwards, but cannot carry the detent spring with it, this being prevented by the inside part of the head of the adjusting screw *m*; after passing the lifting spring, it goes along with the vibration of the balance, on whose return the face of it will again meet with the lifting spring; unlocking then takes place, and so on. The unlocking here is performed by carrying the detent outward from the centre of the wheel, which is locked by the extreme points of the teeth. Mr Earnshaw gives as a rule for making the inclination of the faces of the teeth and main pallet, that they should be in a line drawn from the points of the teeth as a tangent to a circle, whose diameter is half of that of the wheel; and the same rule is used for the face of the pallet, which is shewn by the dotted lines and circle in the figure. As the detent stone piece on which the tooth D is locked, being set into that side of the detent spring lying undermost in the Figure, it cannot therefore be well represented here. The points or dots at the letters *k* and *a*, shew the relative positions of being locked and unlocked. The flat part of the stone detent goes a very little way in, as at *k*, to receive the point of the tooth A, on the opposite side of the wheel when locking is supposed; and at unlocking, the dot at *a* may be supposed to be the utmost extent of the detent, when carried out by the detent and lifting springs at that time. The detent spring lies above, and clear of the wheel; and the detent stone piece may be either a semi-cylinder or an angular piece. A flat side is, however, in either way, requisite for the tooth of the wheel to lock on it; and the height or length of this stone should be a little below the under side of the wheel, so that the teeth may at all times have a sure hold on it. Mr Earnshaw has stated, that he makes the diameter of his roller or pallet larger than that of Arnold's, which will no doubt allow the teeth of the wheel to give a more direct impulse on it; the diameter of the roller, however, if carried too far, would lessen the hold of the teeth on the pallet. Where a wheel of 12 teeth is used, it will give scope for getting in a pallet of considerable length. If the drawings in the specifications are correct, the proportion between the diameter of the balance-wheel and of the roller seems to be the same, or nearly the same, in Arnold's and Earnshaw's 'scapements.

Fig. 4. Is a contrivance of Mr Owen Robinson's, for a detached or free 'scapement, where the unlocking should be easier effected than it is done, either in Arnold's or Earnshaw's. AB, AB is a view of the balance wheel, both in plan and edgewise, being somewhat similar to the wheel in the duplex 'scapement, that is, the upright teeth are those which give impulse to the pallet, while the long teeth in the plane of the wheel are those which lock on the detent; R is the roller or pallet, the acting face of which may be supposed to have a piece of fine stone inserted there, as in the two former 'scapements; *d s*, the detent spring screwed to the potence plate, and made rather weaker at a place between *s* and the sole than any where else. It is at this place only where it will readily bend or yield, which becomes, as it were, a centre of motion to the detent. At the thick part *d* the stone for the detent is inserted; the white part at *d* may be supposed the upper end of it, and a tooth of the wheel locked on the flat side next the centre of the roller; *l l* is the lifting spring attached to the inside of the detent spring. A part of both these springs lying under the roller cannot properly be represented. The extreme or free end of the lifting spring goes a little beyond that of the detent spring, so that the lifting pallet can never pass without touching it, but while passing, it never can touch the end of the detent spring: The lifting pallet is not easily seen, but is of the same form as that in Fig. 3. where the adjusting screw and stud is the same as may be supposed for Fig. 4. although not drawn there. The face of the lifting pallet is just on the eve of touching the lifting spring; carrying it on a little way would unlock the wheel, and the pallet face being brought to a part where its edge, as seen in the Figure, would be ready to receive impulse from one of the upright teeth. The action of this 'scapement is quite the same as that of the others; the great difference of radius in the diameter of the wheel of impulse, and of the locking wheel, causes this to press with less force on the detent than those which have been mentioned; the unlocking is outwards, or receding from the extremity of the points of the teeth; and when locked, the roller stands free between the teeth of impulse.

Fig. 5. Is a view of a free or detached 'scapement, contrived by Mr Mudge, and which may be said to be the first of the kind where any ingenuity was displayed, or from which any utility was derived. It gives impulse at each vibration, whereas those which have been described give an impulse at alternate vibrations. The 'scapement, or balance wheel AB, and pallets *a*, are nearly like those in Graham's dead beat 'scapement. When the point of the tooth escapes the flanch of the right hand pallet, the point of another tooth is ready to fall on the outside circular part of the left hand pallet, just within the edge formed by the flanch and circular part; here it rests during the going and returning part of the vibration of the balance from the impulse received or given. Fixed on the same arbor with the pallets is a long arm, on the end of which, and near to the arbor of the balance, a forked piece is put or fixed, between the prongs of which a small pallet works; this pallet being on the

axis or arbor of the balance, returns with it, and getting within the prongs, carries the right hand one a little more to that side, this setting the main pallet on the left hand away from its state of rest, and being carried a little more to the same side, by which the wheel is unlocked getting forward, it gives impulse by the tooth that had just now been reposing from its action on the flanch of the pallet, and which is communicated to the small pallet by the left hand prong impelling it on the opposite side to that by which it unlocked the wheel. After the tooth has escaped from the main *pallet* on the left hand, another tooth will fall on the inside circular part of the right hand one, and repose there until the return of the balance from its course of vibration, when the unlocking of the wheel again takes place, by the small pallet carrying away to a side the prong on the left; that on the right following, gives new impulse on the small pallet, by the force of the wheel tooth on the flanch of the main pallet on the right hand, and so on. In order that no external or any sort of motion shall make the main pallets recede from their state of rest, which might happen, and would derange the 'scapement if there was no provision made against accidents of this sort, a small roller, having a notch in the edge of it, is fixed on the arbor of the balance, and a pin on the long arm from the pallets remains on the outside of the roller during the time of rest by the wheel teeth; the edge of the roller prevents by this means the unlocking, until the return of the small pallet; and to prevent the pin getting away in an opposite direction, two pins in the potence plate limit the excursions *that way*, by confining the long arm connected with the main pallets: when they are in their relative situation to the pin outside of the roller, these pins are represented white, and seen near the end of the arm; the fork, and the parts of action connected with it, are seen at *b*. When the balance vibrates freely and independently of every part, it is at the time when the teeth rest on the circular part of the pallets either inside or outside. The arm in this drawing is rather longer than in the original drawing of Mudge's, and was taken from a 'scapement of this sort in a watch made by Emery for the late M. le President Sarron in France, which is said to have performed extremely well. The spiral and stud, shewn by dotted lines, will easily be recognised as the pendulum or balance spring, whose inner end is fixed to the axis of the balance, and the outer end to the stud.

Fig. 6. Shews the wheels and pallet of Mr Kendal's 'scapement, which the late Mr Howells made into a detached one. AB, AB are two crown wheels, fixed on *p*, *p*, the balance-wheel pinion arbor; the pallet is a semi-cylindric one, to a collet on the axis of which the balance RR is rivetted; *h* is the axis or centre of motion to the long forked arm, and its counterpoise the lowest *d*; the highest *d* is a detent on both sides of the arm; the two screws *b b*, are screwed into fixed studs, (not represented here) for adjusting the quantity of holding of the teeth on the detents *d* of the long arm, which has a fork and pin at the end of it. On the lower end of the arbor of the balance is fixed a notched roller, and an unlocking or locking pallet, for it serves both purposes, which gets occasionally for this purpose between the prongs of the fork, and the pin gets either at one edge or other of the roller, passing the notch with it; the screws *b*, *b*, serve not only as adjusting screws for the detents, but also as a sort of banking, as it may technically be called, to keep them in their places of locking. For example, the outer arm in the Figure is close by the screw on the right hand, and the pin at the end of the other arm is at the same time on the left edge of the roller; the wheel AB on the left being now locked, the arms cannot turn either way on the pivots of the axis at *h*, until the return of the balance, and with it the unlocking pallet, as at this time it may be so called, which, getting in between the prongs of the fork, carries away the arm and detent *d* from the locking of the wheel; so soon as the tooth has escaped the detent, the semicylindric pallet by this time is in the way of being impelled by a tooth of the wheel on the right; and before the tooth has escaped from the pallet, one of the detents *d* is in the way ready to receive, and lock a tooth of the wheel on the right hand; the arm going in between the wheels, locks those teeth at a place which stands nearly at right angles to those which give impulse to the pallet. During the time the wheels are locked, either on the one detent or the other, the balance vibrates freely from any thing that could impede its motion, and it gets an impulse at every vibration. The sole use of the fork here, is for leading the detents to lock or to unlock the wheels, no impulse being given by it to the pallet which works between the prongs, as was the case with the fork in Mudge's 'scapement. The impulse given by the teeth of the wheels here is very direct, and of course with little friction, and this will depend on the distance of the tops of the teeth of the wheels from each other, which determines the diameter or face of the semicylindric pallet. Indeed it is of little consequence here whether the face of the pallet has a semicylinder behind it or not, which, in Kendal's way, was absolutely necessary; it may, however, as well be semicylindrical as otherwise. From what has been said here, and in our article Horology, p. 134, we hope the nature of this detached 'scapement, and the manner of its action, will be understood.

## PLATE CCCIV.

Fig. 1. Is a perspective view of the balance, the compensation and other parts connected with it, in M. P. Le Roy's marine timekeeper, tried by order of the King of France, in a voyage on board the Lively frigate, in the year 1768. From its good performance, a prize was awarded to him by the Royal Academy of Sciences. The balance or regulator *v v v v* of this timekeeper was steel: It was four inches in diameter, weighed five ounces, and was fixed on an arbor AA, about five inches long. A brass frame or mounting *x x x x x*, to which the movement is fixed, keeps the balance horizontally suspended by the upper end of its arbor, by means of F, a very fine harpsichord wire, to which it is attached; the length of the wire is three inches or so, forming one vertical right line with the axis. The movement cannot well be seen here, being behind the upper part of the brass mounting; the dark shade is part of the dial. The timekeeper goes 38 hours, and has no equalizing for the mainspring by means of a fusee. The ba-

lance-wheel is a star of six radii or teeth, and extremely light; it gives impulse to a pallet on the upper side of the rim of the balance at every alternate vibration; and the 'scapement is a free or detached one. In order that the balance may turn freely on its axis, each of its pivots is retained with proper play, between four rollers turning freely in two small frames *c c*, *c c*, one for the lower pivot, fixed to the under part of the brass mounting; the upper pivot runs in the uppermost frame, fixed to the brass mounting also, at a little distance from the lower end of the harpsichord, or suspending wire. The whole is arranged with the necessary precautions, so that the wire and the axis of the balance may form always one vertical right line. The balance thus suspended would make vibrations, each of which would take about twenty seconds of time, by means of the elasticity of the wire of suspension. Two spiral springs *s s*, *s s*, like those which serve as main-springs to common watches, are adjusted to the lower end of the balance arbor, by means of their collets or virrels, like what the spiral or pendulum springs have in ordinary watches, and are placed opposite each other in a centre of equilibrium absolutely at rest, so as to cause the vibrations to be made in half a second. The sliding cocks *d d*, serve to adjust to any position the pendulum springs, whose outer ends are fixed to these cocks. To regulate the timekeeper, there is placed near to the lower end of the balance-arbor, a small plain circular crossed wheel G G; on the upper side of which, and diametrically opposite, two studs are fixed, through which the two screws *z* G, *z* G pass, in such a manner that turning them by the hand will make them come equally nearer or farther from the arbor. These screws, by their mass, which can be diminished at pleasure, according to the exigency of the case, can be made to describe a great space, and allow the machine to be regulated in the nicest manner. If the effects of heat and cold were of short duration, the inconveniences that have been exposed might be neglected; but as the machine may be placed so as to undergo such trials of temperature for six months at a time, it is obvious that the vibrations of different extent of the regulator, having then no longer the isochronism required, the causes which might be able to vary the largeness of the vibrations, would considerably alter the regularity of the time keeper. "Convinced of the principle," says Le Roy, "that I have just established to compensate the effect of different temperatures on my machine, I took quite a new way. I adapted to the balance several small bars of brass and steel, disposed in such a manner, that by their lengthening in heat, or shortening in cold, they brought nearer to or farther from its centre, two considerable parts of its mass, placed each at the extremity of a lever, and diametrically opposite.* By the calculation which I had made of it, it appeared that the whole mass of the balance approached to or receded from the centre of the balance about one thirteenth of a line, to compensate a variation in heat, which would have produced one second out of fifteen in an hour in the going of the watch. The inconvenience of the preceding method made me soon give it up; the play of the levers or bars, and the want of solidity of the balance, produced errors greater than those which I wanted to compensate; this made me have recourse to a method, which afterwards answered my utmost expectations. It consists in the application to the balance of two small thermometers *t t t t*, *t t t t* made each of a glass tube, bent, and open at one end, and having a ball at the other. These thermometers, composed of mercury and spirit of wine, would have formed each an exact parallelogram, if the upper side which carries the ball wherein the spirit of wine is contained, and partly on this side of it, had not been a little inclined. Both these thermometers are adjusted firmly to the axis of the balance, and in opposition to each other, in such a manner, that the axis of their tubes and that of the balance meet in the same plane which intersects the balls in the middle. It must be understood, previous to explaining this compensation, that the mercury fills the lower side of the tube, and about half way up the side parts of it. It will easily be conceived how this construction produces the compensation required. The thermometers, making part of the regulator or balance, when the spirit of wine by its expansion pushes a part of the mercury of the outward branch of the tube *t t* towards that which is near the axis of motion, a portion of mercury, as part of the mass of the regulator, passes then from its circumference towards its centre. At the mean of temperature, for example, the mercury occupies the tubes half way up in each side, whereas in extreme cold, when the thermometer of Reaumur is 15°, or that of Fahrenheit is 33.75° below the freezing point or —1.75°, the outward branch of the tube is filled with mercury, whilst its inward corresponding branch is empty. And as the mass of the balance resists, in the ratio of the square of its distance from the centre, there evidently follows from this a compensation. If the chronometer goes slow, from a loss in the elasticity of the springs, and from the expansion of the balance by too great a heat, it is compensated by less weight or mass at the circumference of the regulator; and, *vice versa*, in the passage to cold, this effect is so much the more sure, as there is no shake or play to be apprehended here; besides, the expansion of spirit of wine by heat, and its contraction by cold, are constant effects, as has been found by experience with thermometers of this liquor, which had lost nothing of their exactness at the end of thirty years. From the calculation made for these thermometers, it was found necessary to have them in the form represented here, by bringing the balls near to the centre of the balance, in order to diminish that resistance of the air to its motion, which it would have experienced had the balls been placed at or near the circumference.

Fig. 2. and 3. Are two views of Berthoud's different modes of compensation for correcting the effects of heat and cold on the going of his watches, and of his marine time-keepers. In one of them, Fig. 2. BB is the upper or potence plate, and 1, 2, 3, and 4, the ends or pivots formed on the pillar tops, by which the potence plate is pinned down with the pillar plate. CC is the balance. DE is the cock for supporting the balance, and for the arbor which

* This method, or something like it, was once used by the late Arnold, which is the same nearly as has been noticed in our article Horology, p. 493.

carries a double arm *a b*, on one end of which at *a* are the curb pins; the sole D is screwed to the potence plate; the small cock E screwed to the main one DE, and is that which carries one of the pivots of the arbor of the arm for the curb pins, the other pivot running in the main cock a quarter of an inch below the cock E. The arbor for the arm of the curb pins is hollow, and through it the balance arbor comes, the upper pivot of which runs in a jewelled hole in E, and the end supported by a diamond piece, which will be the lower end when the watch is in its case and the dial uppermost. GH is a potence or bridge screwed to the plate, having chops at H to receive one end of the compound bar of brass and steel, the other end has a thick part to receive the adjusting screw *c*, acting on the shorter arm *b*. A very delicate spring is screwed to the plate at lower *d*, serving to press the arm *b* against the end of the screw *c*, which is in a thick part of the compound bar; screwing it in will, by bringing the arm *a* with the curb pins to a greater distance from the small stud, make the watch go faster, and *vice versa*. The brass part of the compound bar of brass and steel is on the left hand, (the steel being on the right hand side,) will expand with some degree of heat, and become a little convex outside, bending as it were, and causing the screw *c* to press the arm *b* a little to the right, which would make the watch go fast, and the same degree of heat will weaken the powers of the pendulum spring; but these are compensated by the motion of the compound bar of brass and steel. An opposite degree of temperature would make the brass to contract, the motion of the screw would then be the reverse, and the curb pins would approach nearer to the small stud, and give a greater length beyond the curb pins for the action of the pendulum spring, to counteract the effects of cold on it. The compensation bar can be made to act with more or less effect according as it is moved in the chops H, where there is a screw for fixing it at whatever distance the screw *c* may be brought from the centre of the balance. It is obvious that the nearer it is to this centre, the greater will be the effect of any motion given to the arm *b*, and *vice versa*. It is by the screw *c* that the watch is regulated to mean time.

Fig. 3. Is another contrivance adopted by Berthoud, the compensation being on the balance itself. B is the circle of the balance, on the plane of which, and inside of it a contrate rim is formed or raised up, for the purpose of fixing to it at *a*, *b*, and *c*, the ends of the compound blades or laminæ of brass and steel *e d*, *e d*, *e d*; the ends of the blades are fixed by screws at *e* to the parts *a*, *b*, *c*, of the contrate rim reserved for this purpose, the rest of the rim being taken away. The free ends of the blades carry the masses of compensation C, D, E. These masses are fixed to the blades each by a screw and two steady pins. By this disposition of the balance, when the masses have a proper weight for regulating the watch, the balance being in equilibrium, if the compound blades are well executed, the balance will preserve this state of equilibrium, although the masses recede or come nearer the centre of the balance by the effect of different temperatures, making the equilibrium of such a regulator as invariable as if the balance was a simple one. The circle of the balance carries three small masses *d*, *d*, *d*, which are destined to regulate the machine to the nearest time, by giving them more or less weight. The blades or laminæ of steel and brass, which are either pinned, soldered, or melted together, have the brass outwards: Hence if we suppose any degree of heat that is greater than the medium temperature takes place, it will weaken the elasticity of the pendulum spring, and make the machine to go slow; but the same cause will operate on the laminæ of brass and steel, but with greater effect on the brass one, which will make it bend as it were inward, and force the laminæ of steel with it, and the masses C, D, E being also carried inward, will compensate the effects of heat on the pendulum spring, by their less resistance to motion, as well as by the effect of their gravity being lessened; when an opposite degree of temperature takes place, the masses will be carried outwards, and the same cause will strengthen the elasticity of the pendulum spring; hence the compensation will keep pace with the changes of temperature.

Fig. 4. Represents Arnold's Compensation Balance, both in plan and edgewise. The circular part *a*, *b*, and the cross or diametrical arms are steel, as well as the parts carried beyond the circle, to the extremes of which the circular laminæ of brass and steel are fixed: It is into these parts also that the screws *d*, *d*, for adjusting the chronometer to mean time, turn, bringing them out making the chronometer go slow, and putting them in makes it go fast. On the circular part are three small masses of brass, one of which is seen at *a*, no letters of reference being to the other two; they can be made to slide back and forward on the circular ring *a*, *b*, and serve to adjust for positions. A part of the steel lamina is left a little thick at the outer end, which is tapped, to receive the masses of brass *c*, *c* which are screwed upon it; bringing them out gives a greater scope for the laminæ to have more effect in compensating, and screwing them farther home a less effect; the small screws *e*, *e* not only serve for this purpose, but also for more minutely altering the going to mean time. The lamina of brass being outward, and the steel one inward, the masses of brass *c*, *c* are carried out and in according to the change and degrees of temperature, compensating the effects of temperature on the pendulum spring, in the same way as we described it in Berthoud's balance.

Fig. 5. Represents a view in plan, and also an edgeview of the Compensation Balance by Earnshaw. It is composed of a bar or two steel arms, at the middle of which it is rivetted on the verge or balance-arbor; at the ends of these arms, a part is raised up to which the laminæ of brass and steel are fixed, or rather are made to proceed from; it is also in these ends that the screws *a*, *a* turn out or in, so as to adjust the chronometer to mean time; the compensation brass masses *d*, *b* have a groove turned in them, by which they can be made to slide farther or nearer the ends of the laminæ, when adjusting for compensation, and the masses can be fixed any where to the laminæ, by the small screws *c*, *c*. The steel part of this balance is formed by turning a thick and flat piece of steel outside, so as the diameter shall be that of the steel part of the compensation, and brass is melted on the turned edge of the steel to form the brass part; the steel being afterwards hollowed out, a contrate sort of rim is formed

from it as well as the brass, a great part of which is then taken away: The remainder, with the masses attached to the free ends, makes the compensation against the effects of heat and cold on the pendulum spring, acting in the same way as has been described for the other compensation balances. There is a facility in adjusting the compensation here, by the easy sliding of the masses, which cannot be obtained in Berthoud's balance, in consequence of his masses being fixed with steady pins as well as a screw. Arnold's screwing and spring-tight masses have, in some degree, the disadvantage also of Berthoud's method.

Fig. 6. Represents the Machinery for going in time of Winding, used in Huygen's Clock, and invented by that celebrated philosopher. See p. 759, col. 2. where it is already described.

Fig. 7. Represents a view of some wheels adapted for an Equation Clock, so as to make a hand representing the sun give solar time, while the minute hand gives mean time as in common. *m* is one of the minute wheels of 56 teeth, fixed to the minute pinion arbor, the upper pivot of which runs in the cock C screwed to the fore-plate of the clock frame, the lower pivot turns in a hole made inside of the bevelled wheel *c*, and in the end of its arbor the bevelled wheel *b*, of 38 teeth, and the flat wheel above it of the same number, have one common socket, and turn on the minute pinion arbor, independent of it and the minute wheel. The three bevelled wheels *b*, B, and *c*, are all of one number, and pitch with one another; the arbour of the wheel *c* turns in the cock A, screwed on to the inside of the pillar plate, and independent of the minute pinion arbor; the lower pivot of it runs in the cock K, screwed to the back of the pillar plate. The wheel W of 32 teeth is by its socket pinned fast with the arbor of the bevelled wheel *c*. W is the wheel which leads the toothed rack, the arbor of which at the opposite end carries the tail which bears on the elliptical plate, and this causes the variation necessary to show the equation of time. For farther particulars, the reader is referred to p. 497. of our article Horology.

Fig. 8, 9. AA is a view of the Month Wheel in the Equation Clock; AA, in Fig. 9. is a view of it seen edgewise; BB in both figures is a segment of a circle of three teeth, which is pumped up and down on the socket of the month wheel, by means of the fork, which takes hold of a round groove or pulley, seen near the lower end of the socket in Fig 9; the pillars *b*, *b*, fixed to C with the pulley, and to the segment BB, move up and down on the socket of the month wheel, and on the small ends of the pillars *a*, *a*, which are rivetted below to the month wheel; *d* is a kneed piece fixed to the month wheel also, a pin from which is that which in common shifts the day of the month ring; the teeth of the segment serve for this purpose when the month has 30 or 28 days. See p. 501 of Horology, for more particular information regarding the mechanism of shifting the day of the month.

## PLATE CCCV.

## PLATE CCCVI.

Fig. 1.—9 Represent a repeating Watch with Grahame's Horizontal 'Scapement. See the description of it, p. 505. of our article Horology.

## PLATE CCCVII.

Fig. 1. Represents the Mercurial Pendulum improved by Reid.

Fig. 2. Gridiron Pendulum.

Fig. 3. Ellicott's Pendulum.

Fig. 4. Cumming's Improvement upon it.

Fig. 5. Smeaton's Compensation Pendulum.

Fig. 6. Reid's Compensation Pendulum with a zinc tube and steel rods.—We have said in Horology, p. 516, that the zinc tube pendulum had not easily the means of adjusting for compensation. This objection, however, has since been removed by the contriver of it. Let a brass socket be made, about three or four inches long, whose outside fits easily the inside of the zinc tube, and the inside of the socket fits easily the centre steel rod, at the lower end of it. Let two holes be put through the zinc tube, brass socket and steel rod, one of the holes being about one inch or so above the lower end of the tube, and the other hole two or two inches and a half above the lower end of the zinc tube, two pins being pretty well fitted to them. Should the compensation, after trial, be found rather defective, release or take away the pin in the uppermost hole; and should the pendulum be still found defective in its compensation, let the other pin be taken away, and the zinc tube will now be operating its compensation by means of both ends; in the case of the pins, this was effected by the length of the tube from a pin to the upper end of it. This is a very easy way of rectifying the compensation, and it may soon be brought to the greatest nicety. For this and other reasons we are of opinion, that it will be found to be the most complete and convenient of any compensation pendulum that has yet been applied to a clock.

## PLATE CCCVIII.

Contains several Figures illustrative of the method of transferring tunes to the barrels of Musical Clocks.

## PLATE CCCIX.

*Modes of Grafting.*

Fig. 1. Tongue Grafting.

Fig. 2 Cleft Grafting. *a*, The graft placed in the cleft. *b*, The graft separate, to shew the wedge-shape of its extremity.

Fig. 3. Side Grafting.

Fig. 4. Inarching, or Grafting by Approach. *a*, The stock, placed in a flower pot, so as to be *approached* to another tree or shrub. *b*, The spring or branch of that other tree, to be engrafted on the stock.

Fig. 5. Budding, (figures of natural size.) *a*, The bud as cut from the tree. *b*, The bud dressed and ready

for being inserted. *c*, Transverse and longitudinal incision in the stock, for receiving the bud. *d*, The bud placed in the incision in the stock, and ready for being tied.

## PLATE CCCX.

*State of Hot-houses at Dalmeny Park.*

Fig. 1. Ground Plan. A, B, C, Peach-houses. D, Double Peach-house. E, F, G, Grape-houses. H. Mushroom-house.
Fig. 2. Elevation of the Suite.
Fig. 3. Section of the Grape-house.
Fig. 4. Section of the Mushroom-house H, and of the Peach-house A.
Fig. 5. Section of the double Peach-house A. *a*, *a*, *a*, in Figures 3, 4, and 5, shew the situation of the weights and pullies for moving the upper sashes.
Fig. 6. Cock, pipe, and director, for watering and washing the trees, &c. *a*, the brass cock ; *b b*, the leathern pipe ; *c*, the brass director.

## PLATE CCCXI.

*Pine-stoves designed by Mr Hay for Dalmeny Park Garden.*

Fig. 1. Ground Plan. A, First Succession-pit. B, Second Succession-pit. C, Fruiting-pit. DDD, Nursing-pit. *a a*, *c c*, Small openings for the passage of heated air. *b b*, *d d*, Openings for the same purpose, furnished with covered dampers.
Fig. 2. Elevation.
Fig. 3. Section (on an enlarged scale). The line *e f g h i* shews the declivity of the ground, *k* is a moveable gangway.

## PLATE CCCXII.

*Plan, Section, and Elevation of a Hot-house proposed by Sir George Mackenzie, Bart. the glazing being a segment of a sphere, &c.*

Fig. 1. Elevation of the Hot-house.
Fig. 2. Section.
Fig. 3. Ground Plan. A, A, A, &c. Sliding shutters in the low wall, to admit air. B, (in the section,) Shutters along the back wall, to open and shut on pivots with a cord, or in any other manner. There are also hatches in the roof. C, Half the plan of the glass cover, formed of hammered iron. *x x x x*, Iron rods for supports, if necessary. D, Half the plan, shewing the flue F going round to E, and out at the vase at top. G, Treillage for vines, with an opening in the centre to allow a person to pass. H, Iron astragals glazed.
Fig. 4. Section of a wrought iron rib for the glass frames, (full size.)

Since the engraving has been thrown off, Mr T. A. Knight has hit upon a very neat contrivance for obviating the inconvenience of the rapid contraction of the bars near the top. He proposes that every alternate pair of astragals shall be joined as in the annexed cut, when the contraction comes to be 6 or 5 inches. Thus the greatest possible quantity of light seems to be admitted by this form of hot-house.

Fig. 5. Blanching Pots for Sea-cale.
Fig. 6. Averuncator.
Fig. 7. Pruning Shears. *a*, Opposite side of the nail, with the groove in which the nail moves, by which means the cutting blade makes a *drawing* cut.

## PLATE CCCXIII. No. 1.

Fig. 1. Represents the earlier form of the Clepsydræ or Water Clocks.
Fig. 2. Is another Clepsydra of a more ingenious construction.
Fig. 3, and 4. Represent the Clepsydra invented by Ctesibius.

## PLATE CCCXIII. No. 2.

Contains various Diagrams illustrative of the principles of Hydrostatics.

## PLATE CCCXIV.
